*Second route (source 29).* For a nonempty subclass of a finite union, intersect it with each carrier for which the intersection is nonempty and take the smallest of their finitely many least points. This proves the first assertion and applies in particular to the symmetric difference. Below its least point the carriers agree. Their inherited numerical relations agree there automatically.

If both carriers have a point after  $C$ , compare their least such points numerically. If one carrier is exactly  $C$ , a prefix convention is necessary. Denote the shorter-first order by  $\prec_{\text{sf}}$  and the longer-first order by  $\prec_{\text{lf}}$ . The latter has the particularly simple expression

$$A \prec_{\text{lf}} B \iff \min(A \triangle B) \in A.$$

It is characteristic-function lexicography with the bit order  $1 < 0$ , but its scan is the well-ordered union of the carriers being compared, not the whole numerical surreal line. Transitivity follows by comparing first differences in the union of three carriers. The shorter-first version reverses proper-prefix pairs and uses the same genuine first-difference comparisons.

### 83.2 Exact adjacency at an unattained supremum

For a numerical carrier  $A$ , define its class of possible next labels by

$$U(A) = \{x \in \mathbf{No} : \forall a \in A (a < x)\}.$$

If  $A$  is a set,  $U(A)$  has no least point by the set-cut property. For a proper-class  $A$ , it can have one. ([merge] For a set  $A$  this is the class  $U(q)$  of admissible next letters in the proof of [theorem 35.1](#).)

**Theorem 83.2** (Proper-class adjacency). *Two numerical well-ordered carriers  $A \prec_{\text{sf}} B$  are adjacent if and only if*

$$B = A \cup \{b\}, \quad b = \min U(A).$$

*Equivalently,  $b$  is a numerical supremum of  $A$  that does not belong to  $A$ . In every such pair,  $A$  is a proper class and has no greatest member.*

*Proof.* Suppose first that there is a genuine mismatch after the shared initial segment  $C$ , with next points  $a < b$ . Numerical density gives  $a < c < b$ . The carrier  $C \cup \{c\}$  is numerically well-ordered and lies strictly between the two given carriers. This argument remains valid when  $C$  is a proper class: adjoining one point above all its members preserves well-ordering.

Thus an adjacent pair must have  $A$  as a proper initial segment of  $B$ . Let  $b$  be the least point of  $B \setminus A$ . If the remainder has more than one point,  $A \cup \{b\}$  lies strictly between  $A$  and  $B$ . If some  $c \in U(A)$  satisfies  $c < b$ , then  $A \cup \{c\}$  lies strictly between them as well. Necessity follows.

Conversely, suppose  $B = A \cup \{b\}$  with  $b = \min U(A)$ . A carrier strictly between  $A$  and  $B$  must extend  $A$ : an earlier numerical divergence puts it on the same side of both, and a proper prefix of  $A$  lies below  $A$ . Its first new label  $c$  belongs to  $U(A)$ . If  $c > b$ , it lies above  $B$ ; if  $c = b$ , it is  $B$  or extends  $B$  and again cannot lie strictly between. The case  $c < b$  is impossible.

If  $A$  had a greatest member  $a$ , density would supply an upper bound strictly between  $a$  and  $b$ , contrary to the minimality of  $b$ . Thus the least strict upper bound is exactly an unattained supremum. If  $A$  were a set, the cut  $(A, \{b\})$  would have a surreal filler, giving the same contradiction.  $\square$

**Example 83.3** (A jump over every surreal). For every  $b \in \mathbf{No}$ , put

$$A_b = \left\{ b - \frac{1}{\alpha + 1} : \alpha \in \text{Ord} \right\},$$

where the ordinal values are embedded in  $\mathbf{No}$  and the arithmetic is surreal arithmetic. This is an increasing class of numerical type  $\text{Ord}$ , and it is cofinal below  $b$ . Indeed, if  $x < b$ , choose an ordinal  $\alpha$  with  $\alpha + 1 > 1/(b - x)$ . Then  $x < b - 1/(\alpha + 1) < b$ . Consequently

$$A_b \prec_{\text{sf}} A_b \cup \{b\}$$

is an adjacent pair. The upper carrier has type  $\text{Ord} + 1$ . The example is uniform in the set parameter  $b$ .

**Corollary 83.4.** *Every nontrivial adjacency component in the shorter-first numerical class-carrier order has exactly two members. Contracting these pairs gives a dense order with a minimum, in an external collection or in any appropriate higher-order formulation.*

*Proof.* An upper member of a jump has a greatest numerical point. A lower member has none. Hence one carrier cannot be both the upper member of one jump and the lower member of another. If two different contracted blocks had no block between them, their facing endpoints would be adjacent and would have belonged to the same block. The empty carrier remains least.  $\square$

**Theorem 83.5** (Longer-first density). *The longer-first numerical class-carrier order is dense and has the empty carrier as its greatest element. Therefore the full shorter-first and longer-first orders are neither isomorphic nor anti-isomorphic.*

*Proof.* A genuine mismatch is interpolated exactly as in [theorem 83.2](#). Otherwise  $B$  is a proper initial segment of  $A$  and  $A \prec_{\text{lf}} B$ . Let  $a$  be the first point of  $A \setminus B$ . If the remainder contains more points, the carrier  $B \cup \{a\}$  lies strictly between. If it does not, choose any  $c > a$ . It is still above every member of  $B$ , and

$$A = B \cup \{a\} \prec_{\text{lf}} B \cup \{c\} \prec_{\text{lf}} B.$$

This proves density. The empty carrier is a prefix of all carriers and is greatest under longer-first comparison. Density is preserved by both isomorphism and reversal; the shorter-first jumps therefore exclude either identification.  $\square$

[merge] For set carriers, [proposition 38.6](#) (source 15) embeds the longer-first order into  $\mathbf{No}$ ; source 15 remarks that the construction does not admit proper-class supports. [Theorems 83.2](#) and [83.5](#) show what changes at proper-class carriers: the shorter-first order acquires adjacent pairs, which no set-length word order of [theorem 35.1](#) has, while the longer-first order stays dense.

### 83.3 Every final class segment can occur after a prefix

**Theorem 83.6** (Cofinal numerical representatives). *Let  $L$  be an initial subclass of the numerical surreal line and let  $U = \mathbf{No} \setminus L$ . In GBC there is a numerically well-ordered subclass  $A \subseteq L$ , cofinal in  $L$ , such that*

$$U(A) = U.$$

*The carrier  $A$  can be a set exactly when  $L$  has a set cofinal subset. If no such set exists,  $A$  can be chosen as the range of an increasing class map  $\text{Ord} \rightarrow L$ .*

*Proof.* The empty  $L$  is handled by  $A = \emptyset$ . Otherwise fix a class bijection  $e : \text{Ord} \rightarrow \mathbf{No}$ . Construct an increasing sequence, stopping permanently as soon as its earlier range is cofinal in  $L$ . At stage  $\alpha$ , its earlier range  $S$  is a set. If it is not cofinal, some point of  $L$  is strictly above every member of  $S$ . Choose, by the  $e$ -scan, the least candidate  $y \in L$  satisfying

$$S < y, \quad e(\alpha) \in L \implies e(\alpha) \leq y.$$

Such a candidate exists: take the larger of the available strict upper bound and  $e(\alpha)$  when the latter belongs to  $L$ . Each step is a set-valued elementary recursion. A permanent stop flag can be included in the state, and the class construction is defined by its set-length histories. No recursion with class-valued slices is involved.

If the process stops, its range is set-sized and cofinal. If it does not, the resulting increasing class sequence is cofinal because every point  $x = e(\alpha) \in L$  is passed at its scan stage. Its range is numerically well-ordered, being isomorphic to  $\text{Ord}$ . If  $L$  has a set cofinal subset  $C$ , the set of indices  $e^{-1}[C]$  is ordinal-bounded. After that bound all of  $C$  has been passed, so the construction stops. The converse is immediate.

Finally, every point outside  $L$  is strictly above  $A$ , while every point of  $L$  is at most some member of  $A$ . Thus  $U(A) = U$ .  $\square$

This theorem describes the precise failure of a set-prefix argument at class length. After a set increasing prefix, the next-letter order has the full set-cut property. After a proper-class prefix, it can be any final class segment: empty, with a least point, with a set coinital sequence, or with no such sequence. A uniform tree isomorphism that relied on the same saturated successor alphabet at every set node cannot simply be continued through every class node.

### 83.4 A direct obstruction to extending the set-tree isomorphism

**Theorem 83.7.** *In GBC, the virtual prefix tree of all auxiliary class well-orders on arbitrary surreal subclasses is not isomorphic to the corresponding tree of inherited numerical class well-orders. In particular, the isomorphism between injective and increasing set-length word trees (theorems 35.1 and 35.7) cannot extend to an isomorphism of these full class-carrier trees.*

*Proof.* An immediate extension in either tree appends exactly one unused label. Global Choice provides an auxiliary class well-order of  $\mathbf{No} \setminus \{z\}$ . As a node of the full auxiliary tree, it has exactly one immediate extension, obtained by appending  $z$ .

In the numerical tree the immediate extensions of  $A$  are indexed by  $U(A)$ . This class is either empty or a proper class: with any  $x \in U(A)$  it contains every larger surreal. Thus no numerical node has exactly one immediate extension. A tree isomorphism would preserve that property, a contradiction.  $\square$

The proof can be read as a two-sorted assertion about any proposed uniform map, or as an ordinary external set-theoretic argument in a specified class model. It does not require a GB class of all nodes.

[merge] Theorem 83.7 limits the word isomorphisms of Part VII in length, not in choice: it does not bear on the question of sources 16 and 18, recorded at the end of section 39, whether they survive without a global well-order.

## 84 Relation-table lexicography: spectra, scans, extensions and density (sources 27 and 30)

[merge] Relation-table lexicography compares the characteristic functions of two relations at the first scanned pair on which they differ. Before batch 83 the report knew three facts about it: at class level its order of all class well-orders is equimorphic with  $\mathbb{B}_{\text{Ord}}$  for every scan (proposition 17.1, source 08); its endpoints are artifacts of the scan, each of the patterns “minimum only”, “maximum only” and “neither” occurring and “both” never (theorem 38.2 and corollary 38.3, source 15); and

it is not enumeration lexicography (section 38.8). The isomorphism question for two scans stayed open (section 39, item (e)). Two batch-83 sources continue this line.

- Source 27's Section 4 (section 84.1) works first on a set carrier. Every scan gives the same ordinal and reverse-ordinal spectrum (theorem 84.2, the set analogue of proposition 17.1), yet two scans of the same countable carrier, of types  $\omega$  and  $\omega + 6$ , give orders that are not isomorphic: one embeds in  $\mathbb{R}$  and has no isolated points, the other has continuum many (theorems 84.3 and 84.4). This answers the set-level form of item (e) negatively. At class level, under a set-like scan of type Ord, the core meets every nonempty interval of the order of all class well-order tables (theorem 84.5): a natural set-coded dense core, as source 09's direction "Non-set-like well-order relations" asks. Its complete ambient order (proposition 84.6) uses the constraint closure of source 15's endpoint-transfer proof.
- Source 30's Section 7 (section 84.2) shows that a set partial table extends to a class well-order of any prescribed type exactly when its forced relation is well-founded (theorem 84.7), characterizes the relations approximable on finite, countable and set-sized supports (theorem 84.8), and deduces that no continuous invariant detects the order type (corollary 84.10). Its Section 8 (section 84.3) proves that the set-like part of every set-like scan order is dense (theorem 84.11, whose second clause is the set-like part of source 27's theorem 84.5) and computes the local characters of one canonical scan, where bounded inversion support has an intrinsic description (theorem 84.13 and corollary 84.14).

Source 27's scan  $q : \theta \rightarrow X \times X$  is printed  $s : \vartheta \rightarrow X \times X$  (this report's  $q$  is cf  $\mu$  and its  $\theta$  a regular cardinal), its table bits  $b_R$  are printed  $t_R$ , its  $\kappa = |X|$  is printed  $\mu$ , its realized prefix cylinders  $C(p)$  are printed  $N(p)$  (they are source 30's neighbourhoods  $N_D(R)$  for an initial segment  $D$  of the scan), its density and cellularity  $d, c$  are printed  $d, \text{cell}$ , and its core  $\mathcal{D}_b$  is printed  $\mathcal{P}_s(b)$  (codes by moved points). In source 30's Sections 7–8, the supplied class bijection  $e : \text{Ord} \rightarrow X$  is a baseline in the sense of section 1.3; its supplied type  $J$  is a class well-order (not  $\mathfrak{J}$ , and not source 27's centered order); its rank function  $\rho$  and order type  $\theta$  are printed  $\varrho$  and  $\beta$ ; its external set  $\mathcal{W}^{\mathfrak{M}}$  of admitted class well-orders is printed  $\mathfrak{W}_{\text{all}}^{\mathfrak{M}}$ ; and its inversion class  $I(W)$  is printed  $\text{Inv}(W)$ , since  $\mathcal{I}$  is the class of injective words.

## 84.1 Source 27: six delayed comparisons change the topology

Relation-table lexicography orders the same well-order relations using different data. Its dependence on the scan is much stronger than a finite relabelling effect. Throughout the set-sized part of this section we work in ZFC and let  $|X| = \mu$  be infinite.

### 84.1.1 The scan and the information it uses

Fix a bijection  $s : \vartheta \rightarrow X \times X$ , where  $\vartheta$  is an ordinal of cardinality  $\mu$ . For a relation  $R$  define

$$t_R(\xi) = \begin{cases} 1, & s(\xi) \in R, \\ 0, & s(\xi) \notin R. \end{cases}$$

Compare these binary words with  $0 < 1$ , at their first disagreement. Write  $\mathcal{W}_s(X)$  for the well-orders with this comparison and  $\mathcal{W}_{s,\alpha}(X)$  for the relations of ordinal type  $\alpha$ . The numerical order on  $X$  does not occur in this definition. It matters only if an additional rule uses it to select  $s$ .

Diagonal entries are always zero. For an unordered pair  $\{x, y\}$ , the two directed entries are complements. Only whichever appears first can decide a comparison. Deleting diagonal entries

and the later directed entry of each pair produces an *effective scan*: a well-ordered list of oriented unordered pairs with the same induced order on relations.

The discrepancy from enumeration lexicography is visible on three labels. Let  $a < b < c$ , and compare the enumerations  $(a, c, b)$  and  $(b, a, c)$ . The first is enumeration-smaller. If the table scan first inspects  $(a, b)$ , its bits are respectively 1 and 0, so the first is table-larger. There is no contradiction: the two definitions ask different questions at their first step.

### 84.1.2 An invariant spectrum shared by every scan

**Lemma 84.1** (Independent adjacent-pair coding). *For every scan  $\mathbf{s}$  and every ordinal  $\alpha$  with  $|\alpha| = \mu$ , the lexicographic binary cube  $\mathbb{B}_\mu = (2^\mu, <_{\text{lex}})$  embeds into  $\mathcal{W}_{\mathbf{s}, \alpha}(X)$ .*

*Proof.* Choose one labelled well-order of type  $\alpha$ . Its initial length- $\mu$  segment contains  $\mu$  disjoint adjacent pairs at positions  $2 \cdot \xi, 2 \cdot \xi + 1$ . Swapping either pair changes only the two directed comparisons internal to that pair and leaves the ordinal type unchanged.

The first effective coordinates of these pairs form a well-ordered set of cardinality  $\mu$ , of order type at least  $\mu$ . Select its first  $\mu$  pairs. For  $s \in 2^\mu$ , orient selected pair  $\xi$  so that its first scheduled bit equals  $s(\xi)$ . Leave all other comparisons fixed. The first disagreement of two inputs is precisely the first disagreement of their output tables, proving the embedding.  $\square$

**Theorem 84.2** (Exact scan-independent ordinal spectrum). *For any scan  $\mathbf{s}$  and any fixed type  $\alpha$  of cardinality  $\mu$ , every linear order of size at most  $\mu$  embeds into  $\mathcal{W}_{\mathbf{s}, \alpha}(X)$ . The ordinal and reverse-ordinal embedding spectra of both this slice and  $\mathcal{W}_{\mathbf{s}}(X)$  are exactly*

$$\{\beta : \beta < \mu^+\}.$$

*Both spaces have cardinality  $2^\mu$ .*

*Proof.* For a linear order  $L$  with  $|L| \leq \mu$ , index some cube coordinates by its elements and encode  $l \in L$  by the bits  $s_l(t) = 1$  exactly when  $t < l$ , fixing unused coordinates at zero. If  $l < l'$ , the code increases coordinatewise and changes at  $t = l$ , so it increases under any lexicographic coordinate order. Compose with lemma 84.1. This proves the positive spectrum and the lower cardinality bound; the number of tables gives the upper bound.

For the negative spectrum it suffices to exclude a strictly increasing  $\mu^+$ -sequence in  $2^\vartheta$ . Recursively through the coordinates of  $\vartheta$ , pass to a final segment of the sequence on which the current bit is constant. Once the earlier bits are constant, the current binary coordinate is nondecreasing and therefore eventually constant. At a limit coordinate take the supremum of the previously chosen starting indices. There are at most  $\mu$  such indices, so regularity of  $\mu^+$  keeps the supremum below  $\mu^+$ . After all coordinates, a final segment consists of the same word, a contradiction. The decreasing case reverses the two bits. Every ordinal of cardinality greater than  $\mu$  contains  $\mu^+$  as an initial segment.  $\square$

This spectrum cannot detect the topological distinction proved next. The argument also explains why agreement on the list of embeddable ordinals is a weak form of classification.

[merge] The spectrum is that of enumeration lexicography (theorem 6.1), and the proofs are the same pair-orientation coding and the same stabilization argument. At class level the corresponding statement is source 08's proposition 17.1, whose lower embedding also orients two-element blocks at their first scanned pair.

### 84.1.3 Scans of the least possible order type

Now suppose  $s : \mu \rightarrow X^2$ , with  $\mu$  the initial ordinal of its cardinality. All topology below is the *order topology* of the indicated linear order. Its density  $d$  is the minimum cardinality of a dense subset; its cellularity  $cell$  is the supremum of cardinalities of disjoint families of nonempty open sets.

A realized prefix cylinder is

$$N(p) = \{R \in \mathcal{W}_s(X) : t_R \upharpoonright \gamma = p\}, \quad \gamma < \mu.$$

Every order-neighborhood of  $R$  contains such a cylinder about  $R$ . For a neighborhood  $(U, V)$ , choose  $\gamma$  beyond the first disagreements of  $U, R$  and  $R, V$ ; agreement through  $\gamma$  settles both comparisons. A one-sided neighborhood needs only one bound. This says that cylinders refine neighborhoods. It does not claim that every cylinder is itself open.

**Theorem 84.3** (Dense slices and exact topology). *For a scan of type  $\mu$ , every slice  $\mathcal{W}_{s,\alpha}(X)$  with  $|\alpha| = \mu$  is dense in  $\mathcal{W}_s(X)$ . Neither the full order nor any such slice has isolated points. Moreover*

$$d(\mathcal{W}_s) = cell(\mathcal{W}_s) = d(\mathcal{W}_{s,\alpha}) = cell(\mathcal{W}_{s,\alpha}) = 2^{<\mu}. \quad (37)$$

*Proof.* A prefix of length  $\gamma < \mu$  involves a set  $C$  of fewer than  $\mu$  labels. If  $R$  witnesses its feasibility,  $R \upharpoonright C$  has ordinal type  $\beta < \mu$ . Put this restriction first, followed by any well-order of  $X \setminus C$  of type  $\alpha$ . Since  $\beta + \alpha = \alpha$ , the result belongs to the desired slice and matches the prefix. The complement admits  $2^\mu$  such orders, so every neighborhood contains many members of that slice. The same argument with neighborhood endpoints in a slice excludes isolated points in its own order topology.

There are  $\sum_{\gamma < \mu} 2^{|\gamma|} = 2^{<\mu}$  possible prefixes. Choosing one representative of each realized prefix gives a dense set in the full order, or in any fixed slice. Thus  $d \leq 2^{<\mu}$  and  $cell \leq d$ .

For the lower bound use the cube embedding in lemma 84.1. For each  $s \in 2^\gamma$ , choose three distinct increasing extensions  $u_s < v_s < w_s$  of length  $\mu$ . There are still at least two coordinates available after  $\gamma$ . The intervals between the images of  $u_s, w_s$  are nonempty, witnessed by the image of  $v_s$ , and are disjoint for different prefixes  $s$ . Hence  $cell \geq 2^{|\gamma|}$  for every  $\gamma < \mu$ . Taking the supremum proves (37).  $\square$

In the countable case the scan can have type  $\omega$ , and there is an explicit order embedding into the real line:

$$R \mapsto \sum_{n < \omega} \frac{2t_R(n)}{3^{n+1}}. \quad (S27.2)$$

The first different digit dominates the entire later tail. This is an order embedding; no identification of every intrinsic suborder topology with a product subspace topology is being assumed.

### 84.1.4 A finite terminal block creates maximal isolation

**Theorem 84.4** (Six delayed coordinates). *On the same infinite carrier  $X$  there is a scan of type  $\mu + 6$  for which  $\mathcal{W}_s(X)$  has  $2^\mu$  isolated points. Its density and cellularity both equal  $2^\mu$ .*

*Proof.* Reserve three labels  $Z \subset X$  and put  $Y = X \setminus Z$ . First scan all pairs except the six off-diagonal directed pairs inside  $Z$ , using type  $\mu$ . Put those six comparisons at the end.

For each well-order  $Q$  of  $Y$ , consider the six completions that place all of  $Y$  in order  $Q$ , then the three labels of  $Z$  in any order. These have the same initial  $\mu$  table bits. Conversely those bits force exactly this form: only the order inside  $Z$  is undetermined. The fiber is therefore a convex six-point chain. Its middle four points are isolated in the full order, because their immediate neighbors in the chain delimit singleton open intervals.

There are  $2^\mu$  choices of  $Q$ , with disjoint fibers. Hence there are  $2^\mu$  isolated points. Their singleton neighborhoods give cellularity at least  $2^\mu$ , and any dense set must contain them. The total cardinality supplies the matching upper bounds.  $\square$

For countable  $X$ , the distinction is absolute: a scan of type  $\omega$  is separable with no isolated points, while the displayed scan of type  $\omega + 6$  has continuum many isolated points and cannot embed into  $\mathbb{R}$ . An embedding into  $\mathbb{R}$  would turn the disjoint intervals around these isolated points into disjoint real intervals, each containing a different rational, which is impossible.

Only the placement of six relation entries has changed. For larger  $\mu$  it is possible that  $2^{<\mu} = 2^\mu$ , so density alone may not distinguish the two scans. Absence versus presence of isolated points always does. A scan's order type must therefore be specified; replacing it by an equicardinal ordinal is not innocuous.

[merge] Together, [theorems 84.3 and 84.4](#) answer the set-level form of [section 39](#), item (e), and of source 08's question 9 ("Classification of relation-code orders", [section 113.4](#)), negatively: on every infinite set carrier two scans give non-isomorphic orders, although by [theorem 84.2](#) their embedding spectra agree. Isolated points are an artifact of the scan, in the sense of source 08's question; whether two set-like scans of type Ord can give non-isomorphic orders on **No** is not decided by source 27 (but see [theorem 84.13](#)).

### 84.1.5 A reversal of the global density picture

**Theorem 84.5** (Set-like orders are table-dense). *In GBC, fix a set-like scan  $s : \text{Ord} \rightarrow \mathbf{No}^2$ . The ordinary class of bounded-support codes  $\mathcal{P}_s(b)$ , now compared by its relation tables, meets every nonempty open interval of raw class well-order tables. In particular, set-like class well-orders are dense there. The analogous assertion holds for one-sided neighborhoods. Neither the raw nor the set-like table comparison has isolated points.*

*Proof.* Given  $U < R < V$ , choose a set ordinal  $\delta$  beyond the two first disagreements. The pairs inspected below  $\delta$  involve a set  $C$  of labels. The restriction  $R \upharpoonright C$  is a set well-order, even when  $R$  has proper-class predecessor segments. Enumerate  $C$  in that order as a set prefix, then complete the prefix by a permutation of  $b$  with set support, using [theorem 101.1](#). Its relation table matches  $R$  through the required coordinates, hence lies between  $U, V$ . Appending differently ordered fresh labels before completion gives multiple core elements. One-sided neighborhoods are identical with one bound omitted.  $\square$

In the enumeration comparison, the set-like orders miss all interiors of proper-tail fibers. In the relation-table comparison under an Ord scan, they meet every nonempty interval. This is a direct structural disagreement between the two interpretations. Indeed the relation-table order has a dense uniform ordinary class of codes, whereas [theorem 107.8](#) excludes every such dense family for raw enumeration comparison. The objects agree; their comparison relations differ. No class containing all set-like orders is being constructed in either argument.

Placing a few comparisons "after all ordinal stages" instead would give them proper-class predecessor collections. An  $\text{Ord} + 6$  scan is not a set-like Ord scan. A finite-looking change at the end can therefore change the foundational hypothesis as well as the topology.

[merge] The convex fibres missed in enumeration comparison are those of [proposition 15.3](#). [Theorem 84.5](#) answers source 09's question "Does it contain a natural set-coded dense core?" (its direction "Non-set-like well-order relations", [section 113.3](#)) for every set-like scan: the core  $\mathcal{P}_s(b)$  is one. The rest of that direction (when cuts of the relation-code order are represented by class

well-orders) remains open. Source 30's [theorem 84.11](#) proves the set-like clause again (its second sentence), adds that the set-like part is dense in itself, and needs no completion theorem.

### 84.1.6 Product topology and a complete ambient order

For a set  $X$ , the familiar space of all linear orders  $\mathcal{L}(X) \subseteq 2^{X^2}$  is closed in the product topology: failures of the linear-order axioms are witnessed by finitely many entries. This is the classical relation-table space used, for example, in [62, Section 4]. Every infinite fixed well-order type of cardinality  $|X|$  is product-dense there, since finite constraints can be put first and the remaining labels well-ordered afterward.

Order-density for a long scan is different. Inspect  $(x_{n+1}, x_n)$  first for  $n < \omega$ . The all-one initial prefix forces an infinite descending chain and cannot extend to a well-order, although it extends to many linear orders. Three such extensions, differing on reserved labels, delimit a nonempty table-order interval containing no well-order. Thus finite-coordinate density cannot be substituted for lexicographic density.

There is nevertheless a useful completeness fact for the *set* space of all linear-order tables.

**Proposition 84.6** (Complete ambient table order). *For every set-length scan  $s$ , the linear order  $\mathcal{L}_s(X)$  has endpoints and every subset has a supremum and an infimum.*

*Proof.* Translate each prescribed off-diagonal table bit into a directed constraint. A feasible partial table is exactly a constraint set with no finite directed cycle. It extends to a linear order by orienting unassigned pairs successively: at least one orientation avoids a cycle, since two forbidden orientations would give an old cycle. At limits a new finite cycle cannot appear. Greedily preferring the smaller, or larger, available bit gives the least, or greatest, completion of any feasible prefix, including the empty prefix.

Let  $\mathcal{A}$  be a nonempty subset of  $\mathcal{L}_s(X)$ . Follow the smallest bit realized by some member matching the current prefix. If a full member survives, it is the minimum. Otherwise there is a first limit stage  $\lambda$  at which the accumulated prefix  $p$  has no matching member. Every finite part of  $p$  is matched, so it is acyclic and has completions. Let  $G$  be its greatest completion. Every member of  $\mathcal{A}$  first differs from  $p$  before  $\lambda$ , with bit 1 against 0, so  $G$  is a lower bound. A larger lower bound would first differ upward from  $p$  at some earlier coordinate; a member of  $\mathcal{A}$  still matches  $p$  through that coordinate and lies below the proposed lower bound. Thus  $G = \inf \mathcal{A}$ . Reverse the construction for suprema; empty subsets use the endpoints.  $\square$

This does not identify  $\mathcal{L}_s(X)$  as the Dedekind completion of  $\mathcal{W}_s(X)$ : density can fail, and adjacent points require care even when a dense inclusion is available. Nor is the proposition being extended to a class-length scan without a separate recursion analysis.

[merge] The extension of a feasible partial table is the constraint closure of the proof of [theorem 38.2](#); for well-orders, source 30's [theorem 84.7](#) gives the exact criterion (well-foundedness of the forced relation, not merely acyclicity).

## 84.2 Source 30: extension, local limits, and invisible order types

[merge] Source 30's Section 7, printed whole; its assembly comments (lines 2056–2059 of its L<sup>A</sup>T<sub>E</sub>X source, a “research fragment” header) are not printed. No other source proves its results; source 27's [proposition 84.6](#) contains the acyclic set-level case of the extension step.

Relation-table lexicography admits a useful local theory that does not require aligning the enumeration domains of non-set-like orders. The main result is stronger than density of the set-like orders: every supplied global well-order type realizes exactly the same set-sized partial tables.

Throughout this section work in GBC, and supply a proper class  $X$  and a class bijection  $e : \text{Ord} \rightarrow X$ . The application is  $X = \mathbf{No}$ . A *class well-order* is a strict linear order under which every nonempty admitted subclass has a least element; it need not be set-like. Statements about several orders or an indexed family mean statements about supplied class parameters or one uniformly represented class relation. They do not collect class relations into another class.

### 84.2.1 An exact extension theorem for partial tables

Let  $D \subseteq X^2$  be a set and let  $p : D \rightarrow \{0, 1\}$  prescribe relation bits. Write  $A$  for the set of labels occurring in  $D$ . A positive off-diagonal bit requires its indicated orientation; a negative one requires the opposite orientation, because the extension must be total. Thus define a set relation  $P_p$  on  $A$  by

$$uP_pv \iff u \neq v \text{ and } (((u, v) \in D \ \& \ p(u, v) = 1) \text{ or } ((v, u) \in D \ \& \ p(v, u) = 0)).$$

Well-foundedness of  $P_p$  means that every nonempty subset of  $A$  has a  $P_p$ -minimal element. Transitivity of  $P_p$  is not required.

**Theorem 84.7** (Extension with an arbitrarily prescribed global type). *Fix any supplied class well-order  $J$  of  $X$ . The partial table  $p$  extends to a class well-order  $W$  isomorphic to  $J$  if and only if*

1. *every prescribed diagonal bit is 0;*
2. *the forced relation  $P_p$  is well-founded.*

*In particular, the conditions for extension to a set-like well-order are the same as the conditions for extension to any other supplied global well-order type.*

*Proof.* Necessity follows because  $P_p \subseteq W$ : the  $W$ -least element of any nonempty subset of  $A$  is  $P_p$ -minimal.

For sufficiency, rank the set-sized well-founded relation:

$$\varrho(v) = \sup\{\varrho(u) + 1 : uP_pv\}.$$

Order  $A$  lexicographically by the pairs  $(\varrho(v), e^{-1}(v))$ . This gives a set well-order  $\sigma$  extending  $P_p$ . Let  $\beta$  be its order type.

The first  $\beta$  elements of  $J$  form a set initial segment  $L$  of type  $\beta$ . To see this without invoking class-length recursion, recursively choose the  $J$ -least label outside the previously chosen set, for  $\xi < \beta$ . Such a label exists because  $X$  is proper and  $J$  is a class well-order. This is ordinary set-valued recursion of set length with a class parameter; class replacement makes its range a set. No instance of elementary transfinite recursion along a proper class is being used.

Let  $h : (A, \sigma) \rightarrow (L, J)$  be the increasing bijection. Both  $X \setminus A$  and  $X \setminus L$ , in their inherited  $e$ -orders, have type  $\text{Ord}$ . Their increasing enumerations extend  $h$  to a class permutation  $\pi$  of  $X$ . Pull  $J$  back along  $\pi$ :

$$xWy \iff \pi(x)J\pi(y).$$

Then  $W \cong J$  and  $W \upharpoonright A = \sigma$ , so every bit of  $p$  is realized. Taking  $J$  to be the baseline  $e$ -order gives a set-like extension.  $\square$

For a finite table, condition (2) is just absence of a directed cycle. For an infinite table, acyclicity is insufficient: the requirements  $x_{n+1} < x_n$  for  $n < \omega$  are acyclic but cannot extend to a well-order. The theorem therefore gives the exact additional condition needed at infinite observation scales.

When no particular global type is prescribed, a simpler extension suffices: place  $(A, \sigma)$  first and then append the  $e$ -ordered complement. The transport argument is needed to preserve a specified possibly non-set-like type.

### 84.2.2 Finite and countable observations have different closures

For a supplied class relation  $R$  and a set  $D \subseteq X^2$ , write

$$N_D(R) = \{W : W \text{ agrees with } R \text{ on } D\}.$$

Internally this is a *neighborhood notation*: membership is a formula about supplied class relations. It does not assert the existence of a set or class of all its members.

**Theorem 84.8** (Exact local-approximation criteria). *Fix a supplied class well-order  $J$  of  $X$ , and let  $R$  be an arbitrary supplied class relation on  $X$ .*

1. *Every finite partial table of  $R$  has an extension isomorphic to  $J$  if and only if  $R$  is a strict linear order.*
2. *Every countable partial table of  $R$  has such an extension if and only if  $R$  is a class well-order.*
3. *The criterion in (2) is unchanged if “countable” is replaced by “set-sized”, or by “a bounded prefix of a fixed set-like scan of  $X^2$ ”.*

*Proof.* Irreflexivity, totality and transitivity are all tested on finitely many coordinates. Thus the finite extension condition implies that  $R$  is a strict linear order. Conversely, its restriction to the finitely many labels of a finite table is a finite well-order, and [theorem 84.7](#) applies.

If  $R$  is a class well-order, its restriction to the set of labels of any set-sized table is a set well-order. The same theorem again supplies an extension of the prescribed type.

For the remaining implication, countable extension first gives linearity. Suppose a nonempty admitted subclass  $C$  has no  $R$ -least element. Choose  $c_0$  by the baseline enumeration, and recursively let  $c_{n+1}$  be the  $e$ -least member of

$$\{x \in C : xRc_n\}.$$

Set-valued iteration and class replacement produce the set sequence  $(c_n)_{n < \omega}$ . Its consecutive positive bits form a countable partial table that no well-order can realize. This contradiction establishes (2). The argument uses the supplied global enumeration to make the choices; it does not silently appeal to a stronger class dependent-choice principle.

Finally, any set of scanned coordinates has a set of ordinal positions and is therefore bounded in the scan. Every bounded prefix is itself a set. This proves the last equivalence.  $\square$

Consequently the finite-support closure of *each* admitted global isomorphism type consists of all strict linear orders, whereas its countable-support and set-support closures consist exactly of all class well-orders. These are equalities of closure criteria; they do not identify the three neighborhood topologies.

The numerical surreal order illustrates the finite/countable distinction. Every finite restriction is a well-order, but the countable chain  $0 > -1 > -2 > \dots$  prevents approximation on every countable support. Conversely, set-likeness has no such local obstruction: every set-sized table belonging to a non-set-like well-order also belongs to a set-like one.

More explicitly, put  $A_\alpha = e^{\alpha}$  and, for a class well-order  $R$ , define

$$R_\alpha = (R \upharpoonright A_\alpha) + (e \upharpoonright (X \setminus A_\alpha)).$$

This is a uniform class family of set-like well-orders. It eventually agrees with  $R$  on every set of coordinates. For example, let  $R$  put one distinguished label last and  $e$ -order all remaining labels. Then  $R$  has type  $\text{Ord} + 1$ , although every  $R_\alpha$  has type  $\text{Ord}$  and has no last element.

### 84.2.3 An ordinary class tree of set approximations

There is a useful formalization of this local theory that keeps all nodes set-sized. Let the level  $\alpha$  of a class tree consist of the set well-orders of  $A_\alpha$ , ordered by restriction between levels. Every level is a set, and the entire node collection is an ordinary class of set-coded pairs  $(\alpha, \sigma)$ .

**Proposition 84.9** (Branches and stabilization). *Supplied class well-orders of  $X$  correspond exactly to supplied coherent class branches meeting every level of this tree. The well-order obtained from a branch is set-like if and only if, for each label  $x$ , its predecessor sets in the successive levels eventually stabilize.*

*Proof.* Restriction sends a class well-order to a coherent branch. Conversely, coherence defines a strict linear order  $R$  on  $X$ . Every set of labels lies in some  $A_\alpha$ , so every set restriction is well-ordered. The countable descending-chain argument from [theorem 84.8](#) makes  $R$  a class well-order.

For  $x = e(\xi)$  and  $\alpha > \xi$ , let  $P_\alpha(x)$  be its predecessor set at level  $\alpha$ . These are nested sets whose class union is the full predecessor class. If that class is a set, its  $e$ -indices are bounded, so  $P_\alpha(x)$  eventually becomes constant. Conversely, a constant final value is the entire predecessor class and is a set.  $\square$

The limit-level requirement matters. Coherence of finite well-orders alone can produce an ill-founded limit; requiring a well-order at every set stage excludes the countable descending witness. No collection of all branches is introduced by this description.

### 84.2.4 An external topology and the absence of continuous type detectors

To turn the neighborhood notation into an ordinary topological space, choose an external set-sized two-sorted realization  $\mathfrak{M} = (M, \mathcal{C})$  of the stated theory. Let  $\mathfrak{W}_{\text{all}}^{\mathfrak{M}}$  be the external set of its admitted class well-orders. Give it the topology generated by  $N_D(R)$  with supports  $D$  that *the model regards as sets*. These cylinders are clopen and separate distinct admitted relations, so the space is Hausdorff. Equivalently, one may use the internally bounded scan prefixes.

For an admitted  $J$ , let  $[J]_{\mathfrak{M}}$  denote the orders isomorphic to  $J$  by an admitted class isomorphism. This explicitly fixes the meaning of isomorphism when the external realization is not transitive.

**Corollary 84.10** (Dense type fibers and continuous invariants). *Every  $[J]_{\mathfrak{M}}$  is dense and codense in  $\mathfrak{W}_{\text{all}}^{\mathfrak{M}}$ . The set-like orders and the non-set-like orders are both dense. Every continuous isomorphism-invariant map from  $\mathfrak{W}_{\text{all}}^{\mathfrak{M}}$  to a  $T_1$  space is constant.*

*Proof.* The extension theorem, interpreted in  $\mathfrak{M}$ , puts a member of  $[J]_{\mathfrak{M}}$  in every nonempty basic neighborhood. There are at least two distinct types, Ord and Ord + 1. Thus every type fiber has a different dense fiber in its complement. Type Ord provides the set-like approximants, while type Ord + 1 provides non-set-like approximants.

If  $f$  is invariant and continuous, then it is constant, with value  $f(J)$ , on the dense fiber  $[J]_{\mathfrak{M}}$ . Since the target is  $T_1$ , the preimage of  $\{f(J)\}$  is closed. A closed set containing a dense fiber is the whole domain, so  $f$  is constant.  $\square$

In particular, the indicator of set-likeness, with values in the discrete two-point space, is discontinuous at every point. The same holds for membership in any one type fiber. The full table does determine its order type; the obstruction concerns recovering that type continuously from set-sized observations.

The phrase “model regards as sets” is essential. Externally the whole carrier is a set. If all external coordinate subsets were allowed, observing the entire table would be a permitted basic

neighborhood and the topology would be discrete. The preceding corollary makes no assertion about that different topology.

### 84.3 Source 30: the order topology of relation-table lexicography

Fix a set-like scan of  $X^2$ , and compare table bits with  $0 < 1$ . The first disagreement exists for any two supplied distinct tables. Support neighborhoods and order neighborhoods are related, but they need not generate the same topology.

#### 84.3.1 Density for every scan on the set-like part

We first recall the endpoint-transfer argument, which already appears in the repository ([theorem 38.2](#), source 15). Suppose a well-order  $W$  is claimed to be an extremum but a strict linear order  $L$  improves its table at the first disagreement. Let  $P$  be the set of oriented constraints from the earlier coordinates. If the desired improvement puts  $y$  before  $x$ , take the  $P$ -predecessor closure  $D$  of  $y$ , including  $y$ . It is a set and does not contain  $x$ , since  $L$  extends  $P$ . Moving  $D$  to the front of  $W$ , preserving the old orders inside  $D$  and its complement, respects every earlier constraint and makes the desired improvement. It remains a well-order and remains set-like if  $W$  was set-like. Hence minima and maxima among well-orders, or among set-like well-orders, are also extrema among all strict linear orders.

**Theorem 84.11** (Scan-independent density of the set-like part). *For every set-like scan, the relation-table order of the set-like global well-orders is dense. Moreover, set-like well-orders are topologically dense in the order topology of all admitted class well-orders.*

*Proof.* Let  $R < S$  be set-like and let  $\delta$  be their first disagreement. Start with the set of labels in the scan through  $\delta$ . Close it under predecessors in both  $R$  and  $S$ , iterating this operation  $\omega$  times. Class replacement and set-likeness ensure that the resulting  $A$  is a set, and it is an initial segment of both orders. Put  $B = X \setminus A$ .

If no set-like order lay between  $R$  and  $S$ , replacing their  $B$ -tails independently would imply that  $R \restriction B$  is greatest and  $S \restriction B$  is least among set-like orders of  $B$ , under the induced scan. The endpoint-transfer argument makes them extrema among all linear orders of  $B$ . Reversal complements every nonconstant table bit, so these extrema are reversals of one another. An order on an infinite carrier and its reverse cannot both be well-orders. This is a contradiction.

For the final assertion, a point  $T$  of any nonempty open order interval has a bounded table prefix fixing its comparisons with the interval endpoints. A set-like extension of that prefix still lies in the interval. The same argument treats open rays.  $\square$

The last assertion is topological density, not a claim that every pair of distinct non-set-like orders has an intermediate order for an arbitrary scan. That stronger question requires another argument. The next explicit scan does have the stronger property.

*Note 84.12* ([merge]; one density theorem, two proofs). The second sentence of [theorem 84.11](#) is the set-like clause of source 27's [theorem 84.5](#), which is stronger: the core  $\mathcal{P}_s(b)$  already meets every nonempty open interval, and neither order has isolated points. Source 27 completes a set prefix by a bounded-support permutation ([theorem 101.1](#)); source 30 extends the prefix by [theorem 84.7](#). The first sentence of [theorem 84.11](#), that two set-like orders always have a set-like order strictly between them (no adjacent pairs), is source 30's only; its proof is the reversal argument of [corollary 38.3](#), applied to a tail. Source 30 did not see source 27.

### 84.3.2 A canonical baseline scan with asymmetric local character

Identify labels with their  $e$ -indices. Scan the unordered pairs  $(\xi, \eta)$ ,  $\xi < \eta$ , in increasing order of  $\eta$  and then  $\xi$ , and use bit 1 when  $e(\xi)$  precedes  $e(\eta)$ . This is a set-like class scan. It can be converted to a full directed-pair scan by listing the reverse direction immediately after each pair and inserting the constant diagonal bits.

For a set well-order  $\sigma$  on  $A_\alpha$ , let  $C_\sigma$  be the orders whose restriction to  $A_\alpha$  is  $\sigma$ .

**Theorem 84.13** (Canonical table characters). *For this scan, both the set-like order and the order of all class well-orders have the following properties.*

1. *They are dense, have the baseline order as greatest element, and have no least element.*
2. *Every  $C_\sigma$  has a greatest element and a strictly decreasing countable coinital sequence of set-like elements.*
3. *No point has a uniformly represented set-sized cofinal family strictly below it.*
4. *A nongreatest point  $W$  has a uniformly represented set-sized coinital family strictly above it if and only if its inversion class*

$$\text{Inv}(W) = \{(\xi, \eta) : \xi < \eta \text{ and } e(\eta)We(\xi)\}$$

*is a set.*

*Proof.* The greatest element of  $C_\sigma$  is  $M_\sigma$ , which puts  $\sigma$  first and then appends the baseline tail: every still undetermined bit is 1.

For  $n \geq 1$ , let  $W_n$  put

$$e(\alpha + n - 1), \dots, e(\alpha + 1), e(\alpha)$$

first, then  $\sigma$ , then the remaining baseline tail. These set-like orders form a strictly decreasing sequence in  $C_\sigma$ . They are coinital there. Indeed, their successive new labels are always inserted before every previously scanned label, the least possible insertion. An order that were below or equal to every  $W_n$  would have to make all these least insertions and would contain the descending sequence  $e(\alpha) > e(\alpha + 1) > \dots$ . A class well-order cannot do so. Thus every member of  $C_\sigma$  has some  $W_n$  strictly below it.

Given  $R < S$ , choose  $\alpha$  large enough that agreement with  $S$  on  $A_\alpha$  fixes the comparison  $R < S$ . A member of the preceding sequence below  $S$  lies strictly between  $R$  and  $S$ . This proves density and absence of a minimum. The baseline has all bits 1 and is the maximum.

For a supplied set family  $V_i < W$ , bound all first disagreements with  $W$  using class replacement. In a sufficiently long matching cylinder, choose a set-like element strictly below  $W$ . It still lies above every  $V_i$ , proving (3).

If  $\text{Inv}(W)$  is proper, every matching cylinder  $C_{W|A_\alpha}$  has maximum strictly greater than  $W$ . Bounding the first disagreements of any supplied set family above  $W$  and taking such a later maximum gives a still closer point above  $W$ . Thus no such family is coinital.

If  $\text{Inv}(W)$  is a set, choose  $\gamma$  containing the endpoints of all inversions. Every  $U > W$  first differs on a pair lying in  $A_\gamma^2$ . Therefore  $\tau = U|A_\gamma$  is table-greater than  $\sigma = W|A_\gamma$ . There are set-many such set orders  $\tau$ . Each cylinder  $C_\tau$  lies wholly above  $W$  and has the displayed countable coinital sequence. Their union is a uniformly represented set-sized family coinital strictly above  $W$ , proving (4).  $\square$

**Corollary 84.14** (The eventual-equality core in the canonical table order). *A class well-order has set-sized inversion support for this scan if and only if it is set-like and its ordinal enumeration is eventually equal to  $e$ .*

*Proof.* If all inversion endpoints lie in  $A_\gamma$ , the order puts some set well-order  $\sigma$  of  $A_\gamma$  first and then the unchanged baseline tail. Write  $\beta = \text{otp}(\sigma)$ . Choose an additively indecomposable ordinal  $\lambda > \gamma, \beta$ . The identities  $\gamma + \lambda = \beta + \lambda = \lambda$  align the two enumerations beyond  $\lambda$ , proving eventual equality. Conversely, if an enumeration agrees with  $e$  from  $\lambda$  onward, its first  $\lambda$  entries are exactly  $e[\lambda]$ . All inversions are consequently contained in the set  $\lambda \times \lambda$ .  $\square$

Bounded inversion support thus has an intrinsic description in this particular table order: away from its greatest point, it is exactly the existence of a set-sized right coinital family. The left side has no analogous small character. These properties are different from numerical enumeration lexicography and should not be transferred between the two representations.

The support topology is strictly finer than the order topology for this scan. Order neighborhoods contain sufficiently long matching table cylinders. In the other direction, swap the first two baseline labels and keep the remaining baseline tail. The result is the nongreatest maximum of its two-label cylinder. Every order neighborhood of it contains larger points by density, and those points leave the cylinder. That cylinder is consequently not order-open, although it is clopen in the support topology.

[merge] The canonical scan realizes source 15’s pattern “maximum only” (corollary 38.3) with the baseline as maximum. With  $e$  as the baseline  $b$ , the orders of corollary 84.14 are exactly the enumerations  $b \circ \pi$  coded by the core  $\mathcal{P}_s(b)$  of theorem 84.5: a permutation of Ord with set support fixes every ordinal beyond its support, and conversely, as the proof shows, an enumeration eventually equal to  $b$  permutes an initial segment of  $b$ ’s positions. So the core has an intrinsic description in this table order: apart from the maximum, its members are exactly the points with a set-sized coinital family strictly above them. Theorem 84.13 is the first intrinsic, scan-dependent local invariant of a relation-table order on **No**: item (4) separates points by their right character. It does not decide whether two set-like scans of type Ord can give isomorphic orders.

## 85 What this Part answers

[merge] Dated notes, 3 October 2026, in the form of section 39; where that section or the question index of section 113 says otherwise, these notes supersede it. Open items that remain open are re-scoped, not closed.

- (a) *The isomorphism type of the centered increasing order* (section 39, item (b); source 18’s own question): **answered in part**.  $\mathcal{T}_c^{\text{inc}} \cong \mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$  in GBC, where  $\mathbf{T}_{\min}$  is the endpoint type of theorem 36.2 (source 27’s corollary 82.5; source 29’s note 82.11); the zero conventions  $\dagger_+$  and zero padding give the same type and  $\dagger_-$  differs from it exactly by its adjacent pairs (proposition 82.6 and note 82.13). Open: an identification of  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$  with a simpler order, for instance with  $\mathbf{T}_{\min}^+$  (source 27’s Question 12.4), and an intrinsic description of its factors (source 29’s Question 13.4).
- (b) *Increasing words with an interior terminator at a threshold other than zero* (section 39, items (b) and (d); source 16’s question “Centered increasing words”): **answered in part**. No placement of a marker gives a set-cut saturated order, so none gives **No** (theorem 82.1, source 23). Every actual threshold, under each zero convention, and every gap whose sides have no set cofinal (resp. coinital) subset and no endpoint, gives the centered type of (a) (proposition 82.14, source 29). At every interior gap the point characters and the adjacent pairs are known (proposition 82.8, source 27); they show that a gap with a small cofinality or coinitality on one side gives a type different from  $\mathcal{T}_c^{\text{inc}}$ . Open: the isomorphism types at those

gaps and the cut classification at a general threshold (source 27’s Question 12.5, source 29’s Question 13.5; source 23’s Question 16.2 asks which restrictions repair saturation).

- (c) *The isomorphism question for two scans* (section 39, item (e)) and *source 08’s question 9* (“Classification of relation-code orders”, section 113.4): **answered negatively on set carriers, open on No**. On every infinite set carrier there are two scans whose relation-table orders of well-orders are not isomorphic (theorems 84.3 and 84.4), while the ordinal and reverse-ordinal spectra and the cardinality do not depend on the scan (theorem 84.2): isolated points, density and cellularity are artifacts of the scan, the spectrum is not. For set-like scans of  $\mathbf{No}^2$  of type Ord no pair of non-isomorphic orders is known; the canonical scan of theorem 84.13 supplies a scan-dependent local invariant (right characters separate the eventual-equality core), and corollary 84.10 shows that no continuous invariant of set-sized observations detects the order type. The open forms are source 27’s Questions 12.1–12.3, source 29’s Question 13.11 and source 30’s Questions 12.6–12.7.
- (d) *Source 09’s direction “Non-set-like well-order relations”* (section 113.3; its status after the merge, which says that the dense core and the representation of cuts remain open): **answered in part**. For every set-like scan the core  $\mathcal{P}_s(b)$ , compared by relation tables, meets every nonempty open interval of the order of all class well-orders (theorem 84.5, source 27), and the set-like part is dense in itself (theorem 84.11, source 30). Which order properties depend on the coordinate enumeration is answered for endpoints (corollary 38.3), for isolated points on set carriers (item (c)) and for local characters at one canonical scan (theorem 84.13). Open: which cuts of a relation-code order are represented by class well-orders.
- (e) *Source 13’s question “A classification of termination cuts”* (section 39, item (c)): unchanged; source 23’s notes 81.9 and 81.12 are a second proof for an abstract saturated alphabet (section 81). *Source 23’s Question 16.1*, whether all marker orders with characters  $(\theta, \text{Ord})$  are isomorphic and whether the answer changes between arbitrary and injective words, is **already answered** at this report’s text: all are  $\mathbf{T}_\theta$ , and arbitrary and injective words are isomorphic at every placement (theorem 36.2, source 16, transported along an isomorphism of the alphabet with **No** in GBC). Source 23 had read this report before Part VII was written.

Numerically well-ordered proper-class carriers (section 83) were not the subject of a recorded question; source 29’s Question 13.6 asks for the type of the dense quotient of corollary 83.4.

## Part XIII

# The core and its cylinders: symmetries, decorated completions and class realizations

[merge] (3 October 2026.) This Part of the batch-83 addition continues Part IV (part IV), which built the core, and Part VIII (part VIII), which classified its class cuts, recognized the cuts of global enumerations, and showed that the bare order of the core forgets which of its cuts are represented. Part VIII left four things open (section 50, items (c), (e) and (f)): the stabilizer of the exhaustive cuts and which extra predicates make the reconstruction unique; what the external order type of the admitted enumerations remembers about the class realization; and ordinal support bounds. Eight batch-83 sources take these up, and this Part prints what they prove.

- *The core and its cylinders* (base: source 25). Source 22 shows that unranked cylinder inclusion recovers prefix heights (theorem 87.1) and recognizes represented cuts without ranks

(theorem 87.4). Source 25 classifies the orbits of every set-indexed configuration of injective branches under automorphisms preserving the core order and every cylinder (theorem 90.1): there are exactly two single-branch orbits, the core and the rest. Hence exhaustiveness is invisible to the core with all its cylinders, even with set-many parameters fixed (theorems 91.1 and 91.2), and a cylinder-preserving core automorphism need not extend to  $\mathfrak{W}_{\text{sl}}$  (theorem 92.2), which strengthens theorem 47.7. One cross-node relation, equality of edge labels, makes the structure rigid (theorem 93.3). At a regular  $\kappa$  with  $\kappa^{<\kappa} = \kappa$  the set version has exactly  $2^\kappa$  automorphisms (theorem 94.2); a family of cf  $\kappa$  approximants can force a noncore branch, so the bound in the set version is sharp at regular  $\kappa$  and the method fails at singular  $\kappa$  (theorem 95.1).

- *Ordered prefix trees without the core* (sources 27 and 29): branch transitivity on injective and on increasing words, the exact local obstruction, and families that preserve exhaustion (section 96).
- *Automorphisms of the bare core* (sources 20 and 21): re-proofs of Part VIII's orbit classification and extension criterion, a failure localized inside any interval while fixing any set of core points (theorem 97.7), disjointness of relabelled cores (proposition 97.9) and an explicit cut with no crossing first-level cylinder (proposition 97.20).
- *Decorated completions* (source 19): the Dedekind completion of the external raw order is the core completion with every represented fibre replaced by its interval completion (theorem 98.2); a core automorphism extends to the raw order exactly when it preserves fibre types (theorem 98.5); over residual alphabets at most two initial words share a trace (proposition 99.2); and every countable model omits continuum many amenable branches (theorem 100.1).
- *The least ordinal support* of a completion of a partial injection (source 27, theorem 101.2).
- *Class realizations* (sources 22, 27, 21 and 30): the admitted labelled traces recover the whole class realization (theorem 102.3, proved three times); the external order of a countable model is  $\mathbb{Q}$  even with the core coloured and the baseline fixed, and does not detect ETR (propositions 102.19 and 102.20).

Section 105 records which questions the Part answers.

*Printed once.* Height recovery is printed as source 22's theorem 87.1 (source 25, which credits it, is a note); the label-coherence theorem as source 25's theorem 93.1 (source 27's Theorem 6.5 is a note); the faithful reconstruction as source 22's theorem 102.3 (sources 27 and 30 are notes with their proofs as routes). The extension criterion and the orbit classification are Part VIII's theorems 47.2 and 47.5; their re-proofs in sources 20, 21 and 25 are notes with their proofs, as are the sources' re-proofs of Part IV (section 86). Sources 19–22 were written against pins (d5bd4a67b, 109aaca15) that predate Parts VI–VIII; sources 25, 27, 29 and 30 against 7ff7736ec, which contains Parts I–VIII. Source 25 read source 22 and source 23; source 29 read sources 19, 20 and 21; sources 27 and 30 cite no batch-83 source.

*Notation* (renamings for this Part; the batch-83 notation addendum, section 1.3.2, lists them with the other Parts'). The core is printed  $\mathcal{P}_s(b)$  in the support coding of sources 22, 25, 27 and 30 (their  $\mathcal{D}_b$ ,  $\mathcal{D}$ ,  $\mathcal{D}_b$  and  $\mathcal{B}_b$ ) and  $\mathcal{P}_{\text{bd}}(b)$  in the normalized-permutation coding of sources 19, 20, 21 and 29 (their  $\mathcal{C}$ ,  $\mathcal{C}_b$ ,  $\mathcal{S}_b = \mathcal{P}_b$  and  $\mathcal{P}_e$ ); the two codings have the same evaluations (section 1.3). *False reading:* source 25's  $\mathcal{C}_b$  is not the core but the two-sorted core-and-cylinder structure, printed  $\mathbf{C}_b$ ; sources 24 and 26 write  $\mathcal{C}_b$  for the core itself. The class of injective set-length words,  $\mathcal{T}$  in sources 22, 25 and 27 and  $\mathcal{J}$  in source 29, is printed  $\mathcal{I}$ , and source 29's increasing words  $\mathcal{J}$  are printed  $\mathcal{T}^{\text{inc}}$ ;  $\mathcal{T} = \mathcal{T}$  is all words here. Cylinders are  $\mathcal{C}_p$  (sources 20 and 22 write  $\mathcal{C}(p)$ , source 21  $\mathcal{S}_p$ ). Sources 22 and 25 write  $\mathfrak{E}$ ,  $\mathfrak{J}$  for  $\mathfrak{W}_{\text{sl}}$ ,  $\mathfrak{J}$ ; source 19's script  $\mathcal{H}_{\text{all}}$  is printed  $\mathfrak{W}_{\text{all}}$ . Source 25's

direction sign  $\varepsilon(f, g)$  is printed  $\text{sgn}(f, g)$ , since  $\varepsilon$  is a termination symbol in Part VII; its set-sized version at a regular  $\kappa$  carries a superscript:  $\mathcal{P}_s^\kappa(b)$ ,  $\mathcal{I}^\kappa$ ,  $\mathfrak{J}^\kappa = \text{Inj}(\kappa, X)$ ,  $\mathbf{C}_b^\kappa$ , and its  $\mathfrak{E}_\kappa = \text{Bij}(\kappa, X)$  is  $\mathcal{W}_\kappa(X)$ . Source 20 writes  $\Omega$  for “no set-sized witness”, which Part VIII writes  $\text{Ord}$ ; it is kept. Class realizations over one set universe are  $\mathcal{X} \subseteq \mathcal{Y}$  (sources 22, 27, 21; source 30’s  $\mathcal{C}$ ,  $\mathcal{D}$  are renamed); their external collections of admitted set-like enumerations are written  $H_{\mathcal{X}}$  (sources 21, 27) and  $\mathcal{E}(\mathcal{X})$  (source 30). Displayed equations of source *NN* keep their numbers as (*SNN.n*). Labels: *swo:rs*: (19), *swo:lm*: (20), *swo:fu*: (21, keeping its internal *gl*: and *fnd*:), *swo:rg*: (22), *swo:ph*: (25), *swo:sc*: (27), *swo:bw*: (29, keeping *ta*:, *gl*:), *swo:rt*: (30, keeping *fnd*:); labels written for this Part begin *swo:xiii*:.

## 86 The core as re-proved in sources 25, 22, 21 and 29

[merge] Four sources re-prove the layer of Parts III and IV on which their new results rest, and each credits it to this report. Their sections are printed here whole, as re-proofs; none is new against the repository.

- *Fixed-set spectrum and class universality*: [theorem 6.1](#) and [proposition 5.13](#) (source 25’s [notes 86.1](#) and [86.2](#)).
- *Fresh separators*: [lemma 5.2](#) and source 13’s [lemma 42.1](#) ([notes 86.3](#) and [86.8](#)).
- *Prefix completion with a reserve*: [lemma 19.4](#) with [remark 19.7](#); [theorem 49.7](#) gives the least reserve and source 27’s [theorem 101.2](#) the least ordinal support ([notes 86.4](#), [86.7](#) and [86.13](#)).
- *Interpolation and the core isomorphic to **No***: [theorem 19.10](#) and [corollary 19.15](#) ([notes 86.5](#), [86.9](#), [86.14](#) and [86.18](#)).
- *Trace injectivity*: the uniqueness clause of [theorem 45.1](#) ([note 86.6](#)).
- *Raw comparison*: [theorem 14.2](#) and source 12’s [theorem 14.7](#) ([notes 86.10](#) and [86.17](#), and source 25’s [note 103.1](#) in [section 103](#)).
- *First block, fibres and set-interval blocks*: [theorem 15.1](#) and [proposition 15.3](#), and the block decomposition of sources 15, 16 and 18 printed in Part IX ([theorems 52.3](#), [52.6](#) and [52.11](#)) ([notes 86.11](#) and [86.12](#)); the core sees only the first block: [corollary 46.4](#) and source 14’s [theorem 54.6](#) ([note 86.15](#)).
- *The diagonal theorem*: [theorems 19.37](#) and [19.38](#) ([notes 86.16](#) and [86.19](#); source 25’s [note 104.1](#) in [section 104](#); source 22’s pair-swap form at the end of [section 102.1](#)).
- *Global choice is an assumption*: [theorem 13.1](#) (opening of source 21’s section).

The proofs differ in bookkeeping only. Sources 21, 22 and 29 complete a prefix inside an infinite initial cardinal, as Part IV does; source 25 adjoins a fresh reserve of the size of the prefix data, which is the point of [remark 19.7](#). Source 25’s diagonal ([note 104.1](#)) and source 29’s ([note 86.19](#)) use a guard step at odd positions in place of a pair swap.

### 86.1 Source 25: baseline embedding results and the set/class transition

The following arguments are part of the earlier general-alphabet theory ([theorem 6.1](#) and [proposition 5.13](#); the reals report). They are included because they sharply delimit what changes when one passes from a fixed birthday fragment to the whole surreal line.

*Note 86.1* (Source 25, Theorem 3.1, “Fixed-set size and ordinal spectrum”). *Let  $X$  be an infinite linearly ordered set of cardinality  $\mu$ . Then*

$$|\mathcal{W}(X)| = 2^\mu, \quad \beta \hookrightarrow \mathcal{W}(X) \iff \beta < \mu^+.$$

Every linear order of cardinality at most  $\mu$  embeds already into  $\mathcal{W}_\mu(X)$ . There is no increasing or decreasing sequence of type  $\mu^+$  in  $\mathcal{W}(X)$ . This is [theorem 6.1](#) (the reals report's general-alphabet theorem), with its ordinal spectrum; source 25 recalls it with its proof and does not present it as new.

*Source 25's proof.* Partition  $X$  into  $\mu$  pairs and write the members of the  $\xi$ th pair as  $x_\xi^- < x_\xi^+$ . For a binary word  $s \in 2^\mu$ , enumerate each pair increasingly when  $s(\xi) = 0$  and decreasingly when  $s(\xi) = 1$ , using consecutive positions  $2 \cdot \xi$  and  $2 \cdot \xi + 1$ . Ordinal multiplication is intended; these positions partition  $\mu$  for an infinite initial ordinal  $\mu$ . This gives an order embedding

$$(2^\mu, <_{\text{lex}}) \hookrightarrow \mathcal{W}_\mu(X).$$

If  $L$  has cardinality at most  $\mu$ , inject its elements into  $\mu$  and associate to  $x \in L$  the characteristic word of the elements strictly below  $x$ , with zero at unused coordinates. For  $x < y$  the first word is coordinatewise at most the second and differs at the coordinate of  $x$ , so the assignment is strictly lexicographically increasing. This proves the lower embedding assertion and the lower cardinal bound. The upper bound follows because each well-order is a subset of  $X^2$ .

Suppose, for a contradiction, that  $(e_\xi)_{\xi < \mu^+}$  is a strictly increasing sequence of exhaustive words on  $X$ . The indices whose words extend a fixed prefix form a convex set of indices. If this set is unbounded in  $\mu^+$ , it therefore contains a final segment.

Starting with the empty prefix, recursively construct a common prefix extended by a final segment of the sequence. At a successor stage there are at most  $\mu$  possible next labels. Termination cannot occur on an unbounded set of indices, since an exhaustive word cannot be a proper prefix of another exhaustive word. Regularity of  $\mu^+$  implies that one next-label cylinder is unbounded, and hence contains a final segment. At a limit stage below  $\mu^+$ , the intersection of the previously chosen final segments is still a final segment. The construction would give an injective word of length  $\mu^+$  in  $X$ , a contradiction. Reversing the sequence gives the decreasing version.

Every ordinal below  $\mu^+$  has cardinality at most  $\mu$ , and every larger ordinal contains  $\mu^+$  as an initial segment. The spectrum follows.  $\square$

For an infinite cardinal  $\kappa$ , let

$$\mathbf{No}_{<\kappa} = \{x \in \mathbf{No} : \text{bd}(x) < \kappa\}.$$

The sign-sequence representation gives  $|\mathbf{No}_{<\kappa}| = 2^{<\kappa}$ . Thus the preceding theorem applies with  $\mu = 2^{<\kappa}$ . In particular, the size parameter is not automatically  $\kappa$ . The singular-cutoff results in the repository show why suppressing that distinction can give wrong coding statements ([theorem 8.3](#); source 22).

*Note 86.2* (Source 25, Proposition 3.2, “Class-order universality, in GBC”). *Every supplied class linear order admits a class order embedding into  $\mathbf{No}$ . It consequently admits an embedding into  $\mathfrak{W}_{\text{sl}}$  and into the set-supported core  $\mathcal{P}_s(b)$ .* This is [proposition 5.13](#) with the core universality of [corollary 19.15](#); source 25's embedding into the core uses one-letter completions ([note 86.4](#)).

*Source 25's proof.* Use global choice to arrange the underlying class in a set-like construction order. When treating one element, only a set of earlier elements has been assigned images. Separate the images of its earlier predecessors from those of its earlier successors by a surreal number. The usual surreal small-cut property supplies such a separator. This set-valued recursion gives an order embedding into  $\mathbf{No}$ .

For each surreal  $x$ , choose a core completion of the one-letter prefix  $(x)$ ; the existence of this completion is proved in [Note 86.4](#). The resulting map  $x \mapsto d_x$  is increasing because the first letters already decide the comparison. Composition proves the assertion.  $\square$

This explains an important discontinuity. Each fixed set fragment has a bounded ordinal embedding spectrum, but the full global construction contains every set ordinal and every supplied ordinary class linear order. Neither statement asserts that a same-level class of *all* class orders has been collected or enumerated.

## 86.2 Source 25: foundational framework and the supported core

### 86.2.1 The background theory

Throughout the global arguments, GBC means Gödel–Bernays class theory with global choice. Sets and classes are distinct sorts; classes have sets as members. Elementary class comprehension allows class parameters but does not quantify over classes in its defining formula. A uniformly  $I$ -indexed family of class words means one supplied class relation whose rows, indexed by the set  $I$ , are the words in question. It does not mean a set containing proper classes.

We use a fixed set-like global well-order of the sets to make constructions deterministic when desired. A recursion along  $\text{Ord}$  whose stage values and histories at set stages are sets is available by ordinary set recursion with class parameters and elementary comprehension. The materially stronger principle ETR concerns recursions with class-sized stage values. That distinction is essential and is audited in [Section 104](#); see [\[63, 22, 24\]](#) for the background.

### 86.2.2 Fresh small-cut separation

*Note 86.3* (Source 25, Lemma 4.1, “A separator avoiding a prescribed set”). *Let  $L, R, S$  be sets of surreals with  $L < R$ . Then there is an  $x \in \mathbf{No} \setminus S$  with  $L < x < R$ . Either of  $L, R$  may be empty.* This is [lemma 5.2](#) and source 13’s [lemma 42.1](#), in the exact-birthday form.

*Source 25’s proof.* The surreal separator theorem permits a separator of any birthday strictly above all birthdays of the options. Choose an ordinal  $\gamma$  strictly above the birthdays of  $L \cup R \cup S$  and choose a separator of birthday exactly  $\gamma$ . It cannot belong to  $S$ . The exact-birthday form is supplied by the sign-sequence construction and by the repository declaration `exists_cut_separator_of_birthday_lt` [\[8\]](#).  $\square$

Only this order-theoretic separation property, not multiplication or analysis on surreals, is used in the new homogeneity argument. In particular, every nonempty numerical open interval has points outside any prescribed set. Removing a set from  $\mathbf{No}$  leaves an order with the same small-cut separation property.

### 86.2.3 Normalized codes rather than class objects

A normalized support code consists of a set  $S \subseteq \text{Ord}$  and a fixed-point-free permutation  $\pi_S : S \rightarrow S$ . Extend it by the identity outside  $S$  to obtain a class permutation  $\pi$  of  $\text{Ord}$ , and evaluate the code as the class word

$$d_\pi(\alpha) = b(\pi(\alpha)).$$

The empty support code evaluates to  $b$ . Requiring  $S$  to be the exact support ensures that distinct normalized codes have distinct evaluations. The collection  $\mathcal{P}_s(b)$  of these codes is an ordinary class of sets. Its lexicographic order is elementary in the parameter  $b$ .

All sets of ordinals are bounded, so a core branch agrees with  $b$  beyond some ordinal. Conversely, an *exhaustive* branch eventually agreeing with  $b$  belongs to the core: its transition permutation  $b^{-1} \circ d$  has bounded, hence set, support. Exhaustiveness is necessary in this converse. An injective word can omit a label while still agreeing with  $b$  on a final segment.

*Note 86.4* (Source 25, Lemma 4.2, “Supported prefix completion”). *Every  $p \in \mathcal{I}$ , of any set-ordinal length, extends to a core branch. Core completions can be selected uniformly from their set-coded prefixes.* This is [lemma 19.4](#). Source 25 adjoins a fresh reserve of the size of  $A$ , the device of [remark 19.7](#); [theorem 49.7](#) computes the least reserve and source 27’s [theorem 101.2](#) the least ordinal support.

*Source 25’s proof.* Write  $\alpha = \text{lh}(p)$  and let  $q = b^{-1} \circ p : \alpha \rightarrow \text{Ord}$ . This is a set partial injection. Put  $A = \alpha \cup q[\alpha]$ .

If  $A$  is finite, the sets  $A \setminus \alpha$  and  $A \setminus q[\alpha]$  have the same finite cardinality, so complete  $q$  to a permutation of  $A$ . If  $A$  is infinite, choose a fresh set  $R$  of ordinals, disjoint from  $A$ , with  $|R| = |A|$ . In  $U = A \cup R$ , both  $U \setminus \alpha$  and  $U \setminus q[\alpha]$  have cardinality  $|A|$ . Choose a bijection between them and adjoin it to  $q$ . This is a permutation of  $U$ , and extension by the identity outside  $U$  is a set-supported permutation of  $\text{Ord}$ .

Normalize its support. The associated core word extends  $p$ . Selecting the first valid normalized code in the fixed global well-order gives a uniform selection. All searches and restrictions here involve sets and supplied class parameters.  $\square$

The reservoir in the infinite case is not cosmetic. Two complements of equinumerous infinite subsets inside their union need not have the same cardinality. Adding a reserve on both sides avoids an invalid cancellation of infinite cardinals.

*Note 86.5* (Source 25, Lemma 4.3, “Core separation of full branches”). *If  $f, g \in \mathfrak{J}$  and  $f <_{\text{lex}} g$ , there exists  $d \in \mathcal{P}_s(b)$  with*

$$f <_{\text{lex}} d <_{\text{lex}} g.$$

*Every cylinder  $C_p$  is nonempty and has at least two distinct child cylinders.* The first assertion is the two-family case of [theorem 19.10](#), which is stated for injective words; the second is the nonemptiness of cylinders used throughout Part VIII.

*Source 25’s proof.* Let  $\delta = \delta(f, g)$  and  $p = f \upharpoonright \delta = g \upharpoonright \delta$ . Choose

$$f(\delta) < x < g(\delta), \quad x \notin \text{ran}(p),$$

using [Note 86.3](#). Complete  $p \frown (x)$  by [Note 86.4](#). The first disagreement with both words occurs at  $\delta$ . Nonemptiness and the existence of distinct children follow in the same way from fresh labels.  $\square$

*Note 86.6* (Source 25, Corollary 4.4, “Injectivity of the cut trace”). *For a supplied branch  $f \in \mathfrak{J}$ , define its lower core trace by*

$$L_f = \{d \in \mathcal{P}_s(b) : d <_{\text{lex}} f\}.$$

*Distinct branches have distinct traces.* This is the uniqueness clause of [theorem 45.1](#) and its routes ([note 46.1](#)).

*Source 25’s proof.* A core branch strictly between two distinct branches belongs to exactly one of their lower traces.  $\square$

The core is proper because every surreal occurs as the first letter of a core completion, while the image of a set under evaluation at zero would be a set. Therefore global choice supplies a class enumeration of its normalized codes. This enumeration will be used only to schedule the back-and-forth construction, not as an enumeration of  $\mathfrak{W}_{\text{sl}}$ .

### 86.3 Source 22: global enumerations and their set-coded core

From this section onward, unless otherwise stated, work in GBC: Gödel–Bernays set theory with Global Choice. The convention GB alone includes no choice axiom. A class function is represented by its class graph, and a uniformly indexed family of class functions is one class graph with an additional *set-valued* index coordinate.

#### 86.3.1 The virtual enumeration order

Fix a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . Write

$$\mathfrak{W}_{\text{sl}} = \{e : e \text{ is a class bijection } \text{Ord} \rightarrow \mathbf{No}\}$$

only as shorthand for a predicate on class variables. This display does not assert that  $\mathfrak{W}_{\text{sl}}$  is a set or an ordinary class. Distinct enumerations have a least disagreement ordinal: restrict a nonempty disagreement class to one ordinal witnessing a disagreement and use the well-ordering of that set. Comparing the two surreal labels there gives a strict linear order on the available enumerations.

The same comparison applies to injective class words  $h : \text{Ord} \hookrightarrow \mathbf{No}$  which need not be exhaustive. Every set-length restriction of such a word is a set by class replacement. This fact will be used repeatedly; a proper-class word itself is not a permissible element of a set-coded family.

#### 86.3.2 Canonical support codes

Let  $\mathcal{P}_s(b)$  consist of canonical set codes for permutations  $\pi : \text{Ord} \rightarrow \text{Ord}$  whose support

$$\text{supp } \pi = \{\xi : \pi(\xi) \neq \xi\}$$

is a set. One canonical code is the set of all moved ordered pairs  $(\xi, \pi(\xi))$ , with the identity recovered off its domain. The code for the identity is empty. Membership in the code class is elementary: the code is a set bijection from a set onto itself with no fixed points, extended by the identity outside that set. Such codes are unique, so  $\mathcal{P}_s(b)$  is an ordinary class of sets. Evaluate its code as the global enumeration  $b \circ \pi$ , and compare codes by their evaluations. We occasionally write a code as if it were its evaluation when no ambiguity results.

This distinction between codes and evaluations is indispensable:  $\mathcal{P}_s(b)$  is an ordinary class, whereas its evaluations are class functions. The evaluation relation is a single class with set-coded arguments.

*Note 86.7* (Source 22, Lemma 7.1, “Every set prefix has a supported completion”). *Every injective set word  $p : \alpha \hookrightarrow \mathbf{No}$  extends the evaluation of some code in  $\mathcal{P}_s(b)$ . Completions can be chosen uniformly from the set prefix code and the fixed global-choice parameters.* This is [lemma 19.4](#), completed inside an infinite initial cardinal as in Part IV.

*Source 22’s proof.* Transport  $p$  along  $b^{-1}$  to a set partial injection  $q : \alpha \rightarrow \text{Ord}$ . Choose an infinite initial cardinal  $\theta$  larger than  $\alpha$  and all members of  $\text{ran } q$ , with  $|\alpha| < \theta$ . Both complements

$$\theta \setminus \alpha, \quad \theta \setminus \text{ran } q$$

have cardinality  $\theta$ . Choose a bijection between them, join it to  $q$ , and extend the resulting permutation of  $\theta$  by the identity outside  $\theta$ . Its moved-pair graph is a set. This gives the required code. Fixing a global choice of the relevant set bijections makes the construction uniform. Every stage is a set construction with class parameters; no class-valued transfinite recursion is involved.  $\square$

*Note 86.8* (Source 22, Lemma 7.2, “Fresh separators”). *If  $a < b$  are surreal numbers and  $S$  is a set of forbidden surreal labels, there is  $z \in (a, b) \setminus S$ . There are also fresh labels on either side of any prescribed surreal.* This is lemma 5.2 and source 13’s lemma 42.1.

*Source 22’s proof.* Choose an ordinal birthday bound strictly above the birthdays of  $a, b$  and every member of  $S$ . The small-cut separator theorem at that exact birthday supplies  $z$  between  $a$  and  $b$ , and its birthday excludes membership in  $S$ . For rays, use a small cut with only one nonempty side and again prescribe a sufficiently large birthday. This is precisely the smallness boundary respected by the repository’s sign-sequence construction [7, 8].  $\square$

For an injective set prefix  $p$ , write

$$C_p = \{d \in \mathcal{P}_s(b) : \text{ev}_b(d) \text{ extends } p\}.$$

Every  $C_p$  is nonempty and convex. If  $h$  is an injective Ord-word extending  $p$ , then there are points of  $C_p$  both below and above  $h$ : choose at the next coordinate a fresh label on the desired side of  $h(\text{dom } p)$  and apply note 86.7.

*Note 86.9* (Source 22, Proposition 7.3, “Density in all injective global words”). *For any distinct injective Ord-words  $h < k$ , there is a code  $d \in \mathcal{P}_s(b)$  with  $h < d < k$ . In particular,  $\mathcal{P}_s(b)$  is dense without endpoints, and its comparisons separate distinct global words.* This is the two-family case of theorem 19.10.

*Source 22’s proof.* Let  $\beta$  be the first disagreement of  $h, k$ . Choose a fresh label strictly between  $h(\beta)$  and  $k(\beta)$ , avoiding the set of common earlier labels. Complete the resulting set prefix by note 86.7. Both comparisons are decided at  $\beta$ . The endpoint assertion follows by applying the one-sided construction to the empty prefix.  $\square$

The earlier report proves the stronger assertion that  $\mathcal{P}_s(b)$  fills every uniformly set-indexed separated cut of global enumerations, and consequently that  $\mathcal{P}_s(b) \cong \mathbf{No}$  in GBC (theorem 19.10 and corollary 19.15). The classical universality and homogeneity of the surreal order underlie that identification [15]. Our reconstruction arguments below use only the explicitly proved prefix-completion and separation properties, not an unproved inference from density to saturation.

## 86.4 Source 21: class well-orders, canonical blocks, and a genuine dense core

[merge] Source 21’s Section 8, printed whole. Every numbered statement in it is a result of Parts III and IV or of Part IX and is printed as a note; source 21 calls two of them “repository baseline” and says, of the others, that canonical block decompositions “also arose in the preceding research” and are included “rather than treating every restatement as a new result”. Its theorem 65.6 is its set-level fibre theorem, printed in Part X.

We now pass from set carriers to the entire surreal class. A class well-order means a strict linear class relation for which every nonempty admitted subclass has a least element. It is *set-like* if each predecessor class is a set. In GBC, a set-like well-order of a proper class has unique order type Ord: sending a point to the ordinal type of its predecessor set gives an initial subclass of Ord, and properness forces that subclass to be all of Ord.

Thus  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  can be described using class bijections  $\text{Ord} \rightarrow \mathbf{No}$ . The unrestricted predicate  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  is larger. For example, enumerate  $\mathbf{No} \setminus \{a, b\}$  in type Ord and then append  $a, b$ . Interchanging the final two labels gives a second well-order. The two agree throughout a proper-class prefix, so no set ordinal is the first disagreement position of the complete orders. The comparison nevertheless has a direct elementary definition.

Existence of a global baseline is a substantive choice assumption. The repository proves, over its choice-free GB convention, that existence of a class well-order of **No** is equivalent to global choice ([theorem 13.1](#); Theorem 13.1 at the pin). We use GBC openly rather than treating the baseline as a canonical choice-free enumeration.

#### 86.4.1 Direct comparison of labelled class relations

For a class well-order  $R$  on a fixed linearly ordered class  $X$ , write  $\text{Pred}_R(x) = \{y : yRx\}$ . Given  $R, S$ , define a class  $C(R, S)$  by the elementary condition

$$x \in C(R, S) \iff \begin{array}{l} \text{Pred}_R(x) = \text{Pred}_S(x), \\ R \text{ and } S \text{ agree on this common predecessor class.} \end{array}$$

Equality here expands into quantification over set elements of the classes. There is no quantification over a class of candidate prefixes.

*Note 86.10* (Source 21, Theorem 8.1, “Largest common labelled prefix; repository baseline”).  $C(R, S)$  is the largest common labelled initial segment of  $R$  and  $S$ . If  $R \neq S$ , the least labels  $a, b$  outside it, in  $R, S$  respectively, exist and are distinct. The rule

$$R <_{\text{lex}} S \iff a <_X b$$

defines a strict linear comparison on the class well-orders of  $X$ . It uses elementary comprehension and does not require comparing abstract class order types or invoking ETR. This is [theorem 14.2](#) (source 12’s [theorem 14.7](#)); the source calls it a repository baseline.

*Source 21’s proof.* If  $x \in C(R, S)$  and  $yRx$ , the two orders agree below  $x$ . Thus  $ySx$ , its predecessors agree in the two orders, and the restrictions below  $y$  agree; hence  $y \in C(R, S)$ . The symmetric argument gives initiality in  $S$ . Any two members have the same ordering in  $R, S$  by the predecessor equality for the later member. Every common labelled initial segment is contained in  $C(R, S)$  by its defining condition.

If  $C(R, S) = X$ , the predecessor equalities give  $R = S$ . Otherwise each well-order has a least element outside the prefix. If these least elements were the same  $x$ , both would have predecessor class  $C(R, S)$ , with equal restricted orders, so  $x$  would belong to  $C(R, S)$ , a contradiction.

Totality and asymmetry now follow from the label order. For transitivity, suppose  $R <_{\text{lex}} S <_{\text{lex}} T$ . Their two common prefixes are initial in the same order  $S$  and are therefore comparable by inclusion. If one is shorter, the earlier first disagreement also decides the comparison of  $R$  with  $T$ . If they coincide, the three next labels satisfy  $a <_X b <_X c$ , so again  $R <_{\text{lex}} T$ .  $\square$

This is the direct proof developed in the repository ([section 14](#); Section 14 at the pin). It also proves that completion cylinders of a fixed labelled prefix are convex. A completion that departs earlier compares with every extension of the prefix in the same direction. For ordinal enumerations the definition agrees with the usual first-coordinate comparison.

#### 86.4.2 The first ordinal-class block and all residual fibers

*Note 86.11* (Source 21, Theorem 8.2, “Canonical first block”). For  $R \in \mathfrak{W}_{\text{all}}(\mathbf{No})$ , put

$$I_R = \{x : \text{Pred}_R(x) \text{ is a set}\}.$$

Then  $I_R$  is an initial proper class, possibly all of **No**, whose induced order is set-like. It has a unique enumeration  $F_R : \text{Ord} \rightarrow I_R$ . The remaining labels carry the residual well-order, and  $R$  is their concatenation after  $F_R$ . This is [theorem 15.1](#); the paragraph after it is [proposition 15.3](#).

*Source 21's proof.* Initiality follows because an earlier predecessor class is a subset of a predecessor set. If  $I_R$  were a set, the least point  $x$  outside it would have predecessor class exactly  $I_R$ , contradicting its exclusion. Thus  $I_R$  is proper. Its inherited predecessor classes are sets, so their ordinal types yield its unique Ord enumeration.  $\square$

Conversely, every injective class word  $F : \text{Ord} \rightarrow \mathbf{No}$  has an extension to a class well-order of the whole carrier: append a chosen well-order of  $\mathbf{No} \setminus \text{ran}(F)$ . Its first block is exactly  $\text{ran}(F)$ , because all later points have that proper class as a subset of their predecessor class. The completions of  $F$  are a convex fiber with the order of all well-orders of the unused carrier. This is the class analogue of [theorem 65.6](#). It is a statement about given class parameters and their completions, not the assertion that the displayed fibers form an ordinary class-sized lexicographic sum.

### 86.4.3 All set-interval blocks at once

The canonical first block can be extracted without recursion. In fact, the same idea gives every such block simultaneously.

*Note 86.12* (Source 21, Theorem 8.3, “Canonical set-interval decomposition”). *For a class well-order  $R$  on  $\mathbf{No}$ , define*

$$x \sim_R y \iff \text{the closed } R\text{-interval between } x, y \text{ is a set.}$$

*This is an elementary convex equivalence relation. Each class has a least element and, in its induced order, is either a set ordinal or a copy of Ord. There is at most one set-sized block, and if it exists it is final. Therefore  $R$  has a canonical representation*

$$R \cong \left( \sum_{b \in B_R} \text{Ord} \right) + \theta_R, \tag{S21.5}$$

*where  $B_R$  is the class of least representatives of its proper blocks with the induced order and  $\theta_R$  is a set ordinal, zero when there is no final set block. The representation uses no ETR. This is the canonical block decomposition of sources 15, 16 and 18, printed in Part IX ([theorems 52.3, 52.6 and 52.11](#)); source 21 proves it independently.*

*Source 21's proof.* Reflexivity and symmetry are immediate. An interval between  $x, z$  is contained in the union of the intervals between  $x, y$  and  $y, z$ , which proves transitivity. Convexity follows by taking subintervals. The condition that an interval is a set is expressed as existence of a set with exactly its members, so elementary comprehension defines the relation.

A block is a nonempty admitted subclass, hence has an  $R$ -least member  $m$ . The predecessors of  $x$  inside its block form the set interval  $[m, x)_R$ . Thus its induced order is set-like, and its ordinal-rank map identifies it either with a set ordinal or with all of Ord.

If a block  $A$  were a set and not final, choose the least point  $y$  after it. With  $m$  its least point,  $[m, y]_R = A \cup \{y\}$  would be a set. Hence  $y \sim_R m$ , contradicting its being outside the block. This proves the assertion about the final set block.

The least representatives are specified directly by the elementary relation. Within a proper block, the point of any specified ordinal rank is unique and is found using a set interval. Consequently the map evaluating  $(b, \alpha)$  at rank  $\alpha$  in block  $b$  is a class function given by an elementary formula. Together with the ordinary enumeration of the optional final set block it yields (S21.5). No sequence of class-valued residual states is constructed.  $\square$

The index order  $B_R$  need not be set-like. For any class well-order  $J$ , the class order  $\sum_{j \in J} \text{Ord}$ , transferred to  $\mathbf{No}$  by global choice, has  $J$  as its proper-block index order. Thus the theorem is a canonical decomposition, not a reduction of every class well-order to a set ordinal. These set-interval blocks inside  $R$  are also different from the finite permutation blocks in the lexicographic order of all such  $R$ , studied later.

#### 86.4.4 Normalized support codes

Fix a baseline class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . A normalized code is a set permutation  $\sigma : \gamma \rightarrow \gamma$  satisfying

$$\gamma = \sup\{\xi + 1 : \xi < \gamma, \sigma(\xi) \neq \xi\}.$$

The empty permutation is permitted. Extend  $\sigma$  by the identity outside  $\gamma$ , and evaluate it as  $E_\sigma = b \circ \hat{\sigma}$ . Let  $\mathcal{P}_{\text{bd}}(b)$  be the ordinary class of these codes, ordered by their evaluations. Normalization makes evaluation injective. Its range is exactly the exhaustive enumerations eventually equal to  $b$ .

*Note 86.13* (Source 21, Lemma 8.4, “Uniform completion of a set prefix”). *Every injective set word  $p : \delta \rightarrow \mathbf{No}$  extends to a core evaluation. The completion can be chosen by one elementary class construction from  $p$  and the fixed baseline and global well-order.* This is [lemma 19.4](#); the warning after it is [remark 19.7](#).

*Source 21’s proof.* For each  $\xi < \delta$ , let  $a_\xi = b^{-1}(p(\xi))$ . The prescribed partial permutation is  $\xi \mapsto a_\xi$ . Choose an infinite initial cardinal  $\nu$  strictly larger than  $\delta$  and all the  $a_\xi$ . Both the unused domain and unused range inside  $\nu$  then have cardinality  $\nu$ , so the partial injection extends to a permutation of  $\nu$ . Choose a completion using the fixed global well-order, extend by the identity, and normalize its support. Its evaluation has prefix  $p$ .  $\square$

Enlarging to a strictly larger cardinal is useful here. A partial injection cannot in general be completed on the mere union of its domain and range: the map  $n \mapsto n + 1$  on  $\omega$  is a simple counterexample. The preceding completion is the version verified in the repository, and it works uniformly for all set prefixes.

*Note 86.14* (Source 21, Theorem 8.5, “Uniform set-cut interpolation; repository baseline”). *Let  $(A_i)_{i \in I}$  and  $(B_j)_{j \in J}$  be uniformly set-indexed families of injective Ord-words, with  $A_i <_{\text{lex}} B_j$  for every cross pair. There is an injective set prefix every extension of which lies strictly between the two families. In particular, a point of  $\mathcal{P}_{\text{bd}}(b)$  lies between them. Empty sides are allowed.* This is [theorem 19.10](#), which the source credits; the paragraphs after it are [corollary 19.15](#) and [proposition 5.13](#).

*Source 21’s proof.* When both families are nonempty, class replacement bounds their cross first-disagreement ordinals by a set ordinal  $\beta$ ; otherwise take  $\beta = 0$ . Build a prefix and call a row active when it still agrees with the prefix. At stage  $\alpha$ , the next active left and right values form sets  $L, R$ . Every member of  $L$  is at most every member of  $R$ , because active cross rows have agreed so far. Thus their intersection has at most one member.

If they share a value  $z$ , append  $z$  and retain exactly the rows with that next value. It is fresh since every retained row is injective. The discarded rows have their desired strict inequality permanently decided. If the sets are disjoint, choose a fresh value strictly between them, using the surreal set-cut property after removing the set of previously used labels, append it, and stop. Removing a set does not destroy set-cut interpolation: first obtain more than that set’s cardinality many distinct separators by set recursion, then take one outside it. This also covers empty sides.

At limit stages take the union of the previous prefixes. Both sides cannot remain active through length  $\beta$ , since that would give an active cross pair agreeing longer than its bounded first

disagreement. So the procedure stops with a set prefix. Apply [note 86.13](#). All recursion states and restrictions of the uniformly indexed rows used in the construction are sets.  $\square$

This proof records the uniformity and size facts behind the repository interpolation theorem ([theorem 19.10](#); Theorem 19.10 at the pin). In particular,  $\mathcal{P}_{\text{bd}}(b)$  is a proper-class  $\eta_{\text{Ord}}$  order without endpoints. A set-valued ordinal back-and-forth identifies it with **No**: enumerate the two genuine classes by Ord, alternately insert the least unused point from each, and use set-cut interpolation to extend the current set partial isomorphism. This is the same structural principle as the classical uniqueness theorem for the surreal order [15].

The same insertion argument embeds every given class linear order into  $\mathcal{P}_{\text{bd}}(b)$ , because the set of already placed points supplies only set-sized constraints at each stage. This gives class-order universality of the core, with the input order and a global choice function as parameters. It does not produce an ordinary class whose elements are all input class orders.

*Note 86.15* (Source 21, Lemma 8.6, “The core sees exactly the first ordinal block”). *For*  $R \in \mathfrak{W}_{\text{all}}(\mathbf{No})$ , *let*  $F_R$  *be its canonical word from* [note 86.11](#). *Then*

$$\{d \in \mathcal{P}_{\text{bd}}(b) : E_d <_{\text{lex}} R\} = \{d \in \mathcal{P}_{\text{bd}}(b) : E_d <_{\text{lex}} F_R\}.$$

*Consequently any cut of the core represented by a full class well-order is represented by an injective Ord-word.* This is [corollary 46.4](#) and source 14’s trace-fibre theorem [theorem 54.6](#) (Part IX).

*Source 21’s proof.* If  $E_d \neq F_R$ , they first disagree at an ordinal coordinate, before any residual tail of  $R$  begins. That first disagreement also compares the well-order represented by  $E_d$  with  $R$ . If  $E_d = F_R$ , the word is exhaustive, so  $R$  has no unused labels or residual tail and equals the core well-order itself. Both strict comparisons then fail.  $\square$

Thus a cut forgets the residual well-order. In particular, the core is dense in the set-like fragment, but it is not dense inside a nonsingleton residual fiber of the full fragment. A proof using density must specify which of these ambient orders it concerns.

#### 86.4.5 Diagonal size obstruction

*Note 86.16* (Source 21, Proposition 8.7, “No exhaustive uniform set-code family”). *There is no class relation with a class of set codes whose evaluations include every set-like global enumeration of No.* This is [theorem 19.37](#).

*Source 21’s proof.* Under global choice, a class of set codes can be listed by Ord (with repetitions if it is a nonempty set). Suppose its rows are  $E_\alpha$ ,  $\alpha \in \text{Ord}$ . Decode from each row a bit at coordinate  $\alpha$ , setting the bit to 1 exactly when  $E_\alpha(2 \cdot \alpha) = b(2 \cdot \alpha + 1)$ . Form a new exhaustive enumeration by swapping baseline pair  $\alpha$  exactly when this decoded bit is 0. The new enumeration differs from row  $E_\alpha$  on that pair for every  $\alpha$ . It is given by elementary comprehension from the proposed uniform family, contradicting exhaustiveness. An empty family is immediately nonexhaustive.  $\square$

This is the relevant Cantor diagonal argument. The core has set codes because its support is a set; arbitrary class support cannot be compressed into an exhaustive uniform family of set codes. Moving to a larger universe permits the larger collection as a set there, but does not invalidate the internal diagonal statement.

## 86.5 Source 29: global well-orders, represented cuts, and the higher-order boundary

[merge] Source 29’s Section 10, printed whole. Its three numbered statements are results of this report, which source 29 marks as inherited; its subsection on the core-cut theorem summarizes Part VIII.

### 86.5.1 Raw comparison is elementary

Let  $R, S$  be class well-orders of the same carrier  $\mathbf{No}$ . Define  $C$  to consist of those labels  $x$  whose predecessor carriers in  $R$  and  $S$  agree and on which the two predecessor orders agree:

$$x \in C \iff \begin{aligned} &\forall u (uRx \leftrightarrow uSx), \\ &\forall u, v [(uRx \wedge vRx) \implies (uRv \leftrightarrow uSv)]. \end{aligned}$$

This is an elementary formula with the supplied class parameters. The class  $C$  is an initial segment of both orders and their restrictions to it agree. If  $R \neq S$ , both complements have least points

$$a = \min_R(\mathbf{No} \setminus C), \quad b = \min_S(\mathbf{No} \setminus C).$$

They are distinct; otherwise the common next point would belong to  $C$ . Define  $R <_{\text{lex}} S$  exactly when  $a < b$  numerically.

*Note 86.17* (Source 29, Proposition 10.1, “Inherited direct comparison”). *This construction linearly orders the available class well-orders of  $\mathbf{No}$  in the virtual sense. It needs elementary comprehension, not the comparability of abstract class well-orders and not ETR. For set-like orders it agrees with first disagreement of their Ord-enumerations.* This is [theorem 14.2](#); source 29 calls it inherited.

*Source 29’s proof.* Totality and asymmetry follow from the two different next labels. For transitivity, the common initial segments for  $(R, S)$  and  $(S, T)$  are both initial in  $S$ , so are comparable by inclusion. At the shorter segment, two of the orders still agree and the third comparison is inherited from the given strict inequality. If the segments are equal, the three next numerical labels give transitivity directly. This is comparison of labelled initial segments, not construction of an isomorphism between unrelated class orders. In the set-like case each common initial segment has an ordinal position unless the orders agree everywhere, and the description becomes ordinary first-coordinate disagreement. The full argument is part of the repository baseline ([theorem 14.2](#)).  $\square$

The formula explains why comparing raw well-orders and comparing their abstract order types are different foundational tasks. The latter asks for a new class map witnessing an initial-segment isomorphism; that map is not supplied merely by numerical comparison of two labels. The distinction will be central to source 29’s condensation section ([section 108.3](#)).

### 86.5.2 Set-like enumerations and an ordinary class core

Fix a class bijection  $e : \text{Ord} \rightarrow \mathbf{No}$ . A set-like global well-order has an exhaustive enumeration of this form. Denote the virtual collection of these enumerations by  $\mathfrak{W}_{\text{sl}}$  and the larger collection of all class well-orders on  $\mathbf{No}$  by  $\mathfrak{W}_{\text{all}}$ .

The bounded-support core relative to  $e$  consists of the enumerations  $e \circ \pi$ , where  $\pi$  is a permutation of  $\text{Ord}$  that is the identity outside some set ordinal. Such a permutation has a set code. Using the least possible support bound removes duplicate codes. The core, denoted  $\mathcal{P}_{\text{bd}}(e)$ , is therefore an ordinary class of sets. It is a small-code substructure of a higher-order collection, not an identification of that entire collection with a class of sets.

*Note 86.18* (Source 29, Theorem 10.2, “Inherited core theorem”). In GBC,  $\mathcal{P}_{\text{bd}}(e)$  has the set-cut property and is order-isomorphic to **No**. It interpolates every strict cut specified by two uniformly set-indexed families of set-like global enumerations. In particular,  $\mathfrak{W}_{\text{sl}}$  is dense and has no endpoints in the corresponding virtual sense, and every ordinary class linear order embeds in its core. This is [theorem 19.10](#) and [corollary 19.15](#) with [proposition 5.13](#); the source states it without proof and summarizes the repository’s proof in the next paragraph.

The proof in the repository bounds the first disagreements relevant to the set-indexed constraints, chooses a fresh numerical separator, and completes the resulting bounded modification to a permutation. The last assertion uses the usual Ord-stage back-and-forth: every stage has a set of earlier constraints, so the set-cut property supplies the next value. The same method proves that any two ordinary class orders with the full set-cut property are isomorphic in GBC ([proposition 5.13](#)) [14].

This universality includes every set ordinal, reverse ordinal, set linear order, and supplied class linear order with set-valued points. It does not assert an embedding of every *higher-order collection* of classes into **No**.

### 86.5.3 What the core-cut theorem records

The inspected article has a detailed normal form for proper normalized cuts of  $\mathcal{P}_{\text{bd}}(e)$ . Its three mechanisms are a boundary of a prefix cylinder, a numerical cut inside a next-letter alphabet, and a coherent injective branch. A cut is represented by an Ord-length injection exactly when it crosses appropriate prefix cylinders at every set length; exhaustivity additionally requires that the resulting prefixes cover all surreal labels ([theorems 43.3](#) and [45.1](#)). The explicit branch-automorphism theorem of this article shows why that coverage condition cannot be discarded even if the full ordered prefix tree is named.

An arbitrary class well-order can begin with a proper-class set-like segment and continue with a residual tail. Distinct tails can share the same first-block trace on the core. A faithful completion must therefore retain residual-order information in addition to a numerical cut. Earlier project work develops such decorated completions (sources 19, 21 and 20; [theorem 98.2](#)).

The unrestricted order  $\mathfrak{W}_{\text{all}}$  is not dense. For distinct labels  $a < b$ , enumerate  $\mathbf{No} \setminus \{a, b\}$  first, then append  $(a, b)$  or  $(b, a)$ . These two class well-orders are adjacent: every intermediate presentation would have to share their entire initial class prefix, and there are only the two permutations of the residual labels. More generally, a fixed prefix with  $n$  unused labels leaves a finite convex block of  $n!$  presentations. These terminal blocks cannot occur in an exhaustive set-like enumeration of type Ord.

### 86.5.4 Why uniform set codes cannot enumerate everything

*Note 86.19* (Source 29, Proposition 10.3, “Diagonal boundary”). No uniformly class-indexed family of set-like global enumerations, indexed by an ordinary class of sets, exhausts all such enumerations available in GBC. This is [theorem 19.37](#), in the guard-step form of source 25’s [note 104.1](#).

*Source 29’s proof.* An empty proposed family omits the baseline enumeration. For a nonempty family, Global Choice permits a listing as  $(F_\alpha)_{\alpha \in \text{Ord}}$ , allowing repetition if its index carrier is a set. Construct a new enumeration  $G$  in pairs of stages. At  $2 \cdot \alpha$ , choose an unused label different from  $F_\alpha(2 \cdot \alpha)$ . At  $2 \cdot \alpha + 1$ , choose the least still unused label in the baseline  $e$ -scan. There are always fresh labels because only a set has been used. Set-valued recursion gives one class map  $G$ .

It is injective by construction. The odd stages make it exhaustive: by transfinite induction they eventually pass every fixed baseline index. It differs from  $F_\alpha$  at coordinate  $2 \cdot \alpha$  for each  $\alpha$ . Thus the proposed family omits  $G$ .  $\square$

The statement is about uniform coding. It does not quantify over an imaginary GB class of all enumerations. An even more concrete size comparison is available in a specified full model. If  $\kappa$  is strongly inaccessible and one works externally with  $(V_\kappa, \mathcal{P}(V_\kappa))$ , then its surreal carrier has external cardinality  $\kappa$ , whereas its set-like global enumerations have external cardinality  $2^\kappa$ . They cannot all be injected into that carrier. Using this full-model semantics is a conditional modeling choice; it is not a proof in ZFC that an inaccessible cardinal exists.

### 86.5.5 Class extensions and external countability

For a fixed set universe and a fixed available class relation, well-foundedness is absolute between GBC class expansions. Under Global Choice, a failure of class well-foundedness yields a set-coded descending  $\omega$ -sequence. The equivalence is established in the primary class-theory literature [27, §3]. Enlarging the class collection can change which relations or branches are available; it does not thereby change well-foundedness of an old fixed relation.

A countable class model has only countably many available global enumerations externally. Its set-like enumeration order is then a countable dense linear order without endpoints and is externally isomorphic to  $\mathbb{Q}$ . This does not make the class model itself recoverable from that bare order. Nor does internal class well-foundedness automatically imply external well-foundedness; that stronger correctness property belongs to a beta-model assumption. Internally finite terminal blocks can also be externally infinite in an  $\omega$ -nonstandard model [27] (sources 19 and 20).

[merge] The last paragraph's remark that a countable class model has set-like enumeration order  $\mathbb{Q}$  is source 13's [proposition 55.5](#) (Part IX), proved again in source 21's [theorem 102.13](#) below. Its adjacent pairs and  $n!$  blocks are [theorem 16.2](#).

## 87 Unranked cylinders recover prefix heights (source 22)

[merge] Source 22's Section 8, printed whole. Its [theorem 87.1](#) is printed here once; source 25 re-proves it as its Proposition 5.1 and credits source 22 ([note 88.1](#)). Its [theorem 87.4](#) is a rank-free form of the represented-cut theorem [theorem 45.1](#) ([note 46.1](#)).

The earlier continuation recognizes global branches when cylinder labels and levels are supplied (sources 13 and 17: [theorems 46.15](#) and [46.21](#)). It asks whether the level predicate is additional essential structure. The answer is no, provided the full cylinder incidence structure is retained.

### 87.1 A size-safe meaning of the cylinder family

Let  $\mathcal{I}$  be the ordinary class of injective set-length prefixes. Use the class incidence relation

$$I(p, d) \iff d \in C_p, \quad p \in \mathcal{I}, \quad d \in \mathcal{P}_s(b).$$

The nodes  $p$  are sets; the cylinder  $C_p$  is its class of incident core points. We never collect those class subsets as elements of an ordinary class. To say that the cylinders are *unranked* means that the node sort, the core order, and incidence are retained, but the domain-length map is not supplied as an additional predicate. Inclusion is still expressible by the elementary formula

$$C_q \subseteq C_p \iff \forall d \in \mathcal{P}_s(b) (I(q, d) \Rightarrow I(p, d)).$$

All quantified objects in this formula are sets.

**Theorem 87.1** (Cylinder inclusion recovers prefix and height). *For  $p, q \in \mathcal{I}$ ,*

$$C_q \subseteq C_p \iff p \text{ is a prefix of } q.$$

*In particular, distinct prefixes have distinct cylinders. The strict ancestors of  $C_p$  under reverse inclusion form a set well-order of order type  $\text{dom } p$ . Consequently, in the ambient class set theory, the ordinal height is definable from the unranked incidence structure, and any available class incidence isomorphism preserves it.*

*Proof.* The forward implication for genuine prefixes is immediate. If  $p, q$  are incompatible, their cylinders are disjoint and nonempty, so inclusion is impossible. If  $q$  is a proper prefix of  $p$ , choose a fresh label at coordinate  $\text{dom } q$  different from the corresponding label of  $p$ , and complete this alternative prefix. Its code lies in  $C_q$  but not in  $C_p$ . These cases exhaust all possibilities.

The strict ancestors of  $C_p$  are therefore precisely

$$C_{p \upharpoonright \beta}, \quad \beta < \text{dom } p.$$

Their node codes form a set by replacement. Ordered from the largest cylinder toward the smaller ones, their order type is exactly  $\text{dom } p$ . Equivalently, height is the unique ordinal order-isomorphic to the set of strict ancestors under reverse inclusion. This description uses only incidence and the ambient set theory. It is not a claim of first-order definability of arbitrary ordinal heights in the pure two-sorted incidence language alone. It is not an appeal to a recursively constructed class-valued rank. An available class incidence isomorphism preserves inclusion and restricts to a set bijection on each ancestor set. It therefore preserves the unique ordinal order type. This is an internal statement; an arbitrary external map over a nonstandard model is not silently asserted to be an available class isomorphism.  $\square$

*Remark 87.2* (The fresh-choice hypothesis is real). The analogous assertion can fail for a finite exhaustive permutation tree. If one unused label remains, appending that forced label does not change the cylinder, so two different prefix lengths have the same cylinder. Here the whole surreal alphabet always leaves fresh labels after a set prefix; [notes 86.7](#) and [86.8](#) rule out that collapse. The finite regression suite records both the positive fresh-reserve case and this counterexample.

## 87.2 A rank-free criterion for a represented cut

A *normalized cut* of  $\mathcal{P}_s(b)$  is an initial subclass  $L \subset \mathcal{P}_s(b)$  such that  $L$  and  $U = \mathcal{P}_s(b) \setminus L$  are nonempty and  $L$  has no greatest point. The upper class  $U$  is allowed to have a least point. This convention agrees with strict lower traces

$$L_h = \{d \in \mathcal{P}_s(b) : d < h\}.$$

Normalization matters when  $h$  itself is the evaluation of a core code: it prevents choosing the wrong side of that point.

Say that  $L$  *crosses*  $C_p$  when both  $L \cap C_p$  and  $U \cap C_p$  are nonempty. Let

$$B_L = \{p \in \mathcal{I} : L \text{ crosses } C_p\}.$$

This is an ordinary class of set nodes, defined by elementary comprehension from  $L$  and incidence.

**Lemma 87.3** (Crossed cylinders form an initial branch). *The class  $B_L$  is a chain in the prefix order and is closed under taking prefixes. At most one crossed node has a given height.*

*Proof.* Ancestor closure follows from cylinder inclusion. Two incompatible cylinders are disjoint convex subsets of a linear order, with one entirely before the other. They cannot both meet both sides of an initial cut: an upper-side point in the earlier cylinder and a lower-side point in the later cylinder would contradict initiality. Thus crossed nodes are compatible. Nodes of equal length which are compatible are equal.  $\square$

**Theorem 87.4** (Unranked branch-recognition theorem). *For a normalized cut  $L$  of  $\mathcal{P}_s(b)$ , the following are equivalent:*

- (i)  $L = L_h$  for an injective class word  $h : \text{Ord} \hookrightarrow \mathbf{No}$ .
- (ii) The crossed-node class  $B_L$  is proper: it is not contained in any set.
- (iii) The recovered heights of crossed cylinders are unbounded in  $\text{Ord}$ .
- (iv) For every ordinal  $\alpha$ , there is exactly one crossed node of height  $\alpha$ .

*The representing word is unique and is definable by elementary comprehension from  $L$  and the labelled node incidence. No ETR is needed.*

*Proof.* If  $L = L_h$ , then every prefix  $h \upharpoonright \alpha$  is crossed, by the two-sided completion construction preceding [note 86.9](#). Conversely, a prefix incompatible with  $h$  has its cylinder wholly on one side. Therefore the crossed nodes are exactly the prefixes of  $h$ , proving (i) $\Rightarrow$ (iv).

By [lemma 87.3](#), there is at most one crossed node of each height. If all heights are bounded by an ordinal  $\lambda$ , class replacement applied to the uniquely specified nodes of heights at most  $\lambda$  shows that  $B_L$  is a set. This proves (ii) $\Rightarrow$ (iii). Unbounded heights together with ancestor closure give exactly one node of every height, proving (iii) $\Rightarrow$ (iv). A set of nodes has bounded ordinal heights, so (iv) $\Rightarrow$ (ii).

Assume (iv). The unique crossed nodes are compatible and nested. Define

$$h(\xi) = x \iff \exists p \in B_L (\xi \in \text{dom } p \wedge p(\xi) = x).$$

This is an elementary class definition, with set quantifiers only. Existence at each coordinate follows from the crossed node of height  $\xi + 1$ ; uniqueness and injectivity follow from compatibility. Thus  $h$  is an injective  $\text{Ord}$ -word.

Fix a core point  $d$  whose evaluation differs from  $h$ , and let  $\xi$  be the first disagreement. The cylinder of  $h \upharpoonright (\xi + 1)$  lies wholly above  $d$  if  $d < h$ , and wholly below  $d$  if  $d > h$ . Since that cylinder is crossed, initiality of  $L$  forces  $d \in L$  in the first case and  $d \in U$  in the second. If  $d = h$  is a core point, it cannot belong to  $L$ : all larger points lie in  $U$ , so it would be the greatest member of  $L$ . Hence  $L = L_h$ . Distinct words have distinct traces by [note 86.9](#), proving uniqueness.  $\square$

The properness assertion in (ii) is itself elementary in the class parameter  $L$ :

$$\forall a \exists p (p \in B_L \wedge p \notin a),$$

where  $a, p$  range over sets. Thus “proper class” is not concealing quantification over a new sort of classes of cylinders.

**Corollary 87.5** (Exhaustiveness is label coverage). *The word reconstructed in [theorem 87.4](#) is exhaustive if and only if*

$$\forall x \in \mathbf{No} \exists p \in B_L \quad x \in \text{ran } p.$$

*Therefore unranked cylinder incidence, together with the label-occurrence relation on nodes, suffices to recognize traces of global well-orders.*

*Proof.* The reconstructed range is exactly the union of the ranges of the crossed prefixes. Equality of that range with  $\mathbf{No}$  is the displayed condition.  $\square$

### 87.3 What has, and has not, been reconstructed

The level predicate is redundant: it is recovered from the ancestor order. Exhaustiveness still uses labels, and the word itself uses the coordinate-value incidence of a prefix. We have not shown that this label information can be discarded. Nor have we reconstructed cylinders from the pure core order. The earlier continuation gives an automorphism showing that the bare linear order does not determine its original prefix cylinders (source 13, [theorem 47.12](#)). These statements are compatible: once an unranked cylinder family is supplied, its levels are forced; without that family, the order alone need not determine it.

The criterion also sharpens the logical form of the earlier branch description. A normalized cut which crosses only set-many nodes is not an injective full-length branch trace. A failure can arise when a next-label cut is not realized, or at a limit-prefix boundary, as analyzed in the earlier reports. The present theorem does not need to choose a first failure recursively; it detects all such failures by the boundedness of the crossed branch.

*Note 87.6* ([merge]; the represented-cut theorem in batch 83). Part VIII prints six proofs of the represented-cut theorem ([note 46.1](#)). Batch 83 adds three: source 20's Theorem 3.10 ([note 111.16](#)), source 21's [notes 97.10](#) and [97.11](#) ([section 97](#)), and source 22's [lemma 87.3](#) and [theorem 87.4](#) above. Sources 25, 27 and 30 use the theorem and credit it ([note 92.1](#), source 27's display (S27.17), [note 102.18](#)). Source 22's form is the only one stated without the ranks of the crossing prefixes: properness of the class of crossed nodes replaces “a crossing prefix at every length”. Its [corollary 87.5](#) is the coverage clause of [theorem 45.1](#).

Source 22's sentence “We have not shown that this label information can be discarded” is answered by source 25, negatively: the core with all its unranked cylinders does not recognize exhaustive branches, even after naming set-many parameters ([theorems 91.1](#) and [91.2](#)), and the single cross-node relation of [section 93](#) suffices.

## 88 What unranked cylinders remember (source 25)

[merge] Source 25's Section 5. Its Proposition 5.1 is source 22's [theorem 87.1](#) and is printed as a note.

### 88.1 The two-sorted reduct

Let  $\mathbf{C}_b$  have a core sort  $\mathcal{P}_s(b)$ , a node sort  $\mathcal{I}$ , the order  $<_{\text{lex}}$  on  $\mathcal{P}_s(b)$ , the prefix relation on  $\mathcal{I}$ , and the incidence relation

$$\text{Inc}(d, p) \iff p \sqsubseteq d.$$

One may equivalently recover prefix order from cylinder inclusion. The structure has *no* coordinate-value relation, no ambient membership relation on the codes, and no predicate identifying equal letters used at different nodes. Those are genuinely additional relations, not silently included.

The two sorts are ordinary classes of sets. A cylinder is represented by its node code, not used as a proper-class element of a new class. This is how the informal phrase “the family of all cylinders” is made size-safe.

*Note 88.1* (Source 25, Proposition 5.1, “Cylinder recovery”). For  $p, q \in \mathcal{I}$ ,

$$C_q \subseteq C_p \iff p \sqsubseteq q.$$

*Distinct nodes have distinct cylinders. The proper ancestors of a node of length  $\alpha$  form a set-sized chain of order type  $\alpha$ . Hence the unranked cylinder structure determines all prefix lengths.* This is source 22's [theorem 87.1](#), which source 25 credits in the next paragraph; the proof is the same.

*Source 25's proof.* A prefix extension gives the displayed inclusion. Incompatible prefixes have disjoint nonempty cylinders. If  $q$  is a proper prefix of  $p$ , choose at the next position a fresh letter different from that of  $p$  and complete the resulting word to the core. Thus  $C_p$  is a proper subset of  $C_q$ . These observations give the converse and injectivity. The proper ancestors of  $p$  are exactly  $p \upharpoonright \beta$ ,  $\beta < \alpha$ , and their prefix order has type  $\alpha$ .  $\square$

This reconstruction was established in the residual-geometry continuation (source 22, [theorem 87.1](#)). We use it to convert the new profile theorem into a result about *unranked* cylinders rather than an expansion with a gratuitously named length function.

## 88.2 Automorphisms and first-disagreement profiles

An automorphism of  $\mathbf{C}_b$  is a pair  $(F, T)$  of class bijections on its two sorts preserving the displayed relations. An order automorphism  $F$  of  $\mathcal{P}_s(b)$  carrying cylinders onto cylinders determines  $T$  uniquely by

$$F[C_p] = C_{T(p)}.$$

By [Note 88.1](#),  $T$  preserves lengths and prefixes.

For distinct full words define

$$\text{pr}(f, g) = (\delta(f, g), \text{sgn}(f, g)), \quad \text{sgn}(f, g) = \begin{cases} -1, & f <_{\text{lex}} g, \\ +1, & g <_{\text{lex}} f. \end{cases}$$

These profiles determine every pairwise prefix-equivalence relation:

$$f \upharpoonright \alpha = g \upharpoonright \alpha \iff \alpha \leq \delta(f, g) \quad (f \neq g).$$

The inequality includes equality: a disagreement at  $\alpha$  still permits agreement on the restriction to  $\alpha$ .

**Proposition 88.2** (Automatic profile preservation). *Every automorphism of  $\mathbf{C}_b$  preserves the first-disagreement ordinal between distinct core branches. Conversely, an order automorphism of  $\mathcal{P}_s(b)$  preserving these ordinals induces a unique automorphism of  $\mathbf{C}_b$ .*

*Proof.* The longest prefix common to distinct core branches is the unique deepest node incident with both. Its height is their first-disagreement ordinal and is recovered by [Note 88.1](#).

Conversely, for  $p$  of length  $\alpha$ , choose  $d \in C_p$  and set

$$T(p) = F(d) \upharpoonright \alpha.$$

For any other  $e \in C_p$ , either  $e = d$  or  $\delta(e, d) \geq \alpha$ . Profile preservation makes the formula independent of the choice. Applying the same argument to  $F^{-1}$  gives an inverse on nodes. The equality  $F[C_p] = C_{T(p)}$  follows in both directions, and the remaining structural relations are preserved.  $\square$

Every such  $T$  acts on a supplied  $f \in \mathfrak{J}$  by

$$\widehat{T}(f)(\alpha) = T(f \upharpoonright (\alpha + 1))(\alpha). \tag{S25.1}$$

The transformed prefixes cohere, so this is an injective full class word. Its inverse is obtained from  $T^{-1}$ . It preserves all first-disagreement ordinals and lexicographic comparisons and agrees with  $F$  on the core. This is an elementary transformation of supplied class parameters, not the graph of a same-level function whose arguments are proper classes.

## 89 The one-point profile extension theorem (source 25)

The central issue is not extending a partial permutation of labels. Different nodes may relabel the same numerical value differently. What must be preserved is the ordered tree geometry: the first place at which two branches separate and the direction of that separation.

**Lemma 89.1** (One-point extension into the core). *Let  $I$  be a set, and let  $(a_i)_{i \in I}$  and  $(a'_i)_{i \in I}$  be uniformly indexed families of pairwise distinct members of  $\mathfrak{J}$  such that*

$$\text{pr}(a_i, a_j) = \text{pr}(a'_i, a'_j) \quad (i \neq j).$$

*Given  $d \in \mathfrak{J}$  distinct from every  $a_i$ , there is  $c \in \mathcal{P}_s(b)$  such that*

$$\text{pr}(d, a_i) = \text{pr}(c, a'_i) \quad (i \in I).$$

*The witness can be selected uniformly from the supplied class parameters and the set of indices.*

*Proof.* For  $I = \emptyset$ , choose any core code. Otherwise let

$$\delta_i = \delta(d, a_i), \quad \lambda = \sup_{i \in I} (\delta_i + 1).$$

Class replacement makes the collection of these ordinals a set. We construct a set-length injective prefix  $r$  that already decides every required comparison. There are two cases; the second is essential at transfinite lengths.

**Case 1: the disagreement ordinals have a maximum  $\delta_*$ .** Let  $I_* = \{i \in I : \delta_i = \delta_*\}$ . All the source branches with indices in  $I_*$  agree with  $d$  below  $\delta_*$ . Hence their target branches share a common prefix  $r_0$  of length  $\delta_*$ . Partition their next labels according to the required side of the new label:

$$\begin{aligned} L &= \{a'_i(\delta_*) : i \in I_*, a_i(\delta_*) < d(\delta_*)\}, \\ R &= \{a'_i(\delta_*) : i \in I_*, d(\delta_*) < a_i(\delta_*)\}. \end{aligned}$$

If a label lies in  $L$  and another in  $R$ , their source branches first disagree at  $\delta_*$  and are in that increasing order. Profile preservation implies the same for their target labels. Therefore  $L < R$ . [Note 86.3](#) supplies

$$x \notin \text{ran } r_0, \quad L < x < R.$$

Put  $r = r_0 \frown (x)$ . It has the required profile against every top-level constraint.

For an index  $i$  with  $\delta_i < \delta_*$ , choose  $j \in I_*$ . The source branch  $a_j$  agrees with  $d$  through coordinate  $\delta_i$ . Consequently the comparison of  $a_j$  with  $a_i$  has exactly the first disagreement and direction required of  $d$  against  $a_i$ . The target profile transfers this statement to  $a'_j$  against  $a'_i$ . Since  $r$  agrees with  $a'_j$  through coordinate  $\delta_i$ , it has the required profile against this lower-level constraint as well.

**Case 2: the disagreement ordinals have no maximum.** Here  $\lambda$  is a limit ordinal and the  $\delta_i$  are cofinal in  $\lambda$ . For each  $\beta < \lambda$ , define

$$r(\beta) = a'_i(\beta) \quad \text{for any } i \text{ with } \delta_i > \beta.$$

This is independent of  $i$ . Indeed, any two such source branches agree with  $d$  through  $\beta$ , so their target branches agree through  $\beta$ . For  $\gamma < \beta < \lambda$ , choose one  $i$  with  $\delta_i > \beta$ ; both  $r(\gamma)$  and  $r(\beta)$  occur at the corresponding positions of the injective branch  $a'_i$ . They are distinct. Thus  $r$  is an injective word of length  $\lambda$ .

Fix  $i \in I$  and choose  $j$  with  $\delta_j > \delta_i$ . The source  $a_j$  agrees with  $d$  through  $\delta_i$ . The profile of  $a_j$  against  $a_i$  therefore equals that of  $d$  against  $a_i$ . Transferring this profile to the targets and using the definition of  $r$  gives

$$\delta(r, a'_i) = \delta_i$$

with the required direction. This notation concerns a disagreement already occurring within the domain of  $r$ , not a comparison using a termination convention.

In either case [Note 86.4](#) extends  $r$  to a core branch  $c$ . All prescribed first disagreements occur inside  $r$ , so completion changes none of them. For uniformity, choose the least successful core code in a fixed set-like global well-order. The existence just proved guarantees that this elementary selection is defined.  $\square$

*Remark 89.2* (Why no numerical equality pattern is required). The argument does not preserve equality between a letter occurring in one node and a letter occurring at another depth or on another branch. Its only injectivity obligation is within the new prefix  $r$ . In Case 1 this is handled by avoiding  $\text{ran } r_0$ ; in Case 2 it follows from coherence inside individual target branches. This is the precise source of the extra symmetries studied below.

**Example 89.3** (An elementary local distortion). Take the two one-step extensions  $(0, 1)$  and  $(2, 1)$  of different first-letter nodes. An ordered-tree transformation can send their final labels to two different values, provided each local map is increasing and avoids the label already used on its own prefix. Nothing in sibling order or common-prefix lengths identifies these two occurrences of the original label 1. [Section 93](#) isolates exactly the relation that prohibits such a distortion.

## 90 Exact configuration homogeneity (source 25)

**Theorem 90.1** (Classification of set-indexed branch configurations). *Let  $(f_i)_{i \in I}$  and  $(g_i)_{i \in I}$  be uniformly set-indexed families of pairwise distinct members of  $\mathfrak{J}$ . There exists an automorphism  $(F, T)$  of  $\mathbf{C}_b$  such that*

$$\widehat{T}(f_i) = g_i \quad (i \in I)$$

*if and only if the following conditions hold:*

$$f_i \in \mathcal{P}_s(b) \iff g_i \in \mathcal{P}_s(b), \tag{S25.2}$$

$$\delta(f_i, f_j) = \delta(g_i, g_j) \quad (i \neq j), \tag{S25.3}$$

$$f_i <_{\text{lex}} f_j \iff g_i <_{\text{lex}} g_j \quad (i \neq j). \tag{S25.4}$$

*The construction uses GBC, not ETR.*

*Proof.* Necessity follows from [Proposition 88.2](#), the induced branch action, and the fact that  $F$  maps the core onto itself.

For sufficiency, start with the prescribed correspondences between the core members among the  $f_i$  and  $g_i$ . Their unique normalized codes form sets by class replacement. The remaining  $f_i, g_i$  are retained as fixed external-to-the-core constraints. The word “external” here means outside  $\mathcal{P}_s(b)$ , not outside the model or its admitted classes.

Choose a class enumeration of all core codes, indexed by Ord. Construct a growing partial bijection  $H$  between core codes by back-and-forth. At each set stage  $\alpha$ , its graph  $H_\alpha$  is a set. Maintain the invariant that all prescribed correspondences, consisting of  $H_\alpha$  and the noncore markers, preserve the profiles of distinct branches.

At a forth step, take the next enumerated core code  $d$  not yet in the domain. It is distinct from every source constraint: the core constraints already lie in the domain, and the other markers are noncore. [Lemma 89.1](#), applied to the uniformly set-indexed current constraints, gives a core target  $c$  with exactly the required profiles. In particular,  $c$  differs from every current target, so adding  $(d, c)$  preserves injectivity and the invariant.

At a back step, take the next core code not in the range and apply the same lemma with sources and targets interchanged. At a limit set stage, take the union of the earlier partial maps. This is still a set, and every pairwise requirement appeared together at an earlier stage. Choose the least possible witness at each extension step. Thus ordinary set-valued recursion along  $\text{Ord}$  defines the whole construction in GBC.

The union  $F$  is a class bijection of  $\mathcal{P}_s(b)$  preserving every core profile. It is an order automorphism, and [Proposition 88.2](#) gives its unique node action  $T$ .

For a noncore marker  $f_i$ , fix an ordinal  $\alpha$  and choose a core completion  $d$  of  $f_i \restriction \alpha$ . Since  $d \neq f_i$ , their first disagreement is at least  $\alpha$ . The maintained constraint implies that  $F(d)$  agrees with  $g_i$  below  $\alpha$ . By the definition of the node action,

$$T(f_i \restriction \alpha) = F(d) \restriction \alpha = g_i \restriction \alpha.$$

This holds at every set-ordinal length, so  $\hat{T}(f_i) = g_i$ . The prescribed core markers were already mapped correctly by  $F$ . This proves sufficiency.  $\square$

**Corollary 90.2** (Exactly two single-branch orbits). *Under the induced action of automorphisms of  $\mathbf{C}_b$ , the virtual domain  $\mathfrak{J}$  has precisely two orbits:*

$$\mathcal{P}_s(b) \quad \text{and} \quad \mathfrak{J} \setminus \mathcal{P}_s(b).$$

*More explicitly, any two supplied core branches can be carried to one another, and any two supplied noncore injective branches can be carried to one another, but no core branch can be carried to a noncore branch.*

*Proof.* Apply [Theorem 90.1](#) to a one-element index set. Only the membership condition remains. Both cases are nonempty:  $b$  is a core branch, and an injection omitting a label is not.  $\square$

*Remark 90.3* (The logical meaning of an orbit). The corollary abbreviates a quantified assertion about supplied class words and class maps on set codes. It does not construct an ordinary class whose elements are all automorphisms, all branches, or their equivalence classes. In the regular set model of [Section 94](#), these become ordinary sets and an ordinary group action.

The theorem also determines all finite and set-indexed tuple orbits. For example, a pair of noncore branches is classified solely by its first-disagreement ordinal and its order orientation. A triple must satisfy the usual compatibility of first-disagreement data, but once both triples exist, no additional cross-coordinate label pattern is an invariant. Repeated entries can be admitted by first matching their equality pattern and then passing to distinct representatives; a set of representatives exists by set choice.

*Note 90.4* ([merge]; how this compares with Part VIII). Source 14's [theorem 47.2](#) classifies cuts of the bare core order by their characters; the cuts of all noncore injective words have character  $(\text{Ord}, \text{Ord})$  and lie in one orbit there with every other cut of that character, for example the edges of successor-length cylinders. An automorphism that also carries cylinders to cylinders preserves the crossing condition of [theorem 45.1](#), so it maps branch cuts to branch cuts; [theorem 90.1](#) shows that on branches the remaining invariants are exactly core membership, first-disagreement ordinals

and order. Source 27's [theorem 96.2](#) and source 29's [theorem 96.7](#) keep the ordered prefix tree but not the core, and obtain one orbit of all injective branches; [corollary 90.2](#) shows that retaining the core splits it into exactly two.

## 91 Exhaustiveness is invisible to unlabelled cylinders (source 25)

### 91.1 An explicit pair of branches

Let  $e$  be obtained from  $b$  by swapping each pair of consecutive positions

$$2 \cdot \xi, \quad 2 \cdot \xi + 1 \quad (\xi \in \text{Ord}).$$

The finite factor is on the *left* in ordinal multiplication. These pairs partition  $\text{Ord}$ . The word  $e$  is a bijection onto  $\mathbf{No}$  and differs from  $b$  at every position, so  $e \notin \mathcal{P}_s(b)$ .

Define another class word by

$$f(\alpha) = b(1 + \alpha).$$

The map  $\alpha \mapsto 1 + \alpha$  is an increasing bijection from  $\text{Ord}$  onto its nonzero ordinals. Thus  $f$  is injective and omits exactly  $b(0)$ . Moreover,  $1 + \alpha = \alpha$  for every infinite ordinal  $\alpha$ , so  $f$  eventually agrees with  $b$ . This illustrates why eventual agreement without exhaustiveness does not characterize the core.

**Theorem 91.1** (Cylinder preservation does not preserve coverage). *There is an automorphism  $(F, T)$  of  $\mathbf{C}_b$  and branches  $e \in \mathfrak{W}_{\text{sl}}$ ,  $f \in \mathfrak{J} \setminus \mathfrak{W}_{\text{sl}}$  such that*

$$\hat{T}(e) = f.$$

*It preserves the core order, every cylinder as a member of the cylinder family, all prefix lengths, and all first-disagreement ordinals. Nevertheless, it carries an exhaustive branch to one omitting a label.*

*Proof.* The preceding  $e$  and  $f$  are both noncore. Apply [Corollary 90.2](#). □

Here preserving the cylinder family means permuting its members, not fixing every cylinder pointwise. Fixing every cylinder would fix every core branch and every supplied full branch.

### 91.2 The obstruction survives set-many parameters

**Theorem 91.2** (Parameter-robust non-invariance). *Let  $A \subseteq \mathcal{P}_s(b)$  and  $P \subseteq \mathcal{I}$  be sets. There is an automorphism of  $\mathbf{C}_b$  fixing every member of  $A$  and every node of  $P$ , but carrying some exhaustive noncore branch to a nonexhaustive injective branch.*

*Proof.* For each  $p \in P$ , choose a core completion  $d_p$ . Add these codes to  $A$ , obtaining a set  $A'$ . Choose a surreal  $x$  outside the set of first labels  $\{d(0) : d \in A'\}$ , and choose a core branch  $d_0$  beginning with  $x$ .

Construct an exhaustive branch  $e$  beginning with  $x$  by leaving the first position of  $d_0$  fixed and swapping a proper class of disjoint consecutive pairs in its tail. It differs from  $d_0$ , and hence from  $b$ , on a proper class of positions, so it is noncore. Construct  $f$  by

$$f(0) = d_0(0), \quad f(\alpha) = d_0(1 + \alpha) \quad (\alpha > 0).$$

This word begins with  $x$ , is injective, and omits  $d_0(1)$ .

For each  $a \in A'$ , both  $e$  and  $f$  disagree with  $a$  at coordinate 0, and their comparison directions are identical because their first label is  $x$ . The two configurations consisting of all the fixed branches in  $A'$  followed by  $e$ , respectively  $f$ , therefore satisfy [Theorem 90.1](#). The resulting automorphism fixes  $A'$ . It fixes each  $p \in P$  because  $p$  is the prefix of the fixed  $d_p$  at its invariant length. □

**Corollary 91.3** (No invariant unlabelled recognition test). *Exhaustiveness is not invariantly recognizable from  $\mathbf{C}_b$  and any prescribed set of core and node parameters. In particular, an automorphism-invariant definition in this reduct cannot recognize precisely the exhaustive full branches.*

This is deliberately a statement about the specified reduct and admitted branch action. In an ambient set theory that retains the full coordinate-value relation, exhaustiveness is simply the condition that every surreal occurs. We have not made that condition undefinable in the ambient theory; we have shown that the reduct forgets information needed to recover it. The result also does not assert that every enrichment strictly weaker than the one in [Section 93](#) fails.

### 91.3 Other properties lost by forgetting labels

The branch  $\alpha \mapsto \alpha$ , viewing each ordinal as a surreal, is numerically increasing and nonexhaustive. It is therefore noncore. [Corollary 90.2](#) places it in the same orbit as every other noncore injective branch, including an exhaustive branch. Consequently numerical increasingness is also invisible in the unlabelled cylinder structure. It concerns comparisons between labels occurring at *different* coordinates, whereas the prefix geometry orders siblings at one coordinate after a common prefix.

Similarly, the number or order type of omitted labels is not an invariant on the noncore orbit. This statement applies only to omitted ranges realized by supplied injective class words; it does not posit a same-level collection of all class cardinalities or all class order types.

*Note 91.4* ([merge]; relation to the bare-order results). [Theorem 91.1](#) strengthens [corollary 47.3](#), [theorem 47.7](#) with [corollary 47.8](#), and [theorem 47.10](#): those move an exhaustive cut by an automorphism of the bare core, whereas here every cylinder is carried to a cylinder. [Theorem 91.2](#) is the cylinder-preserving counterpart of source 20's [theorem 97.7](#), which fixes a set of core points pointwise in the bare order (written before Part VIII; source 25 did not cite it). Source 13's [theorem 47.12](#) is a different theorem: there an automorphism of  $\mathfrak{W}_{sl}$  moves a cylinder to a non-cylinder.

## 92 Extension to the full enumeration order (source 25)

[merge] Source 25's Section 9. Its Proposition 9.1 is source 17's [theorem 47.5](#), which source 25 credits; it is printed as a note with source 25's proof.

The previous sections construct an automorphism of the small-coded core and its full injective prefix completion. Does it extend to an order automorphism of the exhaustive domain  $\mathfrak{W}_{sl}$ ? The answer can fail even when the core automorphism respects every prefix cylinder.

*Note 92.1* (Source 25, Proposition 9.1, “Represented-trace criterion”). *Let  $F$  be an order automorphism of  $\mathcal{P}_s(b)$ . It has an order-automorphism extension to  $\mathfrak{W}_{sl}$  exactly when it permutes, in both directions, the cuts*

$$L_e = \{d \in \mathcal{P}_s(b) : d <_{\text{lex}} e\} \quad (e \in \mathfrak{W}_{sl})$$

*that are represented by admitted exhaustive branches. If such an extension exists, it is unique. The statement about an extension is understood as a uniform transformation of supplied class words, or externally in a larger universe. This is [theorem 47.5](#) (source 17's Theorem 10.1); sources 20 and 21 prove it again as [notes 97.8](#) and [97.13](#).*

*Source 25's proof.* Any extension must carry  $L_e$  to  $L_{G(e)}$ . Conversely, assume both  $F$  and  $F^{-1}$  carry represented traces to represented traces. By [Note 86.6](#), the branch representing  $F[L_e]$  is unique. Define  $G(e)$  to be this branch. The corresponding construction for  $F^{-1}$  gives its inverse. Density of  $\mathcal{P}_s(b)$  in  $\mathfrak{J}$  shows that trace inclusion strictly reflects the order, so  $G$  is increasing and extends  $F$ .

There is no need to choose from a collection of classes to make the uniform statement precise. For a supplied trace  $L$ , the condition that a prefix cylinder crosses its lower and upper sides is elementary in  $L$  and the core codes. When  $L$  is represented by an injective full branch, these crossing cylinders are exactly its prefixes: an agreeing prefix has core completions on both sides, while an incompatible prefix has its entire cylinder on one side. The unique prefix of each length is therefore recovered by elementary comprehension, and its union defines the representing branch. Apply this decoder to  $F[L_e]$ .  $\square$

The criterion is a conceptual reduction rather than a local classification of the stabilizing automorphism group. The criterion was already proved in the second continuation (source 17's Theorem 10.1, [theorem 47.5](#)); it is re-established here to fix the uniformity convention. The next conclusion strengthens the known obstruction by retaining all cylinders.

**Theorem 92.2** (A cylinder-preserving automorphism with no exhaustive extension). *There exists an order automorphism  $F$  of  $\mathcal{P}_s(b)$  preserving all prefix cylinders that has no order-automorphism extension to  $\mathfrak{W}_{sl}$ , even if the prospective extension is not required to preserve cylinders.*

*Proof.* Choose  $F, T, e, f$  as in [Theorem 91.1](#). The induced order-preserving branch action gives

$$F[L_e] = L_f.$$

An order-automorphism extension  $G$  on  $\mathfrak{W}_{sl}$  would also give  $F[L_e] = L_{G(e)}$ . Trace injectivity on all of  $\mathfrak{J}$  would imply  $G(e) = f$ . This contradicts  $f \notin \mathfrak{W}_{sl}$ .  $\square$

For a cylinder-preserving  $F$ , the action  $\hat{T}$  on  $\mathfrak{J}$  is already determined. The precise condition for an extension to  $\mathfrak{W}_{sl}$  is therefore

$$\hat{T}[\mathfrak{W}_{sl}] = \mathfrak{W}_{sl}.$$

This is not automatic from preserving the core, the lexicographic order, or the entire unranked prefix tree. Exhaustive completion is an additional choice of represented branches inside the injective completion.

[merge] [Theorem 92.2](#) answers in part Part VIII's open item on the stabilizer of the exhaustive cuts ([section 50](#) (c)): not every cylinder-preserving automorphism of  $\mathcal{P}_s(b)$  lies in that subgroup of  $\text{Aut}(\mathcal{P}_s(b))$ . Source 19's [theorem 98.5](#) gives the exact criterion for extension to the unrestricted order in an external set-sized model.

## 93 Cross-node label coherence and rigidity (source 25)

[merge] Source 25's Section 10. Source 27 proves [theorem 93.1](#) independently as its Theorem 6.5, printed as a note in [section 96.1](#) ([note 96.5](#)).

### 93.1 A single additional relation

An extension edge is a pair  $(p, q)$  of nodes such that  $q = p \frown (x)$  for one unused label  $x$ . These are exactly the immediate-successor pairs in the prefix order. Add a relation  $\sim_{\text{lab}}$  on edges by

$$(p, p \frown (x)) \sim_{\text{lab}} (q, q \frown (y)) \iff x = y.$$

The relation connects occurrences of one label at different nodes. It does not initially name any label, any birthday, or any field operation.

Each equivalence class of edges has exactly one root edge, namely  $(\emptyset, (x))$ . Thus labels can be represented by these existing set-coded root edges. There is no quotient whose elements would have to be proper classes. The root edges inherit the numerical order from their cylinders, and this reconstructs the ordered alphabet.

For the next theorem, consider the ordered prefix tree by itself: its node sort, prefix order, and the order of immediate successors at each node. This sibling order can either be included directly or recovered from the core cylinders.

**Theorem 93.1** (Label-coherent tree automorphisms). *An automorphism  $T$  of the ordered injective prefix tree preserves  $\sim_{\text{lab}}$  if and only if there is an order automorphism  $h$  of  $(\mathbf{No}, <)$  such that*

$$T(p) = h \circ p \quad (p \in \mathcal{I}).$$

*The alphabet automorphism  $h$  is unique.*

*Proof.* The action on root edges defines a unique bijection  $h : \mathbf{No} \rightarrow \mathbf{No}$  by

$$T((x)) = (h(x)).$$

Preservation of their sibling order makes  $h$  increasing. If the edge from  $p$  to  $p \frown (x)$  is considered, it is label-equivalent to the root edge for  $x$ . Its image must be label-equivalent to the root edge for  $h(x)$ . Therefore

$$T(p \frown (x)) = T(p) \frown (h(x)).$$

Induction along the set-ordinal length of  $p$  proves  $T(p) = h \circ p$ . At a limit length, the node is the union of its proper prefixes, and their images determine it uniquely. Conversely, coordinatewise application of any order automorphism  $h$  preserves injectivity, prefix order, sibling order, and edge-label equality. Its inverse is coordinatewise application of  $h^{-1}$ .  $\square$

**Lemma 93.2** (No nontrivial set-supported alphabet automorphism). *If an order automorphism  $h$  of  $\mathbf{No}$  fixes all points outside a set, then  $h = \text{id}$ .*

*Proof.* Suppose  $x < h(x)$ . Choose, by [Note 86.3](#), a point  $y$  strictly between them and outside the support of  $h$ . Monotonicity gives  $h(x) < h(y) = y$ , contradicting  $y < h(x)$ . If  $h(x) < x$ , choose a fixed point  $y$  between  $h(x)$  and  $x$ ; monotonicity gives  $y = h(y) < h(x)$ , again a contradiction. Thus every point is fixed.  $\square$

**Theorem 93.3** (The label-coherent core structure is rigid). *Every automorphism  $(F, T)$  of  $\mathbf{C}_b$  preserving  $\sim_{\text{lab}}$  is the identity. No numerical labels need to be named individually.*

*Proof.* [Theorem 93.1](#) gives  $T(p) = h \circ p$  for an alphabet order automorphism  $h$ . Hence the induced action on the baseline is

$$F(b) = \hat{T}(b) = h \circ b.$$

Because  $F(b) \in \mathcal{P}_s(b)$ , there is a set-supported permutation  $\pi$  of  $\text{Ord}$  such that  $h(b(\alpha)) = b(\pi(\alpha))$ . If  $S$  is the set support of  $\pi$ , then  $h$  fixes all labels outside the set  $b[S]$ . [Lemma 93.2](#) implies  $h = \text{id}$ . Thus  $T = \text{id}$ , and the prefixes of every core branch force  $F = \text{id}$  as well.  $\square$

There is a sharp contrast here. Without cross-node label equality the core structure has two large branch orbits and is homogeneous for all the configurations in [Theorem 90.1](#). After adding just this one relation, it is rigid. For the ordered tree without the distinguished supported core, the same relation still permits all coordinatewise alphabet automorphisms. The rigidity is therefore a joint effect of label coherence and the chosen eventual-agreement core.

**Proposition 93.4** (Coverage from coherent edges). *In the edge-coherent expansion, a supplied full branch is exhaustive if and only if every root edge is label-equivalent to some extension edge on the branch.*

*Proof.* Root edges represent every surreal label exactly once. An edge on the branch represents exactly the label introduced at its corresponding coordinate. The condition is therefore equivalent to every surreal occurring in its range.  $\square$

[Theorem 91.1](#) and [Proposition 93.4](#) give a negative and a positive recognition result in explicit languages. They do not establish that  $\sim_{\text{lab}}$  is the weakest conceivable enrichment that recognizes exhaustiveness; its rigidity is stronger than recognition alone, and weaker intermediate expansions are a natural subject for further study.

## 94 Regular set-sized models and an exact group size (source 25)

[merge] Source 25's Section 11. Its set structures are written with a superscript  $\kappa$  ([part XIII](#)):  $\mathcal{P}_s^\kappa(b)$  is source 25's  $\mathcal{D}_{b,\kappa}$ ,  $\mathcal{I}^\kappa$  its  $\mathcal{T}_\kappa$ ,  $\mathfrak{J}^\kappa$  its  $\mathfrak{J}_\kappa$ ,  $\mathcal{W}_\kappa(X)$  its  $\mathfrak{E}_\kappa$ , and  $\mathbf{C}_b^\kappa$  its  $\mathcal{C}_{b,\kappa}$ .

The class argument has a useful set-sized analogue. This provides ordinary sets of branches and an ordinary automorphism group, making the size claims and the nondefinability obstruction accessible without a higher-order interpretation.

### 94.1 The hypotheses and their purpose

Let  $\kappa$  be an infinite regular cardinal such that  $\kappa^{<\kappa} = \kappa$ . Let  $X$  be a linearly ordered set of cardinality  $\kappa$  satisfying

$$L < R, \quad |L \cup R| < \kappa \quad \implies \quad \exists x \in X \ (L < x < R). \quad (\text{S25.5})$$

Empty sides are permitted. This includes density and absence of endpoints.

The analogous fresh-separator property follows. First choose  $z$  between  $L$  and  $R$ . For a forbidden set  $S$  of size less than  $\kappa$ , apply (S25.5) again to

$$L \cup \{z\} \quad \text{and} \quad R \cup \{s \in S : z < s\}.$$

The resulting point lies above  $z$  but below every member of  $S$  above  $z$ , so it avoids  $S$ .

Fix a bijection  $b : \kappa \rightarrow X$ . Define

$$\begin{aligned} \mathcal{P}_s^\kappa(b) &= \{b \circ \pi : \pi \in \text{Sym}(\kappa), \ |\text{supp } \pi| < \kappa\}, \\ \mathcal{I}^\kappa &= \bigcup_{\alpha < \kappa} \text{Inj}(\alpha, X), \\ \mathfrak{J}^\kappa &= \text{Inj}(\kappa, X), \quad \mathcal{W}_\kappa(X) = \text{Bij}(\kappa, X). \end{aligned}$$

These are ordinary sets. Regularity makes support of size less than  $\kappa$  equivalent to bounded support. The code normalization used for the class core may be retained, although here the functions themselves are sets.

Every prefix in  $\mathcal{I}^\kappa$  has a core completion: the reserve argument in [Note 86.4](#) uses fewer than  $\kappa$  positions. Also

$$|\mathcal{P}_s^\kappa(b)| = |\mathcal{I}^\kappa| = \kappa.$$

The upper bounds follow from  $\kappa^{<\kappa} = \kappa$ , and the lower bounds follow already from distinct one-letter prefixes and their completions.

**Theorem 94.1** (Regular-cardinal configuration theorem). *Let  $\mathbf{C}_b^\kappa$  be the set-sized core-and-cylinder structure just defined. For configurations indexed by a set  $I$  of cardinality less than  $\kappa$ , [Theorem 90.1](#) holds with  $\mathcal{P}_s^\kappa(b)$ ,  $\mathfrak{J}^\kappa$ , and first-disagreement ordinals below  $\kappa$  in place of their class counterparts.*

*In particular, its action on  $\mathfrak{J}^\kappa$  has exactly two orbits, the core and its complement. The exhaustive branches are not invariant. Adding cross-node edge-label equality makes  $\mathbf{C}_b^\kappa$  rigid.*

*Proof.* The one-point proof applies verbatim once its supremum  $\lambda$  is below  $\kappa$ . This follows from regularity because there are fewer than  $\kappa$  constraints. The maximum case uses the fresh-separator property above, and the no-maximum case gives a prefix of length less than  $\kappa$ . Complete it to the core.

Enumerate the core in  $\kappa$  steps. At each stage below  $\kappa$ , the partial map together with the fixed markers has size less than  $\kappa$ , so back-and-forth can continue. Its union gives the required automorphism and branch action.

For non-invariance, pair-swap  $b$  throughout  $\kappa$  to obtain a noncore bijection, and use  $f(\alpha) = b(1 + \alpha)$  to omit  $b(0)$ . The latter is defined on  $\kappa$  and has the indicated omitted range for every infinite initial ordinal  $\kappa$ . Both are noncore and hence conjugate under the branch action.

For rigidity, an edge-coherent automorphism is coordinatewise application of an order automorphism  $h$  of  $X$ . Preservation of the supported core forces  $h$  to have support of size less than  $\kappa$ . The fresh-separator property supplies a fixed point between  $x$  and  $h(x)$  whenever they differ, giving the contradiction in [Lemma 93.2](#).  $\square$

**Theorem 94.2** (Exact cardinality of the automorphism group). *Under the preceding hypotheses,*

$$|\text{Aut}(\mathbf{C}_b^\kappa)| = 2^\kappa.$$

*After adjoining  $\sim_{\text{lab}}$ , the automorphism group has cardinality 1.*

*Proof.* An automorphism is determined by its action on the core, which has cardinality  $\kappa$ . Thus the group has size at most  $\kappa^\kappa = 2^\kappa$ .

There are  $2^\kappa$  injective full words: the upper bound is  $|X^\kappa| = 2^\kappa$ , and independent pair swaps of  $b$  give the lower bound. Removing the core, which has size  $\kappa$ , leaves  $2^\kappa$  words. By [Theorem 94.1](#), these form one orbit. A group acting transitively on a set of that size has at least  $2^\kappa$  elements. The equality follows. The enriched assertion is the rigidity theorem.  $\square$

## 94.2 Surreal birthday fragments and the countable example

If  $\kappa$  is regular and  $\kappa^{<\kappa} = \kappa$ , the alphabet  $X = \mathbf{No}_{<\kappa}$  has cardinality  $\kappa$  and satisfies [\(S25.5\)](#). Indeed, fewer than  $\kappa$  birthdays are bounded strictly below  $\kappa$  by regularity, and the exact-birthday separator may be chosen at a still larger ordinal below  $\kappa$ . The equality  $|X| = \kappa$  uses  $2^{<\kappa} = \kappa$ , which follows from the stated cardinal-arithmetic hypothesis for infinite  $\kappa$ .

At  $\kappa = \omega$ , one may take  $X = \mathbb{Q}$ , or the dyadic rational alphabet  $\mathbf{No}_{<\omega}$ . The core consists of the finite-support permutations of a fixed enumeration. Its countable ordered cylinder structure has  $2^{\aleph_0}$  automorphisms, and every infinite injective word outside the core lies in one orbit of their induced action. Yet the edge-coherent expansion is rigid. No continuum hypothesis is used.

This countable example is a concrete testing ground for the group-theoretic questions below. Its infinitary branch space is still indispensable: a complete ordered injection tree over a *finite* linear alphabet is rigid, since every finite sibling order is rigid. One should not expect an exhaustive finite-alphabet model to exhibit the same symmetries.

[merge] The bare countable order  $\mathcal{W}_\omega(\mathbb{Q})$  also has  $2^{\aleph_0}$  automorphisms (source 21's homogeneity theorem, Part X); that is a different structure, without cylinders.

## 95 Cofinality obstructions and singular lengths (source 25)

[merge] Source 25's Section 12. Here  $X$  is any linearly ordered set of size  $\kappa$  with a bijection  $b : \kappa \rightarrow X$ ;  $\mathcal{P}_s^{\text{bd}}(b)$  and  $\mathcal{P}_s^{<\kappa}(b)$  are source 25's  $\mathcal{D}_{\text{bd}}$  and  $\mathcal{D}_{<\kappa}$ , its bounded-support and small-support cores. At a singular  $\kappa$  they differ, as source 14's support hierarchy (section 49.1) shows for the class core.

The regularity restriction in the preceding proof is not cosmetic. A family of approximants cofinal in the word length can determine a noncore full word completely, leaving no core point with its profile.

**Theorem 95.1** (Cofinal profiles force the missing branch). *Let  $\kappa$  be any infinite cardinal and let  $b : \kappa \rightarrow X$  be a bijection onto any linearly ordered alphabet of size  $\kappa$ . Let  $\mathcal{P}_s^{\text{bd}}(b)$  be its bounded-support core and  $\mathcal{P}_s^{<\kappa}(b)$  its support-of-size-less-than- $\kappa$  core. There are a bijection  $d : \kappa \rightarrow X$  outside both cores and a family  $(a_i)_{i < \text{cf } \kappa}$  lying in both cores such that the only full word  $z$  satisfying*

$$\delta(z, a_i) = \delta(d, a_i) \quad (i < \text{cf } \kappa)$$

*is  $z = d$ . In particular, no member of either core realizes that profile over the fixed family.*

*Proof.* Let  $d$  swap every consecutive pair of  $b$ , with pair blocks indexed by  $\xi < \kappa$ . Choose pair-boundary ordinals  $\beta_i = 2 \cdot \xi_i < \kappa$  strictly increasing and cofinal in  $\kappa$ , for  $i < \text{cf } \kappa$ . Such boundaries are cofinal because the ordinal map  $\xi \mapsto 2 \cdot \xi$  is continuous and cofinal in every infinite initial ordinal.

Define  $a_i$  by performing the same swaps below  $\beta_i$  and leaving all positions at or above  $\beta_i$  fixed. Its support is bounded and has size less than  $\kappa$ , and

$$\delta(d, a_i) = \beta_i.$$

If  $z$  has the indicated first-disagreement ordinals, then  $z \upharpoonright \beta_i = a_i \upharpoonright \beta_i = d \upharpoonright \beta_i$  for every  $i$ . Cofinality forces  $z = d$ . But  $d$  moves all  $\kappa$  positions, so it belongs to neither core.  $\square$

For regular  $\kappa$ , the obstruction occurs at  $\kappa$  constraints, immediately beyond the less-than- $\kappa$  extension theorem. This establishes sharpness of that bound for the one-point core-realization mechanism. It does not by itself classify every possible larger partial automorphism.

For singular  $\kappa$ , the obstruction already occurs at  $\text{cf } \kappa < \kappa$  constraints. Consequently the less-than- $\kappa$  one-point extension statement fails even if one replaces bounded support by support of cardinality less than  $\kappa$ . The failure is not repaired merely by adopting a larger small-support core.

**Remark 95.2** (A second singular obstruction: unbounded prefix images). At a singular  $\kappa$ , not every injective prefix of length less than  $\kappa$  extends to the bounded-support core. Choose an injection  $q : \text{cf } \kappa \rightarrow \kappa$  with cofinal range and put  $p = b \circ q$ . A bounded-support permutation extending  $q$  would have to move positions to cofinally many ordinals above its support bound, which is impossible. In contrast, the reserve construction does extend this  $q$  to a permutation of support cardinality less than  $\kappa$ . Thus bounded support, small support, and prefix completeness must be separated at singular lengths.

The global GBC theorem has no analogous set-sized obstruction: every set of disagreement ordinals has a strict ordinal bound. A uniformly proper-class family of approximants can, however, force an entire noncore branch by the same argument. The set-indexing hypothesis is exactly what prevents this cofinality failure in Lemma 89.1.

## 96 Ordered prefix trees without the core (sources 27 and 29)

[merge] Sources 27 and 29 keep the ordered tree of set-length words (lengths, prefixes and the numerical order of children) but not the core. Both prove that its automorphisms act transitively on supplied injective class branches ([theorem 96.2](#); source 29's [theorem 96.7](#), which also covers the increasing-word tree), so exhaustiveness is not invariant ([corollary 96.3](#) and [note 96.8](#)). This is weaker than source 25's [theorem 91.1](#), where the core and every cylinder are preserved as well; retaining the core is what splits the single orbit into two ([note 90.4](#)). The new contributions here are the local description of every tree automorphism and the exact obstruction to preserving exhaustion ([theorem 96.4](#)), two families that do preserve it (source 27's antichain transformations and source 29's [proposition 96.11](#)), source 29's [corollary 96.12](#) (no fixed set height detects the failure), and source 29's increasing tree, where numerical cofinality is not invariant either ([corollary 96.9](#)). Both sources were written after Part VIII; neither cites source 25.

### 96.1 Source 27: prefix symmetries, exhaustiveness, and repeated labels

The corpus shows that the bare order of the bounded-support core does not recognize exhaustive branch cuts ([corollary 47.3](#) and [theorem 47.7](#)). A natural response is to retain the prefix tree as additional structure. We show that even this response is insufficient unless the structure also remembers which labels at different nodes are the same surreal.

Work in GBC with a fixed baseline  $b : \text{Ord} \rightarrow \mathbf{No}$ . Let  $\mathcal{I}$  be the ordinary class of all injective set-length surreal words. Its tree order is initial segment, and the children of  $p$  are  $p \frown (x)$  for  $x \in \mathbf{No} \setminus \text{ran } p$ , ordered by numerical  $x$ . An automorphism of this ordered tree is a class bijection preserving prefixes and each sibling order. It automatically preserves ordinal height, since the proper predecessors of a node of length  $\alpha$  have order type  $\alpha$ .

Every class injection  $E : \text{Ord} \rightarrow \mathbf{No}$  determines a maximal branch consisting of all  $E \upharpoonright \alpha$ . It is maximal whether or not  $E$  is onto: a compatible set-length node must be the corresponding prefix of  $E$ . Thus maximality is not exhaustiveness.

#### 96.1.1 A uniform isomorphism lemma with only set states

**Lemma 96.1** (Uniform pointed residual isomorphisms). *There is one class graph, definable from  $b$ , which for every pair of sets  $S, T \subseteq \mathbf{No}$  and points  $a \notin S$ ,  $c \notin T$  gives an increasing bijection*

$$J(S, T; a, c) : \mathbf{No} \setminus S \longrightarrow \mathbf{No} \setminus T, \quad J(S, T; a, c)(a) = c.$$

*There is also an unpointed version. The graph has set tuples as its elements; it is not a class whose elements are class maps.*

*Proof.* Deleting a set from  $\mathbf{No}$  preserves its ability to fill every separated set cut. To avoid a deleted set of cardinality  $\mu$ , first construct  $\mu^+$  distinct points between the two sides, using the surreal set-cut property at each set stage. At least one remains outside the deleted set. The same argument permits avoidance of the values already used by a set partial map.

Start with the increasing partial map  $\{(a, c)\}$ , or the empty map in the unpointed version. At ordinal stage  $\beta$ , handle the source label  $b(\beta)$  if it is eligible and unused. Its image must lie between the images of its earlier lower and upper domain elements. Choose the feasible fresh target of least  $b$ -index. Next handle  $b(\beta)$  on the target side by the symmetric extension of the inverse. The preceding cut argument ensures both steps are possible. At limits take unions. Every stage is a set partial increasing bijection, and every eligible label on both sides is eventually handled.

For each set ordinal  $\delta$ , the run through  $\delta$  is a unique set sequence. A pair belongs to the final map exactly when some such set run contains it. This is an elementary formula with parameters  $b, S, T, a, c$ . Elementary class comprehension therefore defines one uniform graph for all allowed set parameters. No stage of this construction chooses or collects a proper-class object as a state.  $\square$

The same proof works for the permissible next-letter orders of increasing words used in [section 82.2](#): those orders also fill every set cut, and their restrictions of the baseline enumerate them. The distinction between set-state recursion and a recursion whose individual values are classes is essential to the axiom count.

### 96.1.2 Every tree automorphism is governed by local residual maps

For an ordered-tree automorphism  $A$ , define its local map by

$$A(p \frown (x)) = A(p) \frown (\lambda_p(x)). \quad (\text{S27.8})$$

Then  $\lambda_p$  is an increasing bijection from  $\mathbf{No} \setminus \text{ran } p$  onto  $\mathbf{No} \setminus \text{ran } A(p)$ , uniformly in  $p$ , and

$$A(p)(\xi) = \lambda_{p \restriction \xi}(p(\xi)).$$

Conversely, suppose one class rule  $\Lambda(p, q; x, y)$  gives an increasing residual bijection from  $\mathbf{No} \setminus \text{ran } p$  onto  $\mathbf{No} \setminus \text{ran } q$  for every equal-height pair  $p, q$ . Define the image  $q = A(p)$  by the set recursion

$$q(\xi) = \Lambda(p \restriction \xi, q \restriction \xi)(p(\xi)). \quad (\text{S27.9})$$

The prefixes cohere by uniqueness. Inverting the residual maps in a recursion on a target word constructs its unique preimage, so  $A$  is a bijection at every height. It preserves prefixes and sibling orders. Thus (S27.9) is a precise way to construct an ordered-tree automorphism without selecting unrelated class maps at each node.

**Theorem 96.2** (Transitivity on all injective ordinal branches). *Given any class injections  $E, F : \text{Ord} \rightarrow \mathbf{No}$ , there exists an ordered-prefix-tree automorphism  $A$  such that*

$$A(E \restriction \alpha) = F \restriction \alpha \quad (\alpha \in \text{Ord}). \quad (\text{S27.10})$$

*It preserves ordinal levels, all prefix incidences, and numerical order among the children of each node.*

*Proof.* For equal-height  $p, q$  of length  $\alpha$ , use the pointed residual map

$$J(\text{ran } p, \text{ran } q; E(\alpha), F(\alpha))$$

when  $p = E \restriction \alpha$  and  $q = F \restriction \alpha$ . Its distinguished points are fresh by injectivity. In every other case use the unpointed residual map. This is a single elementary rule with class parameters  $b, E, F$ . Apply (S27.9). Induction on each set ordinal forces the pointed case along the designated branch, which proves (S27.10).  $\square$

**Corollary 96.3** (Ordered prefixes do not recognize exhaustiveness). *Exhaustiveness of an Ord-branch is not invariant under automorphisms of the ordered prefix tree, even if levels and sibling numerical order are retained.*

*Proof.* Take  $E = b$  and define

$$F(n) = b(n+1) \quad (n < \omega), \quad F(\xi) = b(\xi) \quad (\xi \geq \omega).$$

The map  $F$  is injective and omits exactly  $b(0)$ . Apply [theorem 96.2](#). The exhaustive branch is sent to a nonexhaustive branch, so no property invariant under this structure's automorphisms can distinguish the two.  $\square$

The displayed branches even agree outside a bounded set of coordinates. Agreement outside a set is not the same as being related by a permutation supported on that set: the infinite one-sided shift loses a label. This is the same boundary phenomenon measured by the reserve in [section 101](#).

For a set alphabet  $X$ , the full injective-word tree has a different answer. Its terminal nodes are exactly the exhaustive words, and any tree automorphism preserves terminal nodes. Every maximal branch has such a terminal node, because an injective word has length below the Hartogs number of  $X$  and a missing label would allow extension. This argument does not apply to a truncated set tree that stops before the terminal height, nor to the full proper-class tree.

### 96.1.3 An exact obstruction and useful sufficient bounds

An automorphism acts on a supplied class branch by the elementary formula

$$A_*E(\xi) = A(E \upharpoonright (\xi + 1))(\xi).$$

It acts on exhaustive branches precisely when it preserves coverage of the alphabet. A local formulation makes the obstruction explicit. For a target label  $y$ , put

$$\mathcal{I}_y(A) = \{p : y \notin \text{ran } A(p)\}.$$

This is a downward-closed subtree. At a node in it, exactly one available input child is forbidden if the branch is to continue omitting  $y$ , namely  $\lambda_p^{-1}(y)$ . Therefore  $A_*$  sends every exhaustive branch to an exhaustive one exactly when none of these subtrees has an exhaustive Ord-branch. To obtain a bijection on exhaustive branches, impose the same condition on  $A^{-1}$ . This criterion is exact, but it deliberately leaves a substantial branch problem.

**Theorem 96.4** (Set-bounded local inverse images). *Suppose for every label  $y$  there is a set  $K_y \subseteq \mathbf{No}$  such that*

$$y \notin \text{ran } A(p) \implies \lambda_p^{-1}(y) \in K_y$$

*for every node  $p$ . Then  $A_*$  preserves exhaustive branches. If additionally for every input label  $x$  all possible local values  $\lambda_p(x)$  lie in a set  $L_x$ , then  $A_*$  is a bijection on the exhaustive branches.*

*Proof.* Let  $E$  be exhaustive. The elements of the set  $K_y$  all occur in  $E$  before some set ordinal  $\alpha$ , by Class Replacement applied to their unique occurrence times. If  $y$  were absent from  $A(E \upharpoonright \alpha)$ , its local inverse image would have to belong both to  $K_y$  and to the unused source alphabet. This is impossible. Thus every  $y$  occurs in  $A_*E$ . The second hypothesis is exactly the first hypothesis for the inverse automorphism, giving the converse.  $\square$

A useful equivalent formulation bounds the birthdays of all possible local inverse images of labels of birthday below  $\beta$  by one set ordinal  $\mu(\beta)$ . The bounded sign stage is a set. Conversely, per-label set bounds have ordinal birthday bounds, and Class Replacement over a bounded sign stage gives such a uniform modulus. The symmetric forward condition is analogous.

A uniformly given action of a *set* group of numerical automorphisms supplies examples: if each local map is the restriction of a group element, every possible inverse image lies in the set orbit of  $y$ , and every forward image lies in the set orbit of  $x$ . This is a sufficient criterion, not a classification of all permissible local dynamics.

### 96.1.4 Independent transformations after a chosen prefix

Let  $P$  be a uniformly presented prefix antichain. Suppose that for every  $p \in P$  an increasing class bijection  $\varphi_p : \mathbf{No} \rightarrow \mathbf{No}$  is given by one class graph, and  $\varphi_p[\text{ran } p] = \text{ran } p$ . Keep  $p$  fixed and apply  $\varphi_p$  to every later letter in its extension cone; fix words in no such cone. The antichain makes the choice unique, the used set is preserved, and the inverse uses  $\varphi_p^{-1}$ . This is an ordered-tree automorphism preserving exhaustion in both directions. A branch meeting a cone has its remaining alphabet bijectively relabelled, and a branch meeting no cone is fixed.

For example, fix a length- $\omega$  prefix enumerating the embedded ordinary integers  $\mathbb{Z}$ . Above that prefix add 1 to every later letter, and act identically elsewhere. Since  $\mathbb{Z} + 1 = \mathbb{Z}$ , this is a valid transformation. It fixes all first-level nodes but is not the identity, so it is not a single global relabelling.

The bounds in [theorem 96.4](#) are not necessary. Choose a transformation after each first letter  $z$ ; for  $z > 1$  use

$$\varphi_z(x) = zx - z(z - 1),$$

and for  $z \leq 1$  use the identity. The affine map is increasing and fixes  $z$ , so the antichain construction applies. It preserves exhaustiveness, but  $\varphi_z^{-1}(0) = z - 1$  ranges over a proper class. There is no single set  $K_0$  bounding all these local inverse images. Once a first letter is fixed the tail behavior is simple; uniformity over all first letters is much stronger.

### 96.1.5 The additional predicate that gives an exact classification

Enrich the ordered tree by equality of labels on different successor edges:

$$(p, p \frown (x)) \sim (q, q \frown (y)) \iff x = y. \quad (\text{S27.11})$$

This predicate does not name individual surreals. It remembers which occurrences at different nodes refer to the same label.

*Note 96.5* (Source 27, Theorem 6.5, “Automorphisms after retaining label equality”). *The automorphisms of the ordered prefix tree preserving (S27.11) are exactly*

$$A(p) = \varphi \circ p$$

*for increasing class bijections  $\varphi : \mathbf{No} \rightarrow \mathbf{No}$ . They all preserve exhaustive branches. If the alphabet is also fixed pointwise, the only such tree automorphism is the identity.* This is source 25’s [theorem 93.1](#), with the trivial case of [theorem 93.3](#) in which the alphabet is fixed pointwise; source 27’s proof is the same root-edge argument. Source 25 adds that preserving the core as well forces the identity ([theorem 93.3](#)) and that coherent edges recognize coverage ([proposition 93.4](#)).

*Source 27’s proof.* The local map at the root is an increasing bijection  $\varphi : \mathbf{No} \rightarrow \mathbf{No}$ . Every edge appending  $x$  is equivalent to the root edge appending  $x$ . Preservation of the edge equivalence forces every such edge to append  $\varphi(x)$  after transformation. Thus every local map is the restriction of  $\varphi$ , and induction on a set word gives the formula for  $A$ . Conversely, coordinatewise relabeling by  $\varphi$  preserves every indicated relation and is inverted by relabeling with  $\varphi^{-1}$ .  $\square$

This answers a precise version of the question “what extra structure restores the labels?” It does not claim that cross-node label equality is minimal among all possible enrichments. Between the arbitrary tree automorphisms of [theorem 96.2](#) and the global relabellings of [note 96.5](#) lies a substantial subgroup preserving exhaustiveness, of which the bounds and antichain constructions describe useful parts.

All these tree automorphisms preserve first-disagreement comparison on full Ord-branches, which never stand in a proper-prefix relation. On set words they preserve the prefix-first and prefix-last orders. An interior terminator would additionally require the local maps to preserve its cut; that condition is not automatic.

[merge] Lemma 96.1 is the uniform construction of source 18's theorem 35.7 and of source 13's family  $h_S$  (lemma 42.2), with one prescribed point matched; source 29's lemma 96.6 below allows any set partial match and the increasing alphabets as well. The “reserve in section 101” mentioned after corollary 96.3 is source 27's ordinal support theorem (section 101).

## 96.2 Source 29: ordered prefix trees do not determine their exhaustive class branches

[merge] Source 29's Section 9, printed whole. Its theorem 96.7 is, for the injection tree  $\mathcal{I}$ , source 27's theorem 96.2 (a second proof); its case of the increasing-word tree  $\mathcal{T}^{\text{inc}}$  is new. Its Corollary 9.3 is source 27's corollary 96.3 with another target branch and is printed as a note. Its proposition 96.10 is source 27's remark on set alphabets after corollary 96.3.

The ordered prefix tree contains much more information than the pure lexicographic order. It records the length of every set word, all extension relations, and the numerical order of the possible next entries. Even this structure does not recognize which proper-class branches exhaust the surreal labels. We prove this by constructing automorphisms that carry any one supplied branch to any other. The same method applies to increasing branches and can exchange a numerically cofinal range with a bounded one.

### 96.2.1 The structures and the required uniform isomorphisms

Let  $\mathcal{I}$  be the class of all injective functions  $p : \alpha \rightarrow \mathbf{No}$  with  $\alpha$  a set ordinal. Let  $\mathcal{T}^{\text{inc}}$  be its strictly numerically increasing subclass. Both include the empty word. Each carries word length, the prefix relation, and shorter-first lexicographic order. At a node  $p$ , the one-step extensions have the order of their next entries. The respective admissible alphabets are

$$\begin{aligned} D_p^{\mathcal{I}} &= \mathbf{No} \setminus \text{ran}(p), \\ D_p^{\mathcal{T}^{\text{inc}}} &= \{x \in \mathbf{No} : \text{ran}(p) < x\}. \end{aligned}$$

The inequalities in the second line mean that every entry of  $p$  is less than  $x$ .

These are structures on a genuine class of set-coded nodes. A proper-class branch will be supplied separately as a class function  $F : \text{Ord} \rightarrow \mathbf{No}$  all of whose set restrictions are nodes of the relevant tree. The assertion below quantifies over such class parameters; it does not form a class whose members are all branches.

**Lemma 96.6** (Residual alphabets and a prescribed match). *Work in GBC with a fixed set-like global well-order. Each of the alphabets  $D_p^{\mathcal{I}}$  and  $D_p^{\mathcal{T}^{\text{inc}}}$  is a proper class filling every separated set cut, including cuts with an empty side. For two nodes  $p, q$  of the same tree and any set partial order isomorphism between their residual alphabets, there is an increasing bijection*

$$h : D_p \longrightarrow D_q$$

*extending it. If the nodes and the initial partial match are specified uniformly from set parameters and fixed class parameters, these bijections can be given by one elementary class relation.*

*Proof.* First recall set avoidance in the surreal line. Given sets  $A < B$  and a forbidden set  $S$ , choose  $z$  with  $A < z < B$ . If  $z \notin S$ , it is already a suitable filler. Otherwise apply the set-cut property again to obtain

$$A \cup \{z\} < y < B \cup \{s \in S : z < s\}.$$

All constraints are consistent:  $z < B$ , and every newly imposed upper constraint is larger than  $z$ . The point  $y$  is larger than every forbidden element at most  $z$  and smaller than every forbidden element above  $z$ , so  $y \notin S$ . This proves set-cut filling in  $D_p^{\mathcal{I}}$ . It is proper because removing a set from **No** cannot leave a set.

For  $D_p^{\mathcal{T}^{\text{inc}}}$ , append  $\text{ran}(p)$  to the lower constraints of any set cut in the residual alphabet. Every upper constraint already exceeds the whole prefix. Surreal interpolation therefore produces a filler in  $D_p^{\mathcal{T}^{\text{inc}}}$ , including when either original side was empty. If this residual alphabet were a set, using all of it as lower constraints would require a strictly larger point within that same set, a contradiction. It is therefore proper.

For the extension assertion, start a deterministic back-and-forth with the supplied set partial isomorphism. At each stage take the first unmatched source point in the fixed global well-order, and place its image in the cut specified by the present partial isomorphism. The image can be chosen as the first eligible point in the fixed global well-order. Then perform the corresponding inverse insertion for the first unmatched target point. The strict cut constraints automatically exclude previously used points. At a limit set ordinal take the union of the preceding partial maps. The histories and partial maps are sets at every stage, and both directions are eventually exhausted.

For uniformity, membership in the resulting bijection is expressed by existence of a set-length initial history obeying these deterministic rules. The nodes, initial match, stage ordinal, and history are all set variables. Only the original alphabet definitions and global well-order are class parameters. The same elementary formula works for all the specified instances. As in the repository's uniform prefix constructions ([lemma 42.2](#) and [theorem 35.7](#)), this avoids choosing an arbitrary class isomorphism independently for each node. The recursion has set-valued stages and does not require ETR or Class Choice.  $\square$

The extension assertion allows a single point of the source alphabet to be matched with any single point of the target alphabet. This freedom, applied along one distinguished branch, is the key to the next theorem.

### 96.2.2 Transitivity on supplied class branches

**Theorem 96.7** (Branch transitivity of the ordered trees). *Work in GBC. For either  $\mathcal{K} = \mathcal{I}$  or  $\mathcal{K} = \mathcal{T}^{\text{inc}}$ , let  $F, G : \text{Ord} \rightarrow \mathbf{No}$  be two supplied class branches. There is a class automorphism  $A : \mathcal{K} \rightarrow \mathcal{K}$  preserving lengths, prefixes, and lexicographic order such that*

$$A(F \upharpoonright \alpha) = G \upharpoonright \alpha \quad (\alpha \in \text{Ord}).$$

*In particular, it preserves the order of the immediate successors of every node.*

*Proof.* For each pair of nodes  $p, q$  of the same length  $\alpha$ , use [lemma 96.6](#) to define an increasing bijection

$$h_{p,q} : D_p \longrightarrow D_q.$$

When  $p = F \upharpoonright \alpha$  and  $q = G \upharpoonright \alpha$ , begin the deterministic construction with the single prescribed match

$$F(\alpha) \longmapsto G(\alpha).$$

These are admissible unused entries because  $F, G$  are branches. For every other pair  $p, q$ , begin with the empty partial map. The condition selecting the seeded case is elementary in the set parameters  $p, q, \alpha$  and the class parameters  $F, G$ . Thus one class relation gives all the  $h_{p,q}$  simultaneously.

For a source word  $f$  of set length  $\alpha$ , define its image  $g$  by set recursion. Begin with the empty target prefix and set

$$g(\xi) = h_{f \upharpoonright \xi, g \upharpoonright \xi}(f(\xi)) \quad (\xi < \alpha). \quad (\text{S29.20})$$

Take unions at limit stages. Each chosen letter belongs to the target residual alphabet, so the output is injective in  $\mathcal{I}$  and increasing in  $\mathcal{T}^{\text{inc}}$ . Set Replacement supplies the output graph. Restrictions of a construction are the unique constructions for the corresponding shorter input words. The resulting class map  $A$  thus preserves lengths and prefixes.

It is also bijective. Given a target word  $g$ , reconstruct a source prefix  $p$  recursively. At position  $\xi$ , the target prefix  $q = g \upharpoonright \xi$  is known and the next source letter is uniquely

$$h_{p,q}^{-1}(g(\xi)).$$

This belongs to  $D_p$ , so the reconstruction remains in the required tree. It is inverse to (S29.20) at successors and at limits. Hence every target node has exactly one source node.

To check lexicographic order, proper-prefix comparisons are preserved by the already proved prefix and length assertions. Otherwise let  $\xi$  be the first unequal coordinate of two words. They have the same source prefix  $p$  and therefore the same target prefix  $q$  at that stage. Their next entries are transformed by the same increasing map  $h_{p,q}$ , which preserves the comparison. This proves the order assertion and also its restriction to immediate successors.

Finally, set induction on  $\alpha$  proves  $A(F \upharpoonright \alpha) = G \upharpoonright \alpha$ . At each successor stage the appropriate  $h_{p,q}$  contains the prescribed match, and at limits both sides are the unions of their shorter restrictions. The graph of  $A$  is defined from the unique set recursion histories, with the fixed class parameters already described. No family of class-valued outputs is collected into a class of classes.  $\square$

For any supplied branch  $H$ , its image under a tree automorphism is itself an admitted class branch, defined by

$$A_*H(\xi) = A(H \upharpoonright (\xi + 1))(\xi).$$

The prefixes are coherent, and elementary comprehension gives the graph. The inverse tree automorphism supplies the inverse branch operation. This formulation is available within the stated class framework without replacing the virtual collection of branches by an undeclared higher-sort object.

*Note 96.8* (Source 29, Corollary 9.3, “Exhaustivity is additional information”). *There is a length-, prefix-, and lexicographic-order-preserving class automorphism of  $\mathcal{I}$  carrying the prefixes of an exhaustive bijection  $b : \text{Ord} \rightarrow \mathbf{No}$  to those of a nonexhaustive injection. Consequently exhaustivity of proper-class branches is not an invariant of this ordered prefix-tree structure.* This is source 27’s corollary 96.3, here with target branch  $\alpha \mapsto \alpha$ . Source 25’s theorem 91.1 proves more: the core and all its cylinders can be preserved as well.

*Source 29’s proof.* Global Choice gives an exhaustive enumeration  $b$  of the surreal class. Apply theorem 96.7 to  $F = b$  and to  $G(\alpha) = \alpha$ , where ordinals are regarded as surreals. The latter branch omits, for example,  $-1$ .  $\square$

**Corollary 96.9** (Numerical cofinality is also additional information). *An automorphism of the ordered increasing-word tree  $\mathcal{T}^{\text{inc}}$  can carry a numerically cofinal proper-class branch to one whose range is bounded above by zero.*

*Proof.* Take

$$F(\alpha) = \alpha, \quad G(\alpha) = -\frac{1}{\alpha + 1}.$$

Both are strictly increasing class functions. Every surreal is smaller than some ordinal—its sign length gives an ordinal bound—so  $F$  is cofinal in the numerical surreal line. Ordered-field arithmetic makes  $G$  strictly increasing, and every one of its values is negative. Apply [theorem 96.7](#) for  $\mathcal{T}^{\text{inc}}$ .  $\square$

The structures in these corollaries name lengths, prefix extension, and successor orders. They do *not* name the common evaluation relation assigning a literal surreal label to each successor. In particular, equality of labels used at different nodes is not part of the stated reduct. The automorphisms can change that information. If label evaluation were named, it could express exhaustivity directly. Similarly, the ambient set membership relation on the codes is not being asserted invariant under these tree automorphisms.

The automorphism in [note 96.8](#) is an automorphism of the set-word tree, not an automorphism of  $\mathfrak{W}_{\text{sl}}$ : its induced branch map fails to preserve the domain of exhaustive enumerations. The conclusion therefore complements the repository’s core-automorphism extension obstructions ([theorem 47.7](#) and [corollary 47.3](#)), while making a distinct assertion about a richer prefix structure.

### 96.2.3 Why the full tree over a set carrier behaves differently

**Proposition 96.10** (Terminal nodes over a set alphabet). *For a fixed set alphabet  $X$ , consider the full tree of all injective ordinal-length  $X$ -words, with all possible set lengths. Its terminal nodes are exactly the exhaustive enumerations of  $X$ . Every prefix-tree automorphism therefore preserves exhaustivity.*

*Proof.* If a word omits a label  $x \in X$ , appending  $x$  is a permitted one-letter extension. If its range is  $X$ , no label is available for such an extension, and any proper longer word would have to supply one at the first new coordinate. This proves the characterization. Terminality is preserved by every automorphism of the prefix relation.  $\square$

For an infinite set alphabet of cardinality  $\mu$ , the entire tree is a set: every injective domain is below  $\mu^+$ , so its nodes occur in a set-sized collection of function spaces. A truncation changes the argument. For instance, a tree cut off at height  $\mu$  has terminal height- $\mu$  nodes that may omit labels. In the surreal class tree, every node has set range and therefore has unused surreal labels. There is no terminal set node at the end of an Ord-length branch. This is exactly where the set-carrier characterization ceases to apply.

### 96.2.4 Local descriptions and a family preserving exhaustion

Every length- and prefix-preserving automorphism  $A$  of  $\mathcal{I}$  that preserves lexicographic order determines increasing bijections

$$\begin{aligned} h_p : \mathbf{No} \setminus \text{ran}(p) &\longrightarrow \mathbf{No} \setminus \text{ran}(A(p)), \\ A(p \frown \langle x \rangle) &= A(p) \frown \langle h_p(x) \rangle. \end{aligned}$$

Surjectivity on the immediate successors follows from bijectivity of  $A$  and preservation of prefixes. Conversely, a uniform collection of increasing maps between the relevant source and target residual alphabets, used coherently as in ([S29.20](#)), determines such an automorphism. [Theorem 96.7](#) shows that this local description alone imposes no preservation of exhaustion.

There is nevertheless a broad concrete family for which exhaustion is preserved, allowing the relabelling of a tail to depend on its entire initial set prefix.

**Proposition 96.11** (Fixed-stage continuation by residual bijections). *Fix a set ordinal  $\delta$  and a length-, prefix-, and lexicographic-order-preserving automorphism  $B$  of the injection tree through height  $\delta$ , including that height. For every node  $p$  of length  $\delta$ , specify uniformly an increasing bijection*

$$k_p : \mathbf{No} \setminus \text{ran}(p) \longrightarrow \mathbf{No} \setminus \text{ran}(B(p)).$$

*There is a class automorphism  $A$  of the full injection tree agreeing with  $B$  through height  $\delta$  and continuing each tail after  $p$  by the same entrywise map  $k_p$ . Its induced operation on class branches preserves exhaustivity in both directions. Such uniform families  $k_p$  exist in GBC.*

*Proof.* For words of length at most  $\delta$ , use  $B$ . For a longer word  $f$ , put  $p = f \restriction \delta$ , take  $B(p)$  as the initial target word, and define

$$A(f)(\xi) = k_p(f(\xi)) \quad (\delta \leq \xi < \text{dom}(f)).$$

The original tail avoids  $\text{ran}(p)$ , and its image avoids  $\text{ran}(B(p))$ ; injectivity of the tail is preserved. Thus the resulting word is a node. Restrictions are compatible at and on both sides of  $\delta$ . An inverse is obtained from  $B^{-1}$  on the initial prefix and the appropriate  $k_p^{-1}$  on its tail, proving bijectivity.

A first disagreement before  $\delta$  is preserved by  $B$ . If two words agree through  $\delta$ , the same increasing  $k_p$  acts at any later first disagreement. Proper-prefix comparisons are also preserved. Therefore  $A$  has all the asserted tree and order properties.

Now let  $F$  be any supplied class injection, and let  $p = F \restriction \delta$ . Its tail takes values in  $\mathbf{No} \setminus \text{ran}(p)$ . The range of  $F$  is all of  $\mathbf{No}$  if and only if that tail exhausts this residual alphabet. Since  $k_p$  is a bijection onto the residual alphabet of  $B(p)$ , this holds if and only if the image tail exhausts its own residual alphabet, which is equivalent to exhaustivity of  $A_*F$ . The same argument proves the reverse direction.

Finally, apply [lemma 96.6](#) with empty initial matches to obtain the  $k_p$  uniformly from  $p, B$ , and a fixed global well-order. Their elementary class definition supplies the required family without a choice of class-valued stages.  $\square$

At  $\delta = 0$  this includes uniform entrywise increasing relabellings of the entire surreal alphabet. At positive set stages it permits different residual relabellings after different prefixes. The fixed bijection on an entire tail provides the coverage argument that is absent from unrestricted coordinate-dependent choices. The theorem is a sufficient construction, not a classification of every exhaustion-preserving automorphism.

**Corollary 96.12** (Agreement through any prescribed set stage). *For every automorphism  $A$  of the ordered injection tree and every set ordinal  $\delta$ , there is an exhaustion-preserving automorphism  $\tilde{A}$  agreeing with  $A$  on all nodes of length at most  $\delta$ . Nevertheless some automorphisms of the full tree do not preserve exhaustion.*

*Proof.* Restrict  $A$  to the tree through height  $\delta$  and apply [proposition 96.11](#). The second assertion is [note 96.8](#).  $\square$

Thus the failure to preserve exhaustive proper-class branches cannot be diagnosed from the action through any one fixed set height, even when that entire height and all earlier levels are retained. The corollary is stated as a uniform approximation theorem about supplied class maps; it does not presuppose an internal class of all class automorphisms.

[merge] [Proposition 96.11](#) and [corollary 96.12](#) and source 27's [theorem 96.4](#) and antichain transformations are different sufficient families for preserving exhaustion; none classifies the exhaustion-preserving subgroup (sources 25, 27 and 29 each ask for it: [research question 113.165](#); source 27's Question 12.6; source 29's Question 13.7).

## 97 Automorphisms of the core and the failure of extension (sources 20 and 21)

[merge] Sources 20 and 21 were written before Part VIII and prove again, each independently, most of Part VIII’s [section 47](#): the classification of cut orbits by characters (source 20’s Theorem 5.3 is source 14’s [theorem 47.2](#); source 21’s Theorem 9.8 is its (Ord, Ord) case and [lemma 47.6](#)), the extension criterion (source 20’s Theorem 5.8 and source 21’s Theorem 9.4 are source 17’s [theorem 47.5](#)), and the existence of non-extendable automorphisms (source 20’s Corollary 5.6 is [corollary 47.3](#); source 21’s Theorem 9.10 is [theorem 47.7](#), and its Theorem 9.12 follows from [corollary 47.3](#)). Those statements are printed as notes with the sources’ proofs. New here are source 20’s localized failure ([theorem 97.7](#): the automorphism can fix any set of core points and be supported in one interval), its disjointness of relabelled cores ([proposition 97.9](#), which sharpens [proposition 47.9](#)), and source 21’s explicit cut with no crossing first-level cylinder ([proposition 97.20](#)).

Both sources say they answer the repository’s extension question ([research question 113.4](#)) negatively. At the time this was so against their pins (d5bd4a67b and 109aaca15, which predate Parts VI–VIII); at this report’s present state Part VIII has already answered that question in part, negatively ([section 50 \(c\)](#)), and the two sections are second routes to it, except for the three new results named above. Source 20 writes  $\Omega$  for “no set-sized witness”, which Part VIII writes Ord.

### 97.1 Source 20: automorphisms of the core and the failure of extension

The bounded-support core has an exceptionally homogeneous abstract order, but its position among global well-orders carries additional information. We now separate these two structures. The principal new conclusion is that an automorphism of the core need not extend even when only one additional exhaustive enumeration is to be included. This failure can occur while any prescribed set of core points is fixed pointwise. It answers negatively the unrestricted extension question posed in the repository and the previous continuation ([research question 113.4](#); source 18).

Throughout this section we work in GBC and fix a baseline class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . Write  $\mathcal{P}_{\text{bd}}(b)$  for the ordinary class of normalized set codes for permutations of Ord with set support, and  $E_c$  for the global enumeration evaluated from  $c \in \mathcal{P}_{\text{bd}}(b)$ . Codes are ordered by their evaluations. We use the established core theorem:  $\mathcal{P}_{\text{bd}}(b)$  fills every cut specified by sets, including cuts with an empty side, and is class-order-isomorphic to  $\mathbf{No}$ . We also use its stronger uniform interpolation form, whose upper and lower input families may be set-indexed families of arbitrary exhaustive global enumerations. The back-and-forth principle underlying the core theorem is classical in the study of the surreal order [15]; the arguments below record the relevant class-theoretic details explicitly.

#### 97.1.1 Class cuts and their automorphism orbits

**Definition 97.1** (Strict cuts and set characters). A *strict class cut* of  $\mathcal{P}_{\text{bd}}(b)$  is a nonempty proper initial class  $L \subseteq \mathcal{P}_{\text{bd}}(b)$  having no greatest element. Its upper side is  $U = \mathcal{P}_{\text{bd}}(b) \setminus L$ . Define

$$\chi(L) = (\text{cf}_s(L), \text{ci}_s(U)),$$

where  $\text{cf}_s$  is the least cardinality of a set cofinal subset when one exists, and is the marker  $\Omega$  otherwise; define  $\text{ci}_s$  dually. The marker  $\Omega$  means only “no set-sized witness.” It is not a set cardinal and is not used as an object containing all ordinals.

If a class without a greatest element has a set cofinal subset, the usual set-theoretic cofinality argument, applied to that subset, gives a strictly increasing cofinal sequence of infinite regular

length. The dual statement applies to coinitality. The upper side of a strict cut can instead have a minimum, in which case its character is 1. In particular, the strict cut below a core point is included in our convention. A closed principal initial segment is excluded because it has a greatest element.

*Note 97.2* (Source 20, Lemma 5.2, “Saturated sides”). *Let  $C$  be a class linear order filling every set cut. A nonempty initial class  $A \subseteq C$  with no set cofinal subset also fills every set cut, including empty sides. Dually, a nonempty final class with no set coinital subset has the same property. Every such class is class-order-isomorphic to  $\mathbf{No}$  in GBC.* For the sides of a core gap this is the first part of source 17’s lemma 47.6 (and source 21’s note 97.16); source 20 states it for every class order filling set cuts, and its second paragraph is the back-and-forth of proposition 5.13.

*Source 20’s proof.* Let  $P, Q \subseteq A$  be sets with  $P < Q$ . If  $Q$  is nonempty, a point of  $C$  between them belongs to  $A$ , because it lies below a member of the initial class  $A$ . If  $Q$  is empty, the absence of a set cofinal subset gives a point of  $A$  strictly above all of  $P$ . This includes the case  $P = Q = \emptyset$ . Thus  $A$  has the full set-cut property. It cannot be a set: applying that property with lower side all of  $A$  would produce a point of  $A$  above itself. The final-class statement is dual.

For the isomorphism, Global Choice provides set-like enumerations of the two proper classes. Alternately extend a set-sized partial order isomorphism to include the next point of each enumeration. The previous lower and upper images form sets, so the required new point exists. Choose the least eligible point in a fixed global well-order. At each ordinal stage the partial map is a set, and at a set limit its earlier stages have a set union. The resulting class is the union of the unique compatible set computations. This is ordinary set-valued transfinite recursion with class parameters, rather than recursion with a class-valued state; no ETR or class-choice scheme is needed.  $\square$

Every nonempty open interval  $(a, b)$  of  $\mathcal{P}_{\text{bd}}(b)$  also fills every set cut: adjoin  $a$  to the lower constraints and  $b$  to the upper constraints. It is therefore another copy of  $\mathbf{No}$ . This observation will permit the later construction to be confined to a prescribed interval.

*Note 97.3* (Source 20, Theorem 5.3, “Complete cut-orbit classification”). *Two strict class cuts  $L, L'$  of  $\mathcal{P}_{\text{bd}}(b)$  are carried to one another by a class order automorphism of  $\mathcal{P}_{\text{bd}}(b)$  if and only if  $\chi(L) = \chi(L')$ . The possible pairs are exactly*

$$(\Omega, 1), \quad (\lambda, \Omega), \quad (\Omega, \lambda), \quad (\Omega, \Omega),$$

where  $\lambda$  ranges over infinite regular set cardinals. The first pair consists precisely of strict cuts below core points. This is source 14’s theorem 47.2, with the marker  $\Omega$  in place of source 14’s character symbol  $\text{Ord}$ . Source 20 realizes  $(\Omega, \Omega)$  by the repeated-label cut of note 97.5, source 14 by a successor-prefix cylinder edge.

*Source 20’s proof.* An automorphism and its inverse send sets to sets by Class Replacement. They therefore preserve cofinal and coinital set witnesses and their least possible cardinalities. This proves necessity.

At least one coordinate of  $\chi(L)$  is  $\Omega$ . Otherwise take a set  $A_0$  cofinal in  $L$  and a set  $B_0$  coinital in its upper side. Set-cut interpolation gives  $A_0 < z < B_0$ . If  $z \in L$ , cofinality of  $A_0$  contradicts the first inequality; if  $z \notin L$ , coinitality of  $B_0$  contradicts the second. The endpoint and regularity observations following definition 97.1 give the displayed list of possible forms.

To prove sufficiency, construct isomorphisms between the two lower sides and between the two upper sides, then join the maps. A side whose relevant character is  $\Omega$  is a copy of  $\mathbf{No}$  by note 97.2. Suppose instead that the initial sides  $L, L'$  have the same set cofinality  $\lambda$ . Choose increasing cofinal sequences  $(a_\xi)_{\xi < \lambda}$  and  $(a'_\xi)_{\xi < \lambda}$ . Begin back-and-forth with the entire set partial isomorphism

$$a_\xi \longmapsto a'_\xi \quad (\xi < \lambda).$$

For a new  $x \in L$ , the already mapped points below and above  $x$  give a set cut in the ambient target core. Some  $a_\xi$  is strictly above  $x$ , so its image  $a'_\xi$  is an upper constraint. Every realizer of the cut consequently lies in  $L'$ . The inverse step is identical. This produces the required side isomorphism. For final sides with equal set coinitiality, use the dual argument. If both upper sides have a minimum, map the minima to one another and apply [note 97.2](#) to the open final tails. Each stage again has only a set partial map. Joining the two side isomorphisms preserves all comparisons across the cut and gives a class automorphism.

Strict principal cuts realize  $(\Omega, 1)$ . For an infinite regular  $\lambda$ , choose an increasing sequence  $(a_\xi)_{\xi < \lambda}$  in  $\mathcal{P}_{\text{bd}}(b)$  and put

$$L = \{x \in \mathcal{P}_{\text{bd}}(b) : (\exists \xi < \lambda) x < a_\xi\}.$$

The sequence is cofinal in  $L$ . If fewer than  $\lambda$  points were cofinal, choose an index bound for each of them; regularity would bound all these indices below  $\lambda$ , a contradiction. Thus  $\text{cf}_s(L) = \lambda$ . Its complement has no set coinitial subset by the preceding interpolation obstruction. This gives  $(\lambda, \Omega)$ , and the dual construction gives  $(\Omega, \lambda)$ . Finally the explicit cut in [note 97.5](#) below realizes  $(\Omega, \Omega)$ .  $\square$

The theorem is about individually supplied class cuts and class automorphisms. It does not form an ordinary class whose elements are all cuts. It is nevertheless a complete classification of the action: any two allowed cut parameters having the same displayed characters are conjugate.

### 97.1.2 A represented cut and an unrepresented cut in one orbit

For an exhaustive enumeration  $e : \text{Ord} \rightarrow \mathbf{No}$ , write

$$L_e = \{c \in \mathcal{P}_{\text{bd}}(b) : E_c <_{\text{lex}} e\}.$$

If  $e$  is not evaluated by a core code, its two strict comparison sides partition  $\mathcal{P}_{\text{bd}}(b)$ .

*Note 97.4* (Source 20, Lemma 5.4, “The character of a noncore enumeration”). *If  $e$  is an exhaustive global enumeration outside the chosen core, then  $\chi(L_e) = (\Omega, \Omega)$ .* This is source 17’s [proposition 46.26](#) (source 14’s [theorem 44.1](#)) for exhaustive noncore enumerations.

*Source 20’s proof.* For a set  $A \subseteq L_e$ , uniform core interpolation applied to the rows indexed by  $A$  and the one upper row  $e$  gives a core row strictly above every member of  $A$  and strictly below  $e$ . Thus  $A$  is not cofinal. The dual argument excludes a set coinitial subset above  $e$ . Smaller and larger first labels give nonempty sides.  $\square$

Such enumerations exist in GBC. For example, compose  $b$  with the class permutation interchanging each consecutive pair  $2 \cdot \alpha, 2 \cdot \alpha + 1$  of ordinals. The support is a proper class, so the resulting enumeration has no code in the bounded-support core.

For an injective set prefix  $p : \delta \rightarrow \mathbf{No}$ , let

$$C_p = \{c \in \mathcal{P}_{\text{bd}}(b) : E_c \restriction \delta = p\}$$

be its convex cylinder. Every such cylinder is nonempty. A prefix *straddles* a cut when its cylinder meets both sides. The established prefix-recognition theorem says that a strict class cut is represented by an injective Ord-word precisely when it has a straddling cylinder at every set-ordinal length. That word is unique. It represents a set-like global well-order precisely when it is surjective. A raw class well-order has the same cut as the injective enumeration of its canonical initial Ord-block, so raw representability satisfies the same prefix criterion, without the surjectivity requirement (source 18, [theorem 46.28](#); [theorem 45.1](#) and [corollary 46.4](#)).

*Note 97.5* (Source 20, Lemma 5.5, “A local deleted-label cut”). *Let  $p$  be an injective set prefix and choose  $x \in \mathbf{No} \setminus \text{ran}(p)$ . Form the noninjective set word*

$$q = p \frown \langle x \rangle, \quad t = p \frown \langle x, x \rangle.$$

*Every core row differs from  $t$  before  $t$  ends, and hence*

$$D_t = \{c \in \mathcal{P}_{\text{bd}}(b) : E_c <_{\text{lex}} t\}$$

*is well-defined. It is a strict class cut of character  $(\Omega, \Omega)$ , lying inside  $C_p$ , and is represented by no injective Ord-word and by no raw class well-order of  $\mathbf{No}$ .* This is source 18’s [example 46.33](#) (source 15’s repeated-label case, [example 46.11](#)), with its character computed.

*Source 20’s proof.* A core row cannot agree with both occurrences of  $x$ , so ordinary first-difference comparison partitions the core into initial and final sides. All codes below  $C_p$  are on the lower side and all codes above it are on the upper side. Within  $C_q$ , the side is decided by whether the next label is less or greater than  $x$ . Fresh labels on either side, followed by prefix completion, show that both parts are nonempty.

Let  $A \subseteq D_t$  be a set. The members outside  $C_q$  lie below that cylinder. For the members inside, collect their next labels, all of which are less than  $x$ . Choose a surreal  $y < x$  strictly above every collected label and outside  $\text{ran}(q)$ . Such a fresh realizer exists: the realizers of any surreal set cut form a proper class, since a set of all realizers could itself be adjoined to the lower constraints to obtain a still larger realizer. A set of forbidden labels cannot exhaust that class. Complete  $q \frown \langle y \rangle$  to a core row. It remains in  $D_t$  and lies above all of  $A$ . Thus the lower character is  $\Omega$ . The upper side is dual.

If  $\delta = \text{dom}(p)$ , the cylinder  $C_q$  straddles  $D_t$  at length  $\delta + 1$ . At length  $\delta + 2$ , every injective prefix already differs from  $t$ , and all its completions compare with  $t$  in the same direction. There is therefore no straddling cylinder of that length. Prefix recognition excludes an injective representative. The canonical initial-block description excludes a raw representative as well. Equivalently, any putative representative would be forced to begin with  $p, x, x$ , contrary to injectivity.  $\square$

*Note 97.6* (Source 20, Corollary 5.6, “Representability is extra structure”). *The strict cut of every exhaustive noncore enumeration is carried by some class automorphism of  $\mathcal{P}_{\text{bd}}(b)$  to a cut represented by no raw class well-order. Thus the bare core order does not distinguish these two kinds of cuts.* This is [corollary 47.3](#) with a repeated-label cut as target; source 15’s [theorem 47.10](#) uses a first-label cut and source 17’s [theorem 47.7](#) the cut of a nonexhaustive word.

*Source 20’s proof.* Apply [note 97.3](#) to [notes 97.4](#) and [97.5](#).  $\square$

Omitted-range injective branches also have character  $(\Omega, \Omega)$ . For a set of core rows below such a branch, Class Replacement bounds all their first-disagreement coordinates. Follow the branch beyond that bound, choose a fresh smaller next label, and complete the prefix to a core row. This improves the entire set while remaining below the branch; the upper side is dual. Consequently one orbit contains exhaustive branches, branches with residual tails, and nonbranch cuts caused by a repeated label. The prefix-recognition criterion therefore describes the order *with its specified cylinder structure*; it cannot be recovered as an invariant of the bare ordered core.

### 97.1.3 Nonextension while fixing arbitrary set data

**Theorem 97.7** (Localized failure of one-point extension). *Let  $e : \text{Ord} \rightarrow \mathbf{No}$  be an exhaustive enumeration outside  $\mathcal{P}_{\text{bd}}(b)$ , and let  $S \subseteq \mathcal{P}_{\text{bd}}(b)$  be any set. There is a class order automorphism  $\varphi$  of  $\mathcal{P}_{\text{bd}}(b)$ , fixing  $S$  pointwise, for which there is no raw class well-order  $R$  of  $\mathbf{No}$  satisfying*

$$\{d \in \mathcal{P}_{\text{bd}}(b) : E_d <_{\text{lex}} R\} = \varphi[L_e].$$

*In particular,  $\varphi$  has no order-embedding extension from the one-point enlargement  $\mathcal{P}_{\text{bd}}(b) \cup \{e\}$  into the raw comparison structure, and no automorphism extension to either  $\mathfrak{W}_{\text{sl}}$  or  $\mathfrak{W}_{\text{all}}$ .*

*Proof.* Partition  $S$  according to its comparison with  $e$ . Uniform interpolation produces core points  $a, d$  such that

$$\{s \in S : E_s < e\} < a < e < d < \{s \in S : e < E_s\}.$$

Empty outer sides are allowed. The interval  $I = (a, d)$  contains no member of  $S$ . Choose a prefix  $p$  of  $e$  extending beyond the first disagreement of  $e$  with each endpoint. Then  $C_p \subseteq I$ . Choose a fresh  $x$  and let  $D_t$  be the deleted-label cut from [note 97.5](#).

The lower and upper sides of  $L_e$  within  $I$  have no set cofinal and cointial subsets, respectively. For example, given a set on the lower side, adjoin  $a$  and interpolate below  $e$ ; this produces a larger member still in  $I$ . The upper side is dual. The construction in [note 97.5](#) produces its improving points inside  $C_q \subseteq I$ , so the two sides of  $D_t$  within  $I$  have the same characters. By [note 97.2](#), all four sides are copies of  $\mathbf{No}$ . Join isomorphisms of corresponding sides to obtain an automorphism of  $I$  carrying its first cut to its second. Extend it by the identity outside  $I$ . The resulting  $\varphi$  fixes  $S$  and satisfies  $\varphi[L_e] = D_t$ .

If a raw order  $R$  were the image of  $e$  under an order-embedding extension, then for every  $c \in \mathcal{P}_{\text{bd}}(b)$ ,

$$E_{\varphi(c)} <_{\text{lex}} R \iff E_c <_{\text{lex}} e.$$

Its strict core cut would therefore be  $D_t$ , contradicting [note 97.5](#). The same contradiction excludes the displayed cut identity directly, without constructing an encompassing object of all raw orders.  $\square$

This is stronger than the existence of a single bad automorphism. Any set of prescribed core data can be retained, and the failure can be confined to a core interval containing the cut of  $e$ . Accordingly, representedness is not an isomorphism-invariant property of the core order even after an arbitrary set of core parameters has been named. The theorem also identifies the exact limitation of set-sized partial homogeneity: extending a partial isomorphism within the core does not control its behavior at proper-class cuts.

The one-point formulation is legitimate already in GBC. Replace the additional point by one new set marker and compare it with core codes using the class parameter  $e$ . The impossibility asserts that no individual class relation  $R$  can realize its required image comparisons. No ordinary class containing all class relations, and no function whose ordinary arguments are classes, is required.

### 97.1.4 Exactly what an extension must preserve

Write  $\text{Exh}_b(L)$  for the assertion that a strict cut  $L$  is the strict core cut of an exhaustive Ord-enumeration. This is a predicate of a *class variable*, not a subset of an ordinary class of all cuts. Prefix recognition gives the following equivalent formulation using only set quantifiers with  $L$  as a class parameter:

1. at every ordinal length there is a straddling injective set prefix;

2. every surreal belongs to the range of some such prefix.

The straddling prefix at any fixed length is unique, since two disjoint convex cylinders cannot both cross an initial cut.

*Note 97.8* (Source 20, Theorem 5.8, “Extension criterion for the set-like order”). *Fix a class automorphism  $\varphi$  of  $\mathcal{P}_{\text{bd}}(b)$ . It has an extension to the set-like global comparison structure, given by one elementary transformation of each supplied class enumeration, if and only if*

$$\text{Exh}_b(L) \iff \text{Exh}_b(\varphi[L])$$

*for every strict class cut  $L$ . If the extension exists, it is unique. Here the displayed statement quantifies over class parameters; the conclusion does not assert an ordinary class function having arbitrary classes as its elements.* This is source 17’s [theorem 47.5](#), with the predicate  $\text{Exh}_b$  in place of source 17’s  $\mathcal{R}_b$ ; the two predicates agree by [theorem 45.1](#).

*Source 20’s proof.* Necessity follows by comparing the image of an enumeration with the images of all core rows, and then applying the inverse extension.

For sufficiency, supply any exhaustive enumeration  $e$  as a class parameter. Form the class cut  $\varphi[L_e]$ . By the hypothesis it has a straddling prefix at every ordinal length and its uniquely recovered word is exhaustive. Define its image  $e'$  by

$$e'(\alpha) = x \iff \begin{array}{l} \text{there is an injective prefix } p : \alpha + 1 \rightarrow \mathbf{No} \\ \text{straddling } \varphi[L_e] \text{ with } p(\alpha) = x. \end{array}$$

All quantified variables in this definition are sets. Membership in the image cut is the elementary condition

$$d \in \varphi[L_e] \iff (\exists c \in \mathcal{P}_{\text{bd}}(b)) (\varphi(c) = d \wedge E_c <_{\text{lex}} e).$$

Elementary class comprehension therefore produces  $e'$  for every supplied  $e$ , by the same formula. The prefix criterion proves that it is the unique exhaustive enumeration with that cut.

Core density gives, for distinct exhaustive enumerations,

$$e < f \iff L_e \subsetneq L_f.$$

Indeed a core row strictly between them witnesses strict inclusion. The construction consequently preserves and reflects order. At a core row it agrees with  $\varphi$ , because the strict cut below  $c$  is carried to the strict cut below  $\varphi(c)$ . The analogous construction with  $\varphi^{-1}$  gives its inverse. Finally any extension must carry  $L_e$  to  $\varphi[L_e]$ , and density makes the exhaustive representative unique.  $\square$

For one supplied noncore  $e$ , the corresponding criterion is sharper still. An image in  $\mathfrak{W}_{\text{all}}$  exists exactly when  $\varphi[L_e]$  has a straddling prefix at every ordinal length; an image in  $\mathfrak{W}_{\text{sl}}$  exists exactly when the recovered word is also surjective. For the entire raw structure, preserving these cuts alone is insufficient: several raw orders can have the same canonical initial Ord-block. An extension must additionally identify the orders of their residual fibers, with the required uniformity. This is the remaining structural question, after the unrestricted extension assertion has been refuted.

**Proposition 97.9** (Numerical relabeling moves a chosen core). *Let  $h$  be a nonidentity increasing class automorphism of  $(\mathbf{No}, <)$ . The evaluated bounded-support cores based at  $b$  and  $h \circ b$  are disjoint. In particular, no nonidentity numerical relabeling stabilizes one chosen core.*

*Proof.* If a row belonged to both cores, it would differ from each baseline on only a set of coordinates. Thus  $b$  and  $h \circ b$  would differ on a set of coordinates, and Class Replacement would imply that  $h$  moves only a set of surreal labels. If  $x < h(x)$ , then every  $y$  with  $x < y < h(x)$  satisfies  $h(y) > h(x) > y$ . The proper-class interval  $(x, h(x))$  would consist entirely of moved labels, a contradiction. If  $h(x) < x$ , every  $y \in (h(x), x)$  satisfies  $h(y) < h(x) < y$ , giving the same contradiction.  $\square$

Numerical relabeling still gives a natural isomorphism between the two different cores and a natural transformation of global enumerations. The proposition explains why it does not account for the nontrivial internal automorphisms of one fixed core.

[merge] Source 20's last paragraph before [proposition 97.9](#) calls the extension question for the whole raw structure “the remaining structural question”. Source 19's [theorem 98.5](#) answers it in an external set-sized model: a core automorphism extends to the raw order exactly when it preserves the isomorphism types of all residual fibres. Source 25 asks the elementary question about two baselines that [proposition 97.9](#) answers for relabelled ones: two cores coincide exactly when their baselines eventually agree, and are otherwise disjoint (its Question 16.6, [research question 113.170](#)).

## 97.2 Source 21: core automorphisms, a concrete obstruction to extension

The bounded-support core carries much of the local order geometry of  $\mathfrak{W}_{\text{sl}}$ , but its abstract order does not determine which of its large cuts are represented by exhaustive enumerations. This distinction gives a concrete negative answer to one of the repository's extension questions: some automorphisms of the core do not extend even to order embeddings from  $\mathfrak{W}_{\text{sl}}$  into  $\mathfrak{W}_{\text{all}}$ . We first establish a cut reconstruction lemma, then give an exact extension criterion for the set-like fragment and two successive forms of the obstruction.

### 97.2.1 The core and its cuts

Work in GBC, and fix a baseline class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . Write  $\mathcal{P}_{\text{bd}}(b)$  for the genuine class of normalized set-support codes, ordered by the lexicographic comparison of their evaluations. If  $d \in \mathcal{P}_{\text{bd}}(b)$ , write  $E_d : \text{Ord} \rightarrow \mathbf{No}$  for the corresponding global enumeration. Concretely, one can code a permutation of an ordinal, extend it by the identity, and compose with  $b$ . Normalization removes the duplicate codes obtained by adjoining an identity segment. Thus distinct points of  $\mathcal{P}_{\text{bd}}(b)$  have distinct evaluations.

The following established core properties are used below (Part IV: [lemma 19.4](#), [theorem 19.10](#), and [corollary 19.15](#)): every injective set prefix extends to an  $E_d$ ;  $\mathcal{P}_{\text{bd}}(b)$  realizes every separated cut given by two sets of its points, with empty sides allowed; and  $\mathcal{P}_{\text{bd}}(b)$  is order-dense in  $\mathfrak{W}_{\text{sl}}$ . The same density argument applies to injective Ord-words whose ranges need not be all of  $\mathbf{No}$ . In particular,  $\mathcal{P}_{\text{bd}}(b)$  is an  $\eta_{\text{Ord}}$  class order without endpoints. The class version of the back-and-forth underlying this characterization is also central to the usual uniqueness theorem for the surreal order [15].

For an injective class function  $F : \text{Ord} \rightarrow \mathbf{No}$ , define

$$L_F = \{d \in \mathcal{P}_{\text{bd}}(b) : E_d <_{\text{lex}} F\}, \quad R_F = \mathcal{P}_{\text{bd}}(b) \setminus L_F. \quad (\text{S21.*})$$

These are ordinary classes of set codes. When  $F = E_d$ , the lower class is the strict lower cut of that core point, and the upper class includes the point itself. Otherwise both sides are strict. For an injective set word  $p$ , put

$$C_p = \{d \in \mathcal{P}_{\text{bd}}(b) : p \subseteq E_d\}.$$

We say that  $C_p$  crosses a class  $L \subseteq \mathcal{P}_{\text{bd}}(b)$  if it meets both  $L$  and  $\mathcal{P}_{\text{bd}}(b) \setminus L$ .

*Note 97.10* (Source 21, Lemma 9.1, “Elementary reconstruction from a core cut”). *Let  $F : \text{Ord} \rightarrow \mathbf{No}$  be injective. For every injective set word  $p$ ,*

$$C_p \text{ crosses } L_F \iff p \subseteq F.$$

*Consequently  $F$  is recovered from  $L_F$  and  $b$  by*

$$F(\alpha) = x \iff \exists p [\text{dom}(p) = \alpha + 1, p \text{ injective}, \\ p(\alpha) = x, C_p \text{ crosses } L_F].$$

*The defining formula has only set quantifiers and the displayed class parameters. In particular, two injective Ord-words with the same core cut are equal. With [note 97.11](#) this is the represented-cut theorem [theorem 45.1](#) ([note 87.6](#)); the lemma is its uniqueness and reconstruction clause.*

*Source 21’s proof.* If  $p \not\subseteq F$ , the first discrepancy between  $p$  and  $F$  occurs before the end of  $p$ . Every evaluation extending  $p$  has the same comparison with  $F$  at that discrepancy. Thus all of  $C_p$  lies on one side of  $L_F$ .

Conversely, suppose  $p = F \upharpoonright \beta$ . Choose unused labels  $x < F(\beta) < y$ . For example, choose  $x$  below, and  $y$  above, the set  $\text{ran}(p) \cup \{F(\beta)\}$ . Extend  $p \frown \langle x \rangle$  and  $p \frown \langle y \rangle$  to core enumerations. The first is below  $F$  and the second is above it, so  $C_p$  crosses the cut. Applying this equivalence to words of length  $\alpha + 1$  proves the formula and uniqueness.  $\square$

The lemma applies equally to exhaustive and nonexhaustive words. A nonexhaustive word can therefore never induce the cut of an exhaustive one. This is a stronger statement than the mere absence of a core point at the cut. The reconstruction also works for principal core cuts: arbitrarily long prefixes still have core extensions on both sides of the represented enumeration.

*Note 97.11* (Source 21, Theorem 9.2, “Which core cuts are represented by words?”). *Let  $L \subsetneq \mathcal{P}_{\text{bd}}(b)$  be a nonempty lower class with no greatest element. Then  $L = L_F$  for some injective  $F : \text{Ord} \rightarrow \mathbf{No}$  if and only if, for every ordinal  $\alpha$ , some length- $\alpha$  prefix cylinder  $C_p$  crosses  $L$ . When this holds, the crossing prefix at each level is unique, these prefixes are coherent, and their union is the unique representing word. The word is exhaustive if and only if every surreal occurs in some crossing prefix. All these tests and the reconstruction use elementary formulas with the class parameters  $L, b$ . This is [theorem 45.1](#), proved again ([notes 46.1](#) and [87.6](#)).*

*Source 21’s proof.* Necessity follows from [note 97.10](#). For sufficiency, first observe that two distinct cylinders of the same length cannot both cross a lower class. Their fixed prefixes have a first discrepancy, so every point of one cylinder precedes every point of the other. A point outside  $L$  in the earlier cylinder and a point inside  $L$  in the later cylinder would contradict downward closure.

Thus there is a unique crossing prefix  $p_\alpha$  at each level. Every restriction of a crossing prefix also crosses, since its cylinder contains the original cylinder. Consequently  $p_\beta \upharpoonright \alpha = p_\alpha$  whenever  $\alpha < \beta$ . Define  $F(\alpha) = p_{\alpha+1}(\alpha)$ . Existence and uniqueness of these set prefixes give an elementary definition of the graph; there is no choice of a class-valued stage. Coherence shows that  $F \upharpoonright \alpha = p_\alpha$ , and therefore  $F$  is injective.

Take a core point  $E_d \neq F$ , and let  $\delta$  be their first discrepancy. If  $E_d <_{\text{lex}} F$ , then  $E_d$  precedes every point of the crossing cylinder  $C_{p_{\delta+1}}$ . That cylinder has a point in  $L$ , so downward closure gives  $d \in L$ . If  $E_d >_{\text{lex}} F$ , the cylinder has a point outside  $L$  below  $E_d$ , so  $d \notin L$ .

There remains only the possibility  $E_d = F$ . The comparisons just proved show that, if  $d \in L$ , it would be the greatest point of  $L$ . The hypothesis excludes this. Thus  $L = L_F$  also in that case. Finally,  $\text{ran}(F)$  is the union of the ranges of the crossing prefixes, which proves the exhaustivity criterion.  $\square$

The no-greatest-element hypothesis is essential for this formulation. For a core point  $E_d$ , both  $\{c : E_c <_{\text{lex}} E_d\}$  and  $\{c : E_c \leq_{\text{lex}} E_d\}$  have the same crossing cylinders at every level. Reconstruction gives  $E_d$  in both cases, but only the first is its strict lower cut. The second has greatest element  $d$ .

*Note 97.12* (Source 21, Proposition 9.3, “The first failed level of a cut”). *Let  $L$  be a proper nonempty lower class of  $\mathcal{P}_{\text{bd}}(b)$  with no greatest element. Suppose its first level with no crossing cylinder is a limit ordinal  $\lambda$ . The coherent earlier prefixes have a union  $p$  of length  $\lambda$ . If  $C_p$  lies on the upper side, then  $L$  has set cofinality exactly  $\text{cf}(\lambda)$ . If  $C_p$  lies on the lower side, the upper side has set coinitality exactly  $\text{cf}(\lambda)$ . Consequently a cut with no set-sized cofinal lower subset and no set-sized coinital upper subset (“large on both sides,” as in [definition 97.15](#)) either comes from a full injective Ord-word, or first loses its crossing cylinder at a successor level. In the latter case it is a cut between the next-label cylinders inside one fixed set prefix. This is the limit case of the first-failure classification (source 13’s [theorem 46.18](#), source 15’s [theorem 46.9](#), source 16’s [theorem 46.3](#), source 18’s [theorem 46.32](#)) with source 14’s characters ([theorem 44.1](#)).*

*Source 21’s proof.* Write  $p_\beta$  for the unique crossing prefix at level  $\beta < \lambda$ . Their restrictions agree, so their union is an injective set word  $p$ . Its cylinder is nonempty and wholly on one side. Suppose  $C_p \subseteq \mathcal{P}_{\text{bd}}(b) \setminus L$ . Choose a cofinal sequence of  $\text{cf}(\lambda)$  many levels  $\beta < \lambda$  and at each such level a code  $d_\beta \in L \cap C_{p_\beta}$ . Global choice and class replacement make these codes a set. Every  $d \in L$  must disagree with  $p$  at some position  $\delta < \lambda$ , in the smaller direction. For  $\beta > \delta$  one has  $d < d_\beta$ . Thus the chosen set is cofinal.

Conversely, for a family of fewer than  $\text{cf}(\lambda)$  codes in  $L$ , their disagreement positions with  $p$  are bounded below  $\lambda$ . A lower-side point in a later crossing cylinder is strictly above the entire family. Hence the cofinality is exactly  $\text{cf}(\lambda)$ . The other case is the order dual.

If a large cut ever fails the crossing test, it has a least failing level. Level zero crosses, and the preceding argument excludes limit levels. At a successor level  $\alpha + 1$ , the unique length- $\alpha$  cylinder still crosses, but each of its next-label cylinders lies entirely on one side. Their numeric ordering gives precisely the stated next-label cut.  $\square$

### 97.2.2 The exact extension criterion

Let  $h$  be a class automorphism of  $\mathcal{P}_{\text{bd}}(b)$ . For a class  $L \subseteq \mathcal{P}_{\text{bd}}(b)$ , its image

$$h_*L = \{h(d) : d \in L\}$$

is an ordinary class. The expression

$$\mathcal{C}_{\text{exh}} = \{L_E : E \in \mathfrak{W}_{\text{sl}}\}$$

will be used only as virtual notation for the represented exhaustive cuts. It does not assert that this collection of classes is itself a class of GBC.

*Note 97.13* (Source 21, Theorem 9.4, “Extension criterion”). *A class automorphism  $h$  of  $\mathcal{P}_{\text{bd}}(b)$  extends to an order automorphism of  $\mathfrak{W}_{\text{sl}}$  if and only if  $h_*$  carries the represented exhaustive cuts onto themselves. Explicitly, the condition is*

$$\begin{aligned} \forall E \in \mathfrak{W}_{\text{sl}} \exists F \in \mathfrak{W}_{\text{sl}} \quad L_F &= h_*L_E, \\ \forall F \in \mathfrak{W}_{\text{sl}} \exists E \in \mathfrak{W}_{\text{sl}} \quad L_F &= h_*L_E. \end{aligned}$$

*The extension is unique. The first condition alone gives an order embedding of  $\mathfrak{W}_{\text{sl}}$  into itself extending  $h$ . In the two-sorted formulation, the extension is a uniform operator on class parameters.*

*Its output is elementarily reconstructed from  $h, b, E$ ; neither ETR nor Class Choice is required.* This is source 17's [theorem 47.5](#); source 21 adds that the first condition alone gives an extending self-embedding of  $\mathfrak{M}_{\text{sl}}$ .

*Source 21's proof.* Suppose  $\Phi$  is an extending order automorphism. For  $d \in \mathcal{P}_{\text{bd}}(b)$ ,

$$E_d <_{\text{lex}} E \iff E_{h(d)} <_{\text{lex}} \Phi(E).$$

Hence  $L_{\Phi(E)} = h_*L_E$ . Surjectivity supplies the second condition. The same cut equation is necessary for an extending order embedding.

Conversely, given  $E$ , form  $h_*L_E$  by elementary comprehension and apply the formula in [note 97.10](#). The first condition asserts that the reconstructed word is an exhaustive enumeration  $F$ , and the lemma makes it unique. Thus this construction defines  $\Phi(E)$  without making a choice from a collection of class witnesses.

If  $E <_{\text{lex}} E'$ , order-density of the core gives  $L_E \subsetneq L_{E'}$ . Applying  $h$  preserves this proper inclusion, so the represented output cuts satisfy  $L_{\Phi(E)} \subsetneq L_{\Phi(E')}$ , which implies  $\Phi(E) <_{\text{lex}} \Phi(E')$ . For a core point  $E_d$ , the image of its strict lower cut is the strict lower cut of  $E_{h(d)}$ ; therefore  $\Phi(E_d) = E_{h(d)}$ . The second condition gives surjectivity. Finally, every extension must satisfy the cut equation, and reconstruction makes its value at each input unique.  $\square$

[Note 97.11](#) makes the criterion explicit in the prefix language. For each input  $E$ , the transformed lower cut  $h_*L_E$  must have a crossing cylinder at every ordinal level, and every surreal must occur in some such crossing prefix. These tests characterize an extending embedding. Applying the same tests to  $h^{-1}$  as well characterizes an extending automorphism.

*Note 97.14 (Source 21, Corollary 9.5, “Restriction to the core”). In an enlarged universe where the displayed collections are sets, restriction identifies*

$$\text{Aut}(\mathfrak{M}_{\text{sl}}; \mathcal{P}_{\text{bd}}(b)) \cong \text{Stab}_{\text{Aut}(\mathcal{P}_{\text{bd}}(b))}(\mathcal{C}_{\text{exh}}).$$

*Here  $\text{Aut}(\mathfrak{M}_{\text{sl}}; \mathcal{P}_{\text{bd}}(b))$  denotes the automorphisms carrying the core onto itself. In GBC, the same assertion is understood as the corresponding criterion for uniform operators.* This restates [theorem 47.5](#) as an identification of groups in an enlarged universe.

The criterion is exact, but it deliberately retains the represented-cut family as additional data. The next result shows that this data cannot be discarded.

### 97.2.3 Homogeneity of large cuts

**Definition 97.15.** A class cut  $(L, R)$  of  $\mathcal{P}_{\text{bd}}(b)$  is *large on both sides* if  $L, R$  are nonempty, partition  $\mathcal{P}_{\text{bd}}(b)$ , satisfy  $L < R$ , and  $L$  has no set-sized cofinal subset while  $R$  has no set-sized coinital subset.

*Note 97.16 (Source 21, Lemma 9.7, “Each side is an  $\eta_{\text{Ord}}$  order”). If  $(L, R)$  is large on both sides, both  $L$  and  $R$ , with their induced orders, are proper-class  $\eta_{\text{Ord}}$  orders without endpoints.* This is the first part of source 17's [lemma 47.6](#) (source 20's [note 97.2](#)).

*Source 21's proof.* Neither side can be a set, since it would then be its own set-sized cofinal or coinital subset. Consider set constraints  $A < B$  in  $L$ . If  $B \neq \emptyset$ , interpolate them in  $\mathcal{P}_{\text{bd}}(b)$ . The resulting point lies below an element of  $L$ , and hence belongs to  $L$ . If  $B = \emptyset$ , the set  $A$  is not cofinal in  $L$ , so some point of  $L$  lies strictly above all of  $A$ . This also handles  $A = \emptyset$ . The proof for  $R$  is dual.  $\square$

*Note 97.17* (Source 21, Theorem 9.8, “Conjugacy of large class cuts”). *Any two class cuts of  $\mathcal{P}_{\text{bd}}(b)$  that are large on both sides are carried to one another by a class automorphism of  $\mathcal{P}_{\text{bd}}(b)$ .* This is the (Ord, Ord) case of source 14’s [theorem 47.2](#) and the second part of [lemma 47.6](#).

*Source 21’s proof.* Write the cuts as  $(L_0, R_0)$  and  $(L_1, R_1)$ . By [note 97.16](#), the two left sides are proper-class  $\eta_{\text{Ord}}$  orders, as are the two right sides. Global Choice supplies set-like enumerations of these genuine classes of set codes. We give the standard back-and-forth for the left sides.

At stage  $\alpha$ , the partial isomorphism is a set. Insert the first unused point of  $L_0$ , placing its image between the images of all already mapped points below and above it. These are set constraints, so  $\eta_{\text{Ord}}$ -interpolation supplies a point. The strict inequalities make it fresh. Then perform the reverse insertion for the first unused point of  $L_1$ . A fixed global well-order selects the interpolants. At a limit stage take the union of the preceding partial maps. Since the stage is an ordinal, its history and the resulting map are sets. The union over all ordinals is an isomorphism  $L_0 \cong L_1$ .

The same construction gives  $R_0 \cong R_1$ . Join the two maps. Their domains and ranges partition the core, and the cross inequalities are preserved because the left side precedes the right side in each cut. The result is the required automorphism.

Every stage of this recursion is set-valued. Its existence is the ordinary class-parameter recursion available in GBC, rather than an application of ETR.  $\square$

*Note 97.18* (Source 21, Lemma 9.9, “Cuts induced by nonskeleton words”). *If an injective  $F : \text{Ord} \rightarrow \mathbf{No}$  is not the evaluation of any point of  $\mathcal{P}_{\text{bd}}(b)$ , the cut  $(L_F, R_F)$  is large on both sides.* This is source 17’s [proposition 46.26](#) for noncore injective words (source 20’s [note 97.4](#) for exhaustive ones).

*Source 21’s proof.* Let  $T \subseteq L_F$  be a set of core codes. For each  $d \in T$ , the first discrepancy  $\Delta(E_d, F)$  is an ordinal. Class Replacement gives an ordinal  $\beta$  strictly above all these discrepancies. Follow  $F$  up to  $\beta$ , choose a fresh label smaller than  $F(\beta)$ , and extend this set prefix to a core enumeration. The result lies below  $F$  but above every  $E_d$  with  $d \in T$ : at the first discrepancy of  $E_d$  with  $F$ , the new enumeration still agrees with  $F$ . Hence  $T$  is not cofinal in  $L_F$ .

For a set of codes in  $R_F$ , choose a fresh label larger than  $F(\beta)$  instead. This produces a point above  $F$  and below all the specified upper points. Taking empty sets of constraints shows that both sides are nonempty. The hypothesis excludes an equality case at a core point, so the upper side has no principal boundary.  $\square$

*Note 97.19* (Source 21, Theorem 9.10, “Nonextendable core automorphisms”). *There is a class automorphism of  $\mathcal{P}_{\text{bd}}(b)$  that has no extension even to an order embedding  $\mathfrak{W}_{\text{sl}} \rightarrow \mathfrak{W}_{\text{sl}}$ . Consequently the stabilizer in [note 97.14](#) is a proper subgroup of  $\text{Aut}(\mathcal{P}_{\text{bd}}(b))$ .* This is source 17’s [theorem 47.7](#), with the same pair-swapped  $E$  and the target word  $\alpha \mapsto \alpha$ ; source 21 states the failure for order embeddings  $\mathfrak{W}_{\text{sl}} \rightarrow \mathfrak{W}_{\text{sl}}$ , and source 17’s argument gives that too, since it uses only the cut equation.

*Source 21’s proof.* Define an exhaustive enumeration  $E$  by swapping every adjacent pair of positions of  $b$ :

$$E(2 \cdot \alpha) = b(2 \cdot \alpha + 1), \quad E(2 \cdot \alpha + 1) = b(2 \cdot \alpha).$$

Here ordinal multiplication has 2 on the left. The two-element blocks partition Ord, so  $E$  is a bijection. Its support is all of Ord, and therefore  $E$  is not a core evaluation.

Let  $F(\alpha) = \alpha$ , regarding each ordinal as a surreal. This word is injective but not exhaustive; for example, it omits  $-1$ . It too is not a core evaluation. By [note 97.18](#), both  $(L_E, R_E)$  and  $(L_F, R_F)$  are large on both sides. By [note 97.17](#), choose  $h \in \text{Aut}(\mathcal{P}_{\text{bd}}(b))$  with  $h_*L_E = L_F$ .

An extending order embedding  $\Phi$  would satisfy  $L_{\Phi(E)} = h_* L_E = L_F$ . The reconstruction lemma would then force  $\Phi(E) = F$  coordinate by coordinate. This is impossible, because  $\Phi(E)$  must be exhaustive and  $F$  is not.  $\square$

Thus all large class cuts lie in one orbit of the abstract core automorphism group, whereas exhaustive represented cuts form a proper part of that orbit. The distinction between exhaustive and nonexhaustive branches is not recoverable from the core order alone. This obstruction already occurs in the set-like fragment; no residual tail of an unrestricted class well-order is needed.

The result is existential and the construction uses the stated class parameters and Global Choice. It does not classify the extendable subgroup, prove parameter-free definability of the automorphism, or assert that every automorphism of  $\mathfrak{W}_{\text{sl}}$  preserves a chosen core. In a full inaccessible-universe model it becomes an ordinary set theorem: a saturated core of size  $\kappa$  has conjugate  $(\kappa, \kappa)$ -cuts, some represented by bijections of length  $\kappa$  and some represented only by nonexhaustive injective words.

#### 97.2.4 An obstruction even to extension into the unrestricted order

A nonexhaustive word can still be the initial Ord-word of an unrestricted class well-order, by placing its omitted labels afterward. To rule out extension into  $\mathfrak{W}_{\text{all}}$ , one therefore needs a cut that is not represented even by an injective Ord-word. Such a cut has a particularly simple definition.

**Proposition 97.20** (A large cut with no crossing first-level cylinder). *The class*

$$K = \{d \in \mathcal{P}_{\text{bd}}(b) : E_d(0) < 0\}$$

*is a proper lower cut, large on both sides, and no one-letter prefix cylinder crosses it. Consequently  $K \neq L_F$  for every injective  $F : \text{Ord} \rightarrow \mathbf{No}$ .*

*Proof.* Lexicographic comparison makes  $K$  a lower class. A completion of  $\langle -1 \rangle$  belongs to it, and a completion of  $\langle 0 \rangle$  does not, so the cut is nonempty and proper.

Let  $A \subseteq K$  be a set of codes. The set of first entries  $\{E_d(0) : d \in A\}$  lies strictly below 0. Surreal set-cut interpolation gives a label  $z$  strictly above all those entries and strictly below 0. A core completion of  $\langle z \rangle$  lies in  $K$  above every point of  $A$ . Thus no set is cofinal in the lower side.

Now let  $B \subseteq \mathcal{P}_{\text{bd}}(b) \setminus K$  be a set. Form the set

$$U = \{E_d(1) : d \in B, E_d(0) = 0\}.$$

Choose  $x$  below every element of  $U \cup \{0\}$ , and complete the injective prefix  $\langle 0, x \rangle$  to a core point. It lies in the upper side. It precedes every row in  $B$  starting with a positive label by comparison at position 0, and every row in  $B$  starting with 0 by comparison at position 1. Hence no set is coinital in the upper side.

For any one-letter prefix  $\langle a \rangle$ , its entire cylinder lies in  $K$  if  $a < 0$ , and its entire cylinder lies outside  $K$  if  $a \geq 0$ . None crosses. The final assertion follows already from [note 97.10](#) at level 1.  $\square$

*Note 97.21* (Source 21, Theorem 9.12, “No extension even from  $\mathfrak{W}_{\text{sl}}$  into  $\mathfrak{W}_{\text{all}}$ ”). *There is a class automorphism  $h$  of  $\mathcal{P}_{\text{bd}}(b)$  with no extending order embedding  $\mathfrak{W}_{\text{sl}} \rightarrow \mathfrak{W}_{\text{all}}$ . In particular it has no extending order embedding  $\mathfrak{W}_{\text{all}} \rightarrow \mathfrak{W}_{\text{all}}$ .* This follows from source 14’s [corollary 47.3](#), whose target is a cylinder edge, the trace of no unrestricted class well-order; source 15’s [theorem 47.10](#) uses a first-label cut  $\{d : E_d(0) \in A\}$  with  $A \cong \mathbf{No}$ , of which [proposition 97.20](#) is the case  $A = \{x : x < 0\}$ .

*Source 21's proof.* Choose the exhaustive adjacent-pair-swap enumeration  $E$  used in [note 97.19](#). Its core cut is large by [note 97.18](#). The cut  $K$  of [proposition 97.20](#) is also large, so [note 97.17](#) gives a core automorphism  $h$  with  $h_*L_E = K$ .

Suppose  $\Phi : \mathfrak{W}_{\text{sl}} \rightarrow \mathfrak{W}_{\text{all}}$  were an extending order embedding. For every core code  $d$ , order preservation gives

$$E_d <_{\text{lex}} E \iff E_{h(d)} <_{\text{lex}} \Phi(E).$$

Thus the unrestricted class well-order  $\Phi(E)$  would induce exactly the cut  $K$  on the core. By [note 86.15](#), every unrestricted class well-order induces the same core cut as its canonical initial injective Ord-word. This contradicts [proposition 97.20](#). An extending embedding on all of  $\mathfrak{W}_{\text{all}}$  would restrict to one on  $\mathfrak{W}_{\text{sl}}$ , so it too is impossible.  $\square$

The two obstructions locate different boundaries. The cut of a nonexhaustive word fails the exhaustivity test in [note 97.11](#), but does have crossing cylinders at every ordinal level. The cut  $K$  fails already at the first level. The latter failure cannot be repaired by adding a residual tail to a class well-order. These examples do not say that every large cut is unrepresented:  $L_E$  itself is a large represented cut.

For the unrestricted order, preservation of initial-word cuts is a necessary extension condition. A sufficient general extension theorem would also have to control the residual fibers that those cuts do not distinguish. The exact set-like criterion in [note 97.13](#) avoids that additional issue because the core cut uniquely determines an exhaustive enumeration.

## 98 Residual data and the completion of the raw order (source 19)

[merge] Source 19's Sections 9–11, printed whole. The inherited facts it starts from, display (S19.14), are [proposition 15.3](#) for the fibres and the uniqueness clause of [theorem 45.1](#) with [corollary 46.4](#) and source 14's [theorem 54.6](#) (Part IX) for the kernel of the trace map. [Theorem 98.2](#) answers source 15's question "Completion with residual data" ([research question 113.50](#)) in an external set-sized formulation, and [theorem 98.5](#) source 15's "Automorphism extension" ([research question 113.51](#)), source 14's "Automorphisms of raw trace fibers" ([research question 113.39](#)), source 20's [research question 113.108](#) and source 21's [research question 113.120](#) in the same formulation. Source 19's [lemma 98.3](#) is the class version of source 21's set-level endpoint lemma ([lemma 65.7](#), Part X).

The first-block theorem does more than exhibit an obstruction to a naive completion: it specifies the data that a faithful completion must retain. We first recall the established fiber statement, then derive an exact reconstruction at a size level where all the objects involved are sets. The resulting description is exact, although computing the order types of all residual fibers remains a separate problem.

Fix a baseline bijection  $b : \text{Ord} \rightarrow \mathbf{No}$  and its class  $\mathcal{P}_{\text{bd}}(b)$  of normalized bounded-support permutation codes. Write  $E_c$  for the enumeration evaluated from  $c \in \mathcal{P}_{\text{bd}}(b)$ . For a raw class well-order  $R$ , let  $F_R : \text{Ord} \rightarrow \mathbf{No}$  enumerate its initial set-like part, and put

$$B_R = \mathbf{No} \setminus \text{ran}(F_R), \quad t(R) = \{c \in \mathcal{P}_{\text{bd}}(b) : E_c <_{\text{lex}} R\}.$$

The previously proved first-block and represented-cut theorems give

$$t(R) = t(S) \iff F_R = F_S, \quad t^{-1}(t(R)) \cong \mathcal{W}(B_R). \quad (\text{S19.14})$$

These are inherited results. Their second isomorphism is restriction to the residual alphabet; its inverse appends a residual well-order after the fixed word  $F_R$ . The fibers are convex. Distinct initial

words are separated by a core row: at their first ordinal disagreement their common prefix is a set, so a fresh numerical surreal can be inserted strictly between the two unequal labels and the resulting prefix completed to a core enumeration.

An exhaustive initial word has a singleton fiber, as does a word omitting one label. A word omitting  $n$  labels has a finite fiber with  $n!$  points. Only the exhaustive word in the first two cases is set-like. Moreover a principal core cut  $\mathcal{P}_{\text{bd}}(b)_{<c}$  has exactly the representative  $E_c$ , because that enumeration is exhaustive.

### 98.1 An external set-sized formulation

Fix an externally set-sized two-sorted model  $\mathcal{M} = (M, \mathcal{S})$  of GBC. The baseline is an admitted class of this model. Let  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  be the external set of its admitted raw class well-orders, and interpret  $\mathcal{P}_{\text{bd}}(b)$  externally as the set of its core codes. All comparisons are those computed in  $\mathcal{M}$ . No transitivity,  $\omega$ -standardness, or  $\beta$ -model assumption is needed in this subsection. Internal linearity and the internal density and absence of endpoints of  $\mathcal{P}_{\text{bd}}(b)$  yield actual external statements about these interpreted orders.

For a residual carrier  $B$ , the notation  $\mathcal{W}^{\mathcal{S}}(B)$  means the external set of admitted relations satisfying the model's class-well-order predicate. It need not be the collection of all externally well-founded relations on the external carrier. This distinction permits the theorem to cover nonstandard models without an implicit absoluteness assumption.

Let  $\mathcal{Q} = \text{DC}(\mathcal{P}_{\text{bd}}(b))$  be the ordinary external Dedekind completion of the dense order  $\mathcal{P}_{\text{bd}}(b)$ . Concretely its points are all external subsets  $q \subseteq \mathcal{P}_{\text{bd}}(b)$  which are nonempty, proper, initial, and have no greatest member, ordered by inclusion. A core point  $c$  is identified with  $\mathcal{P}_{\text{bd}}(b)_{<c}$ . Thus  $\mathcal{Q}$  is conditionally complete, has no endpoints, and contains  $\mathcal{P}_{\text{bd}}(b)$  densely. For  $q \in \mathcal{Q}$  set

$$H_q = \{R \in \mathfrak{W}_{\text{all}}^{\mathcal{M}} : t(R) = q\}.$$

Each  $H_q$  is empty or is a convex copy of  $\mathcal{W}^{\mathcal{S}}(B_q)$  for the uniquely recovered initial word. Different nonempty fibers compare exactly as their indices in  $\mathcal{Q}$ . In particular, this gives a lexicographic-sum description of  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  over its represented core cuts.

**Definition 98.1** (Completion convention for a nondense order). For a nonempty external linear order  $L$ , let  $\text{DC}(L)$  retain every old point and adjoin one point for each proper unfilled Dedekind gap

$$L = A \sqcup B, \quad A < B, \quad A, B \neq \emptyset, \quad A \text{ has no greatest point, } B \text{ has no least point.}$$

Let  $\text{IC}(L)$  additionally acquire a least point if  $L$  had none and a greatest point if  $L$  had none. Then  $\text{IC}(L)$  is a complete bounded chain. Existing adjacent pairs are retained; they are not split by new points.

Taking all downsets of a nondense order would not enforce this convention: it can separate distinctions which are already realized by an old point or an adjacent pair. The convention above is the gap-filling Dedekind completion relevant to the raw well-order space.

**Theorem 98.2** (Reconstruction by completed residual fibers). *For each  $q \in \mathcal{Q}$  define*

$$K_q = \begin{cases} \{*_q\}, & H_q = \emptyset, \\ \text{IC}(H_q), & H_q \neq \emptyset. \end{cases} \quad K = \sum_{q \in \mathcal{Q}} K_q,$$

where the sum is lexicographic. Embed  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  by retaining each of its points in its own fiber. Then  $K$  is canonically its Dedekind completion  $\text{DC}(\mathfrak{W}_{\text{all}}^{\mathcal{M}})$  relative to this embedding. Every old adjacent pair remains adjacent. For any  $x < y$  in  $K$ , either an old raw order lies strictly between them, or  $x, y$  themselves are an adjacent pair of old raw orders.

*Proof.* Convexity and the comparison of different fibers make the displayed map an order embedding. To prove conditional completeness, let  $A \subseteq K$  be nonempty and bounded above, let  $P$  be its projection to  $\mathcal{Q}$ , and put  $q_0 = \sup P$ . If  $q_0 \notin P$ , then

$$\sup A = (q_0, \min K_{q_0}).$$

Every member of  $A$  has smaller first coordinate, and any candidate with smaller coordinate is exceeded by a member of  $A$  by the definition of  $q_0$ . If  $q_0 \in P$ , the nonempty section  $A_{q_0}$  has a supremum  $z$  in the bounded complete chain  $K_{q_0}$ , and

$$\sup A = (q_0, z).$$

These arguments also establish minimality of the proposed upper bound. Infima are dual. The sum has no endpoints because  $\mathcal{Q}$  has none.

If  $x < y$  have different first coordinates  $q < r$ , choose a core index strictly between  $q$  and  $r$ . Its original core point lies strictly between  $x$  and  $y$ . If they belong to the same fiber, the ordinary interval-completion property supplies an old fiber point between them unless they are adjacent old points. Adding a missing fiber endpoint does not create adjacency, since the original fiber had no endpoint on that side.

It remains to check that the new points represent exactly old unfilled gaps. An internal gap point of  $\text{IC}(H_q)$  has old fiber points cofinal below and coinital above. An added lower endpoint has old fiber points coinital above, while core points with smaller indices are cofinal below; an added upper endpoint is dual. If  $H_q$  is empty, core points on either side of  $q$  approach the new singleton from both sides. Thus every new point has no greatest old predecessor and no least old successor. Conversely conditional completeness supplies a point in every old proper unfilled gap. Exactly the required gap points have therefore been added, giving the canonical completion isomorphism.  $\square$

The interval endpoints in this theorem are essential. For example, suppose  $H_q$  has no least point. Core points with indices below  $q$  must have a supremum in the full completion. Their supremum is the new lower endpoint of the completed fiber, not an arbitrarily selected residual well-order. The analogous statement holds at the upper endpoint.

## 98.2 Which boundary points are already present?

**Lemma 98.3** (Extrema of the residual well-order space). *Let  $B$  be an admitted linearly ordered carrier with  $\mathcal{W}^S(B) \neq \emptyset$ . This external well-order space has a least point if and only if the numerical order on  $B$  is itself an admitted class well-order. In that case this numerical order is the least point. It has a greatest point if and only if the reverse numerical order is an admitted class well-order, in which case that reverse order is the greatest point.*

*Proof.* Suppose  $R$  is least. If  $a < b$  numerically but  $b$  precedes  $a$  in  $R$ , conjugate  $R$  by the transposition interchanging these labels. This gives an admitted well-order which agrees with  $R$  before the old position of  $b$  and then has the smaller label  $a$ . It is smaller in the raw lexicographic comparison, a contradiction. Therefore  $R$  agrees with numerical order on every pair, so that order is an admitted well-order. Conversely, the numerical well-order always selects the least remaining numerical label. At its first disagreement with any other well-order it is therefore smaller. Reverse the comparisons for the greatest-point assertion.  $\square$

Consequently the lower boundary of a represented completed fiber is new exactly when its numerical residual alphabet is not a class well-order; the upper boundary is new exactly when the reverse numerical order fails to be a class well-order. These tests use the model's admitted predicate, while their conclusions concern actual external endpoints.

The empty, one-point, and standard finite residual cases require no boundary additions. An internally infinite residual numerical well-order has an old minimum and acquires a new upper endpoint; a reverse well-order acquires a new lower endpoint. When neither direction is a class well-order, both boundaries are added. Both directions can be class well-orders only when the carrier is internally finite: an infinite carrier would yield, by successive least-element selection, an  $\omega$ -sequence increasing in one direction and decreasing in the other. Without  $\omega$ -standardness, internal finiteness must not be silently replaced by external finiteness.

**Proposition 98.4** (Exactly which suborders embed into the core completion). *Let  $H' \subseteq \mathfrak{W}_{\text{all}}^{\mathcal{M}}$  contain the core. It has an order embedding into  $\mathcal{Q}$  fixing the specified core embedding if and only if it meets each  $H_q$  in at most one point. In that case the embedding is the trace map and is unique.*

*Proof.* A point of the dense completion  $\mathcal{Q}$  is uniquely determined by its comparisons with the core. Hence two raw points with the same trace cannot have distinct images. Conversely the trace map is an order embedding whenever it is injective, because different fibers compare by their cuts. These facts also prove uniqueness.  $\square$

Choosing one representative from each represented cut therefore gives a suborder whose completion is  $\mathcal{Q}$ . Appending the restriction of the baseline to each residual alphabet supplies a parameterwise selector. This is an ordinary external selector here; internally it does not form a class whose elements are arbitrary classes.

### 98.3 Automorphisms and the required decorations

For  $g \in \text{Aut}(\mathcal{P}_{\text{bd}}(b))$  let  $\bar{g} \in \text{Aut}(\mathcal{Q})$  be its unique extension, given on cuts by  $\bar{g}(q) = g[q]$ . Decorate each  $q$  by the order type of  $H_q$ , with the empty fiber counted as a separate decoration. Let  $G$  be the subgroup of core automorphisms preserving these decorations.

**Theorem 98.5** (The exact extension criterion). *A core automorphism  $g$  extends to an automorphism of  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  if and only if  $g \in G$ , equivalently if*

$$H_q \cong H_{\bar{g}(q)} \quad (q \in \mathcal{Q}).$$

Writing  $\text{Aut}(\mathfrak{W}_{\text{all}}^{\mathcal{M}}; \mathcal{P}_{\text{bd}}(b))$  for automorphisms preserving the core setwise, there is a short exact sequence

$$1 \longrightarrow \prod_{H_q \neq \emptyset} \text{Aut}(H_q) \longrightarrow \text{Aut}(\mathfrak{W}_{\text{all}}^{\mathcal{M}}; \mathcal{P}_{\text{bd}}(b)) \longrightarrow G \longrightarrow 1.$$

In the external set setting this sequence splits noncanonically. Every such raw-order automorphism extends uniquely to its Dedekind completion from [Theorem 98.2](#).

*Proof.* If  $h$  extends  $g$ , comparison with each core point gives

$$t(h(R)) = g[t(R)].$$

Thus  $h$  maps  $H_q$  isomorphically onto  $H_{\bar{g}(q)}$ , proving necessity. Conversely, ordinary external Choice selects isomorphisms between the corresponding nonempty fibers. Their union is an automorphism

of the lexicographic sum. At principal core cuts the maps are forced singleton maps, so the union restricts to  $g$ .

An automorphism fixing the core pointwise fixes every trace and hence acts independently within its fibers; every such independent family does give an automorphism. This identifies the kernel and proves exactness. To obtain a noncanonical splitting, choose one representative chain  $L_d$  for every occurring nonempty fiber order type and fixed isomorphisms  $\phi_q : H_q \rightarrow L_d$ . Lift  $g \in G$  on  $H_q$  by

$$\phi_{\bar{g}(q)}^{-1} \circ \phi_q.$$

The intermediate identifications cancel under composition, so these lifts form a homomorphic section. No canonical choice of the  $\phi_q$  is asserted. Extension to the completion is the usual unique extension of an automorphism to its filled Dedekind gaps.  $\square$

Merely preserving which cuts are represented is therefore weaker than the required criterion. The entire residual fiber type, including its adjacencies and endpoint behavior, is the necessary decoration. The external Choice used to select fiber isomorphisms is ordinary set Choice; the theorem does not infer an internal higher-order choice principle.

## 99 Why residual classification is not automatically self-similar (source 19)

[merge] Over **No** itself the trace of an injective word is injective ([theorem 45.1](#)); source 14's trace-fibre theorem ([theorem 54.6](#), Part IX) is that case. Over a general residual alphabet the next statements show that two initial words can share a trace, never three. Source 19 writes  $\mathcal{C}_X$  for a core of exhaustive enumerations of a proper linearly ordered class  $X$ ; it is not the core of **No**.

The initial-word theorem is exact, but an iteration must retain the numerical residual alphabet. Deleting a set from **No** preserves fresh separators. Deleting the entire proper range of an Ord-word need not do so. We can, however, describe the possible failure quite sharply. Work parameterwise in GBC, or with admitted words in one fixed class realization. For a proper linearly ordered class  $X$ , choose a core  $\mathcal{C}_X$  of exhaustive Ord-enumerations such that every injective set prefix has a core completion. A bounded-support core of a fixed baseline has this property. Write  $\tau_X(U)$  for the strict lower trace of an injective admitted Ord-word  $U$  on this core; the trace need not be a normalized cut for a general alphabet.

**Lemma 99.1** (Exact criterion for an unseparated pair). *Suppose  $U < V$  first differ at  $\alpha$ , with common prefix  $p$  and next labels  $a < b$ . There is no core enumeration strictly between  $U$  and  $V$  if and only if all three conditions hold:*

1. *No label of  $X \setminus \text{ran}(p)$  lies strictly between  $a$  and  $b$ .*
2. *For every  $\beta > \alpha$ ,  $U(\beta)$  is the greatest label of  $X \setminus \text{ran}(U \upharpoonright \beta)$ .*
3. *For every  $\beta > \alpha$ ,  $V(\beta)$  is the least label of  $X \setminus \text{ran}(V \upharpoonright \beta)$ .*

*When these hold, neither word is exhaustive, no injective admitted Ord-word lies strictly between them, and  $\tau_X(U) = \tau_X(V)$ . Thus they also characterize equality of the two strict lower traces.*

*Proof.* A label between  $a$  and  $b$ , appended to  $p$ , gives a core separator. If  $U$  later chooses a label below some unused label, complete its prefix through that larger alternative. The result exceeds  $U$  but remains below  $V$  because its label at  $\alpha$  is still  $a$ . A later failure to choose the least unused label in  $V$  gives the dual separator. This proves necessity.

Conversely a word strictly between them must share  $p$  and at  $\alpha$  select  $a$ ,  $b$ , or an intermediate label. The third option is excluded. A word selecting  $a$  is at most  $U$ , since  $U$  selects the greatest unused label at every later stage. A word selecting  $b$  is at least  $V$ . This proves the stronger absence of any injective admitted word strictly between them.

To handle the strict-trace endpoint issue, suppose  $U$  were exhaustive. Its tail after  $a$  would then be the reverse numerical class well-order of  $X \setminus (\text{ran}(p) \cup \{a\})$ . The later tail of  $V$  is numerically strictly increasing and has proper range. Start beyond the possible occurrence of  $a$  and take  $V(\beta_0 + n)$  for  $n \in \omega$ . Class Replacement makes this an available set sequence, descending in the reverse numerical well-order, a contradiction. The dual argument excludes exhaustive  $V$ . Consequently neither word equals a core enumeration. Absence of a strict core separator is therefore exactly equality of their strict lower traces.  $\square$

**Proposition 99.2** (At most two initial words over an arbitrary residual cut). *There cannot be three distinct admitted injective Ord-words over  $X$  with the same core trace. In an external interpretation, each nonempty raw trace fiber is therefore either*

$$\mathcal{W}^S(B_U) \quad \text{or} \quad \mathcal{W}^S(B_U) + \mathcal{W}^S(B_V),$$

where the two-word case is the ordered pair described in [Lemma 99.1](#). Residual well-order completions are supplied by GBC. This assertion is independent of the baseline among cores having the stated prefix-completion property.

*Proof.* For three words with equal trace, apply [Lemma 99.1](#) to the outer pair. The middle word contradicts its absence of intervening injective words. For raw orders the trace is the trace of their initial word, and the orders with one fixed initial word form exactly its residual well-order space. Distinct initial-word fibers compare in the order of their words. These facts give the displayed possibilities. The criterion mentions only the numerical alphabet and the two words, which proves baseline independence.  $\square$

**Proposition 99.3** (An alphabet criterion for failure of core separation). *Keep the hypotheses above:  $X$  is a proper linearly ordered class, all words and class isomorphisms are admitted in the fixed realization, and every injective set prefix extends to an exhaustive row of  $\mathcal{C}_X$ . The following are equivalent:*

1. *Two distinct admitted injective Ord-words over  $X$  have the same strict lower trace on  $\mathcal{C}_X$ .*
2. *For some set  $S \subseteq X$ , the numerical order of  $X \setminus S$  has an admitted initial segment of type Ord and an admitted final segment of type Ord\*, with admitted class isomorphisms witnessing these types.*

*Consequently all distinct admitted injective words are separated by a core row exactly when no such set deletion exists.*

*Proof.* For the first implication, let  $U < V$  be a pair from [Lemma 99.1](#), with common set prefix  $p$  and unequal labels  $a < b$ . Delete  $S = \text{ran}(p) \cup \{a, b\}$ . The range of the later greedy-minimum tail of  $V$ , with  $a$  removed if present, is an initial numerical segment of  $X \setminus S$  of type Ord. Indeed any smaller residual label must have been selected earlier in that tail. Removing at most one label preserves its proper, set-like well-order type. Dually the later greedy-maximum range of  $U$ , with  $b$  removed if present, is a final segment of type Ord\*. These ranges and their canonical enumerations are admitted class constructions from  $U, V, p$ .

Conversely let  $J$  be the initial Ord-segment and  $K$  the final Ord\*-segment of  $Y = X \setminus S$ . They are disjoint: a common point would place an increasing  $\omega$ -sequence from the remaining tail of  $J$

inside  $K$ , contradicting the well-ordering of  $K$  in the reverse numerical direction. Well-order  $S$  as a common set prefix  $p$ , and let  $a < b$  be the first two labels of  $J$ . They are consecutive in  $Y$ . After  $p$ , form  $U$  by choosing  $a$  and then enumerating  $K$  downward; form  $V$  by choosing  $b$  and then enumerating  $J \setminus \{b\}$  upward. Each concatenation has type  $\text{Ord}$  and is an admitted injective word. The first tail always selects the greatest unused label because  $K$  is final; the second always selects the least because  $J \setminus \{b\}$  is initial in  $Y \setminus \{b\}$ . [Lemma 99.1](#) therefore gives equal strict core traces.  $\square$

The following example realizes the two-word obstruction even if the comparison core is enlarged to all exhaustive set-like enumerations.

For  $\alpha \in \text{Ord}$  put

$$\ell_\alpha = 1 - \frac{1}{\alpha + 2}, \quad r_\alpha = 2 + \frac{1}{\alpha + 2}, \quad Y = \{\ell_\alpha : \alpha \in \text{Ord}\} \cup \{r_\alpha : \alpha \in \text{Ord}\}.$$

Here  $\alpha$  is viewed as its ordinal surreal, and every displayed arithmetic operation is a surreal field operation. The left labels increase in type  $\text{Ord}$  inside  $[1/2, 1)$ ; the right labels decrease in type  $\text{Ord}^*$  inside  $(2, 5/2]$ . Every left label lies below every right label, so the numerical order of  $Y$  has type  $\text{Ord} + \text{Ord}^*$ .

**Proposition 99.4** (Different initial words with the same residual core cut). *There are injective  $\text{Ord}$ -words  $U < V$  over  $Y$  with different ranges whose strict lower traces on all admitted exhaustive set-like enumerations of  $Y$  coincide. Each word is the initial word of a raw well-order of  $Y$ . Moreover  $Y$  occurs as a residual alphabet after one proper initial block in a raw well-order of  $\mathbf{No}$ .*

*Proof.* Take

$$U = (\ell_0, r_0, r_1, r_2, \dots), \quad V = (\ell_1, \ell_0, \ell_2, \ell_3, \dots).$$

The first expression means the unique  $\text{Ord}$ -collapse of the order consisting of  $\ell_0$  followed by the  $r_\alpha$  sequence; this is valid because  $1 + \text{Ord}$  has type  $\text{Ord}$ . The second expression is the increasing left sequence with its first two labels transposed. Both words omit proper subclasses of  $Y$ , and  $U < V$  at the first label.

Let  $E : \text{Ord} \rightarrow Y$  be any admitted exhaustive set-like enumeration. If  $E(0) = \ell_0$ , then  $E \neq U$  since  $U$  omits every  $\ell_\alpha$  with  $\alpha \geq 2$  (and also  $\ell_1$ ). At their first later disagreement,  $U$  chooses the greatest still-unused numerical label: it is sweeping the right block downward from its maximum. Consequently  $E < U$ .

If  $E(0) = \ell_1$ , then  $E \neq V$  since  $V$  omits the right block. At their first later disagreement,  $V$  chooses the least still-unused numerical label, so  $E > V$ . If  $E(0) > \ell_1$ , that inequality holds immediately. There is no label below  $\ell_0$  or strictly between  $\ell_0$  and  $\ell_1$ . Therefore

$$\{E : E <_{\text{lex}} U\} = \{E : E(0) = \ell_0\} = \{E : E <_{\text{lex}} V\},$$

where  $E$  ranges over exhaustive set-like enumerations. Appending an admitted residual well-order to either word gives its raw completion, with that word as initial set-like block.

Finally  $\mathbf{No} \setminus Y$  is proper: it contains all negative ordinals. Restricting the baseline and collapsing the resulting set-like order gives a bijection  $F : \text{Ord} \rightarrow \mathbf{No} \setminus Y$ . Its raw completions have residual alphabet exactly  $Y$ .  $\square$

**Proposition 99.5** (An explicit interior completion point). *In an external set-sized interpretation of the preceding example, the shared raw trace fiber of  $U, V$  is exactly*

$$\mathcal{W}^S(\{\ell_\alpha : \alpha \geq 1\}) + \mathcal{W}^S(\{r_\alpha : \alpha \in \text{Ord}\}).$$

*The junction between these summands is a proper unfilled Dedekind gap of  $\mathcal{W}^S(Y)$ . It supplies an interior new point of the completed residual fiber, in addition to any points added at its outer boundaries.*

*Proof.* The two residual alphabets are exactly the labels omitted by  $U$  and  $V$ , respectively. [Proposition 99.2](#) excludes a third initial word with their trace, so their raw trace fiber is the displayed convex sum. The first alphabet is numerically of type  $\text{Ord}$ , and the second of type  $\text{Ord}^*$ . By [Lemma 98.3](#), the first summand has no greatest point and the second has no least point.

The downward closure of the first summand and the upward closure of the second partition the full raw order of  $Y$ : the two summands together form a convex trace fiber, and there is no further raw point between them. The first closure has no greatest point and the second no least point, giving the claimed unfilled gap. Its completion point has raw orders on both sides. Since  $Y$  is realized as a residual alphabet of  $\mathbf{No}$ , the point also occurs inside the interval completion of an actual raw surreal-order fiber in [Theorem 98.2](#).  $\square$

Thus the original surreal theorem cannot simply be reapplied inside every residual fiber. On this residual alphabet, equality of traces on its own set-like core merges different initial  $\text{Ord}$ -words. The merger is limited to two words by [Proposition 99.2](#), but its two residual well-order spaces must both be retained. A recursive theory must preserve this prefix-and-alphabet structure; the set/proper-class distinction alone is insufficient to make the process self-similar.

## 100 Persistent external cuts absent from the class realization (source 19)

The full external completion in [Theorem 98.2](#) uses all external cuts of the core, whereas the internal represented-cut theorem takes an admitted cut as a class parameter. This is a strict distinction in every externally countable model, even for cuts whose every internally bounded prefix exists.

**Theorem 100.1** (Continuum many omitted amenable branches). *Let  $\mathcal{M} = (M, \mathcal{S})$  be any externally countable two-sorted model of GBC. Its external core completion contains  $2^{\aleph_0}$  distinct cuts which have an internally set-coded straddling prefix at every internal ordinal but are represented by no admitted raw class well-order. These cuts can be induced by external exhaustive bijections*

$$F : \text{Ord}^{\mathcal{M}} \longrightarrow \mathbf{No}^{\mathcal{M}}$$

*whose restriction to every internal ordinal is coded by a set of  $M$ . No  $\omega$ -standardness assumption is required.*

*Proof.* Externally enumerate all admitted subclasses of  $\text{Ord}$  as  $A_0, A_1, \dots$ , and enumerate all internal ordinals as  $\delta_0, \delta_1, \dots$ . Set  $\gamma_0 = 0$ . At stage  $n$  put

$$\eta_n = \max^{\mathcal{M}}(\gamma_n, \delta_n), \quad \gamma_{n+1} = \eta_n + 2.$$

These lengths are independent of the following free choices and are externally cofinal in the interpreted ordinal order.

For an external binary sequence  $s \in 2^\omega$ , build coherent internally set-coded binary functions  $p_n : \gamma_n \rightarrow \{0, 1\}$ . Start with the empty function. Extend  $p_n$  by zeros on  $[\gamma_n, \eta_n)$ , and set

$$p_{n+1}(\eta_n) = 1 - \mathbf{1}_{A_n}(\eta_n), \quad p_{n+1}(\eta_n + 1) = s(n).$$

Each step is a finitely specified internal set construction. Their coherent external union defines the characteristic function of an external subclass  $A_s \subseteq \text{Ord}^M$ . For every internal ordinal  $\alpha$ , choose  $n$  with  $\alpha \leq^M \gamma_n$ ; its restriction to  $\alpha$  is then the internal set  $p_n \upharpoonright \alpha$ . This is the claimed amenability to internally bounded initial segments. At  $\eta_n$  it differs from  $A_n$ , so  $A_s$  is not admitted. Distinct  $s$  give distinct classes at the free coordinates  $\eta_n + 1$ .

Use the internal partition of the ordinals into pairs  $(2 \cdot \alpha, 2 \cdot \alpha + 1)$ , with ordinal left multiplication by 2. In the baseline  $b$ , swap the two values of a pair exactly when  $\alpha \in A_s$ . This defines an external exhaustive bijection  $F_s : \text{Ord}^M \rightarrow \mathbf{No}^M$ : the coordinate permutation is an involution on disjoint pairs. Every internally bounded initial restriction is coded in  $M$ , because it uses only an internally bounded restriction of  $A_s$  and of the admitted baseline. If  $F_s$  were admitted, elementary class comprehension from it and  $b$  would recover  $A_s$ , a contradiction.

Although the model's ordinals may be externally ill-founded,  $F_s$  and an admitted core row  $E_c$  have a least disagreement. They cannot be equal, since  $F_s$  is not admitted. Choose one disagreement  $\delta$ . Both restrictions through  $\delta + 1$  are coded internal sets, so their nonempty disagreement subset has an internally least member. Every earlier internal ordinal lies in that restriction; hence this is also their least disagreement in the external interpreted ordinal order.

Define

$$q_s = \{c \in \mathcal{P}_{\text{bd}}(b) : E_c <_{\text{lex}} F_s\}.$$

First-difference comparison makes  $q_s$  initial. Fresh labels and core completion make it nonempty, proper, and without a greatest member. For any internal ordinal  $\alpha$ , the prefix  $F_s \upharpoonright \alpha$  is coded in  $M$ . Complete it once with a fresh label below  $F_s(\alpha)$  and once with a fresh label above. The two core points lie on opposite sides of  $q_s$  in its prefix cylinder. Thus its prefix criterion persists at every internal ordinal.

Suppose an admitted raw order  $R$  represented  $q_s$ . Its admitted initial word  $F_R$  cannot equal  $F_s$ . Their least disagreement exists by the same bounded-restriction argument. A fresh core separator strictly between the two unequal labels, after their common set prefix, distinguishes their lower core cuts. This contradicts  $t(R) = q_s$ . Thus  $q_s$  has empty raw fiber. It cannot itself be an admitted class cut, since the internal persistent-prefix theorem would then assemble an admitted representing word.

Finally, distinct free-bit paths give different  $F_s$ . Their least disagreement exists by the same argument, and a core separator makes their cuts distinct. There are  $2^{\aleph_0}$  paths, proving the claim.  $\square$

These missing cuts are not terminal cuts of the internal first-failure classification. Their crossing prefixes persist throughout the model's ordinal range; the obstruction is that their coherent global branch is absent from the class realization. Their singleton fibers in the external completion are therefore an additional, explicitly exhibited source of completion points.

Here amenability means that internally bounded restrictions, and hence intersections with internal sets of ordinals, are coded in the model. It does not assert that adjoining  $A_s$  or  $F_s$  to the class realization preserves GBC, Class Replacement, or the relevant comprehension closure.

## 101 The exact least ordinal support bound (source 27)

[merge] Source 27's Section 8, printed whole. Its first subsection re-derives source 17's exact reserve cardinal ([theorem 49.7](#); display (S27.13) is (S17.7)), which it credits, and is printed as text. Its [theorem 101.2](#) answers the ordinal half of source 17's question "Ordinal and birthday optima for supported completion" ([research question 113.78](#)) and Part VIII's "Ordinal support bounds ...

remain open” (section 50 (f)); birthday bounds and the forced-prefix length remain open (section 105). Its first example extends source 17’s example 49.8.

Completing a set prefix to a global enumeration is a recurring step in the preceding constructions. A generic proof takes a sufficiently large cardinal block and completes a partial permutation there. The repository has already optimized the *number* of additional moved positions (theorem 49.7). We now optimize their *ordinal location*. A support of two very high ordinals is small in cardinality and large in height, so these are genuinely different problems.

### 101.1 Forced motion and the cardinal reserve

Let  $A \subseteq \text{Ord}$  be a set and  $h : A \rightarrow \text{Ord}$  injective. Write

$$\begin{aligned} D &= \{a \in A : h(a) \neq a\}, & R &= h[D], & S &= D \cup R, \\ u &= |R \setminus D|, & v &= |D \setminus R|, \\ \tau(h) &= \begin{cases} 0, & u = v, \\ \max(\aleph_0, u, v), & u \neq v. \end{cases} \end{aligned} \tag{S27.12}$$

Cardinals are identified with initial ordinals. The prescribed fixed points  $A \setminus D$  are disjoint from  $R$ , by injectivity of  $h$ .

Every extending permutation  $\pi$  must move each point of  $S$ . This is immediate for  $D$ . If  $r \in R \setminus D$ , some distinct prescribed point already maps to  $r$ , so  $\pi(r) = r$  would violate injectivity. For an extension with set support, put  $T = \text{supp } \pi \setminus S$ . Removing the prescribed bijection  $h : D \rightarrow R$  leaves a bijection

$$(R \setminus D) \cup T \longrightarrow (D \setminus R) \cup T. \tag{S27.13}$$

Consequently  $u + |T| = v + |T|$ . If  $u \neq v$  are finite, finite cancellation forces  $T$  to be infinite. If  $u \neq v$  and one is infinite, the rule for addition of well-ordered infinite cardinals forces  $|T| \geq \max(u, v)$ . This proves  $|T| \geq \tau(h)$ .

Conversely, a fresh set  $T$  of size  $\tau(h)$  outside  $A \cup R$  makes the two sides of (S27.13) equipotent. Any bijection between them, combined with  $h$  on  $D$  and the identity elsewhere, completes the partial injection. This is the earlier exact cardinal reserve result. Because all sets here are well-orderable subsets of ordinals, its pointwise existence argument needs no choice for arbitrary sets; it is available in ZF. A uniform simultaneous choice of matchings is a separate assertion.

### 101.2 A necessary and sufficient cutoff criterion

**Theorem 101.1** (Completion below a specified ordinal). *Let  $\beta$  be an ordinal. There exists a permutation  $\pi : \text{Ord} \rightarrow \text{Ord}$  extending  $h$ , with  $\text{supp } \pi \subseteq \beta$ , if and only if*

$$S \subseteq \beta \quad \text{and} \quad |\beta \setminus (A \cup R)| \geq \tau(h). \tag{S27.14}$$

*The second condition is automatic when  $\tau(h) = 0$ .*

*Proof.* Suppose such a permutation exists. Its forced support contains  $S$ . The remaining moved set  $T$  misses  $R$  by definition and misses  $A \setminus D$  because those points are prescribed fixed. Thus  $T \subseteq \beta \setminus (A \cup R)$ . The reserve argument above gives  $|T| \geq \tau(h)$ , proving both necessary conditions.

Conversely, choose  $T \subseteq \beta \setminus (A \cup R)$  of cardinality  $\tau(h)$ . Choose a bijection in (S27.13); both sides are well-orderable and have equal cardinality. Its domain,  $D$ , and the complement of  $S \cup T$  partition  $\text{Ord}$ , and their proposed images partition  $\text{Ord}$  as well. The resulting piecewise map is

therefore a permutation. It extends  $h$ , fixes every point outside  $S \cup T$ , and has support contained in  $\beta$ . Some reserve points may happen to be fixed, but the lower bound forces the cardinality of the moved reserve to remain  $\tau(h)$  when that cardinal is nonzero.  $\square$

### 101.3 A closed formula for the least bound

Let  $f : \text{Ord} \rightarrow \text{Ord} \setminus (A \cup R)$  be the increasing enumeration of the fresh ordinals. It is canonically defined by

$$f(\xi) = \gamma \iff \gamma \notin A \cup R \text{ and } \text{otp}(\gamma \setminus (A \cup R)) = \xi.$$

The complement of a set of ordinals has type  $\text{Ord}$ , so this formula defines  $f$  without a class-valued recursion. Put

$$\delta_S = \sup_{s \in S} (s + 1), \quad \delta_T = \sup_{\xi < \tau(h)} (f(\xi) + 1), \quad (\text{S27.15})$$

with an empty supremum equal to 0.

**Theorem 101.2** (Exact ordinal support optimum). *The least ordinal  $\beta$  for which  $h$  extends to a permutation supported in  $\beta$  is*

$$\boxed{\beta_{\min}(h) = \max(\delta_S, \delta_T)}. \quad (\text{S27.16})$$

*This minimum is attained. The formula specifies a canonical optimum, not a canonical completing permutation.*

*Proof.* We have  $S \subseteq \beta$  exactly when  $\delta_S \leq \beta$ . Since  $\tau(h)$  is an initial cardinal, the fresh set below  $\beta$  has cardinality at least  $\tau(h)$  exactly when its order type is at least  $\tau(h)$ . That is equivalent to  $f(\xi) < \beta$  for every  $\xi < \tau(h)$ , and therefore to  $\delta_T \leq \beta$ . The cutoff criterion now says that the admissible  $\beta$  are exactly the ordinals above both displayed bounds. Their least member is their maximum, and the converse part of [theorem 101.1](#) attains it.  $\square$

**Example 101.3** (The one-sided shift). Prescribe  $h(n) = n + 1$  for  $n < \omega$ . Then  $S = \omega$ ,  $u = 0$ ,  $v = 1$ ,  $\tau(h) = \omega$ , and  $f(n) = \omega + n$ . Hence

$$\beta_{\min}(h) = \omega \cdot 2.$$

An optimum completion maps  $\omega$  to 0 and maps  $\omega + n + 1$  to  $\omega + n$ , while retaining the prescribed shift on  $\omega$  and fixing all ordinals at least  $\omega \cdot 2$ . No finite reserve beyond  $\omega$  can close this one-sided infinite chain.

**Example 101.4** (Prescribed fixed positions can delay the reserve). Add the requirements  $h(\xi) = \xi$  for  $\omega \leq \xi < \gamma$ , where  $\gamma \geq \omega$ . The forced moved set and the cardinal reserve are unchanged, but the first available fresh ordinals are now  $\gamma, \gamma + 1, \dots$ . Therefore

$$\beta_{\min}(h) = \gamma + \omega.$$

This example explains why  $S$  and  $\tau(h)$  alone do not determine the ordinal optimum: the fixed domain  $A \setminus D$  can block the reserve.

**Example 101.5** (High fixed points need not matter). If  $h$  is the identity on  $A$ , then  $S = \emptyset$  and  $\beta_{\min}(h) = 0$ , however high the elements of  $A$  lie. Adding only finitely many fixed points outside  $\omega$  to the one-sided shift still leaves  $\beta_{\min} = \omega \cdot 2$ , even if one of those fixed points is arbitrarily high. The bound measures motion, not the height of the input data.

**Example 101.6** (Balanced infinite motion). For  $A = \{2n : n < \omega\}$  and  $h(2n) = 2n + 1$ , both  $u$  and  $v$  are  $\aleph_0$ , so  $\tau(h) = 0$ . Transposing each even number with the next odd number gives the optimum  $\beta_{\min} = \omega$ . Equal infinite boundary cardinalities require no reserve.

### 101.4 Application and exact limits of the result

For a prescribed injective surreal prefix  $p : \alpha \rightarrow \mathbf{No}$ , put  $h = b^{-1} \circ p$  with  $A = \alpha$ . Then [theorem 101.2](#) gives the least baseline coordinate bound below which one can modify  $b$  so that  $b \circ \pi$  begins with  $p$ . This is an exact optimization for a fixed baseline and a fixed prefix.

It does not optimize the birthday of the set code for  $\pi$ , the birthday of an order-embedded surreal representing that code, or the numerical size of the moved surreal labels. Nor does it select the prefix that optimizes an interpolant between two given cuts. Those involve additional choices and remain distinct research problems. The strict inequality in “support contained in  $\beta$ ” is the reason for every successor  $s + 1$  and  $f(\xi) + 1$  in ([S27.15](#)).

## 102 Class realizations: what labelled and marked enumeration spaces remember (sources 22, 27, 21 and 30)

[merge] Part VIII proved that, over a fixed set universe and baseline, an old core cut is represented in a larger class realization exactly when it is in the smaller one, and that every proper extension of the class part adds a global enumeration and a represented cut ([theorems 48.1](#) and [48.4](#)); it left open what the external order type of the admitted enumerations remembers ([section 50](#) (e)). Four sources answer as follows.

- *Labelled availability recovers the whole class part.* Source 22’s [theorem 102.3](#), printed first: with a common baseline  $b$  and a common class bijection  $g : \text{Ord} \rightarrow M$ , inclusion of the admitted exhaustive traces, or only of the pair-swap traces, is equivalent to inclusion of the class realizations. Source 27 proves it with only  $b$  shared, as a criterion for order embeddings fixing the core ([note 102.5](#)), and source 30 with no baseline given in advance ([note 102.16](#)); both are printed as notes with their proofs. The pair-swap code is the one source 17 uses for [theorem 48.4](#).
- *External size.* The external collection of admitted enumerations has the cardinality of the class part (source 21’s [theorem 102.13](#); source 30’s [note 102.17](#)).
- *Countable models: the bare order forgets.* The external order is  $\mathbb{Q}$  (source 13’s [proposition 55.5](#), Part IX, proved again as [theorem 102.13](#)); it stays  $\mathbb{Q}$  with the core as a dense colour and the baseline fixed ([proposition 102.19](#)), and it does not detect ETR ([proposition 102.20](#)). Fixing the core pointwise recovers everything ([note 102.5](#) and [corollary 102.12](#)).
- *A common baseline exists in every GBC-realization of a countable model exactly when some  $p$  has  $V = \text{HOD}_p$  there* ([theorem 102.21](#) and [corollary 102.22](#), applications of Williams’s minimum-model theorem).

Source 21’s section also proves the well-foundedness facts the comparisons need ([note 102.7](#) is the scope statement already printed in [section 5.6](#)).

### 102.1 Source 22: recovering an available class realization

#### 102.1.1 The coding parameters and the model comparison

Let  $M$  be a fixed set universe, and let  $\mathcal{X}$  and  $\mathcal{Y}$  be class realizations over it such that  $(M, \mathcal{X})$  and  $(M, \mathcal{Y})$  satisfy GBC. Comparisons between these class collections are made in the metatheory. Assume they share a global enumeration

$$g : \text{Ord}^M \longrightarrow M$$

and a baseline enumeration  $b : \text{Ord}^M \rightarrow \mathbf{No}^M$ . Supplied parameters are part of the hypotheses, not claimed to be canonically definable in an arbitrary model.

We may arrange that the two labels in each consecutive pair of baseline positions are numerically ordered:

$$b(2 \cdot \xi) < b(2 \cdot \xi + 1).$$

Indeed, sort each pair of an existing baseline. Every ordinal is uniquely  $2 \cdot \xi + i$  for  $i < 2$ ; this is ordinal multiplication with the finite factor on the *left*. The sorting transformation is elementary and available in both realizations.

Because  $M$  and  $b$  are fixed, the set-coded core  $\mathcal{P}_s(b)^M$ , its ordering, all set-prefix nodes, and their incidence are identical in the two realizations. What may differ is which class cuts and which full class branches are available.

### 102.1.2 Encoding an arbitrary class by pair swaps

For an available class  $A \subseteq M$ , define its ordinal bit class by

$$a_A(\xi) = 1 \iff g(\xi) \in A.$$

Define  $e_A$  by leaving the  $\xi$ th baseline pair in its original order when  $a_A(\xi) = 0$ , and reversing it when  $a_A(\xi) = 1$ . Explicitly,

$$\begin{aligned} e_A(2 \cdot \xi) &= \begin{cases} b(2 \cdot \xi), & g(\xi) \notin A, \\ b(2 \cdot \xi + 1), & g(\xi) \in A, \end{cases} \\ e_A(2 \cdot \xi + 1) &= \begin{cases} b(2 \cdot \xi + 1), & g(\xi) \notin A, \\ b(2 \cdot \xi), & g(\xi) \in A. \end{cases} \end{aligned}$$

It is a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ , since each baseline label occurs exactly once.

**Proposition 102.1** (Pair-swap encoding). *The assignment  $A \mapsto e_A$  is injective and elementary in the supplied class parameter  $A$ . On ordinal bit classes it preserves their first-disagreement lexicographic order. Moreover,*

$$e_A \text{ is evaluated by a code in } \mathcal{P}_s(b) \iff A \text{ is a set.}$$

*Proof.* At the first bit disagreement  $\xi$ , the first label disagreement is at  $2 \cdot \xi$ , where the zero bit yields the smaller baseline label and the one bit the larger. This proves order preservation and injectivity.

The supporting permutation moves exactly the two positions of those pairs with bit one. Its support is a set exactly when the one-bit ordinal class is a set. Since  $g$  is a class bijection, class replacement in either direction identifies this condition with  $A$  being a set. Uniqueness of the permutation relative to  $b$  rules out an alternative supported representation of the same enumeration.  $\square$

**Theorem 102.2** (Elementary decoding from a lower trace). *For every available class  $A$ , its normalized lower trace*

$$T_A = \{d \in \mathcal{P}_s(b) : d < e_A\}$$

*is available. From  $T_A$ , the common set-coded labelled incidence structure, and  $b, g$ , the class  $A$  is recovered by an elementary formula. In particular, no satisfaction predicate or class-valued transfinite recursion is required.*

*Proof.* The trace is an elementary class definition from  $e_A$  and evaluation. It is normalized by [note 86.9](#). Apply [theorem 87.4](#) to reconstruct its unique word, which must be  $e_A$ . Then

$$g(\xi) \in A \iff e_A(2 \cdot \xi) = b(2 \cdot \xi + 1).$$

Substituting the elementary crossed-prefix formula for the reconstructed value gives the promised decoder using only set quantifiers and the supplied class parameters. The existence of a crossed node long enough to read that coordinate is part of [theorem 87.4](#), not an extra choice requirement.  $\square$

Call a normalized represented trace a *binary-swap trace* when its reconstructed branch sends each pair of positions to the corresponding baseline pair in one of the two possible orders. Such a branch is automatically exhaustive, and the preceding decoder yields its unique class  $A$ . Thus the class sort can be represented by this specially recognized collection of traces; the entire family of exhaustive traces is more than is needed.

### 102.1.3 Faithfulness for same-set class realizations

In the metatheory, let  $\mathcal{B}_\mathcal{X}$  be the collection of lower traces on the common core represented by exhaustive enumerations available in  $\mathcal{X}$ . Let  $\mathcal{S}_\mathcal{X}$  be its subcollection of binary-swap traces. These are metatheoretic collections, not objects asserted to exist inside  $(M, \mathcal{X})$ .

**Theorem 102.3** (Faithful reconstruction of the class realization). *With the fixed  $M, b, g$  above, the following are equivalent:*

$$\mathcal{X} \subseteq \mathcal{Y}, \quad \mathcal{B}_\mathcal{X} \subseteq \mathcal{B}_\mathcal{Y}, \quad \mathcal{S}_\mathcal{X} \subseteq \mathcal{S}_\mathcal{Y}.$$

*In particular, equality of the admitted exhaustive traces, or just of the binary-swap traces, is equivalent to equality of the available class realizations.*

*Proof.* Inclusion of class realizations preserves all class enumerations and their elementary lower traces, so it implies inclusion of each trace collection.

Conversely, suppose the exhaustive trace inclusion holds, and take  $A \in \mathcal{X}$ . Construct  $T_A$  in  $\mathcal{X}$ . By hypothesis it is the lower trace of an exhaustive enumeration available in  $\mathcal{Y}$ , and hence it is itself an available class in  $\mathcal{Y}$ . The elementary decoder of [theorem 102.2](#), performed in  $(M, \mathcal{Y})$  using the common incidence and parameters, recovers exactly  $A$ . The decoding formula has only set quantifiers. Its interpretation is identical in the two models because their set universe, trace, and coding parameters agree. Thus the decoded external subclass really is the same  $A$ , and  $A \in \mathcal{Y}$ .

If only binary-swap trace inclusion is assumed, the same argument applies because every  $T_A$  is a binary-swap trace. This proves all equivalences. Applying the inclusion assertions in both directions proves the equality assertion.  $\square$

**Corollary 102.4** (Membership reconstruction). *Over the fixed set sort  $M$ , the class-membership structure is recoverable from a sort of admitted binary-swap traces with core incidence and the parameters  $b, g$ . The decoder interprets  $x \in A$  from the corresponding trace and the unique ordinal  $\xi$  with  $g(\xi) = x$ .*

This is a relative reconstruction statement. It is stronger than merely detecting that a proper same-set class extension adds some traces, which was established in the earlier continuation (source 17, [theorem 48.4](#)). It is not a reconstruction of  $M$ , of  $b, g$ , or of a class realization from the bare order type of  $\mathfrak{W}_{\text{sl}}$ .

### 102.1.4 Why this is not a diagonal paradox

The input to  $A \mapsto T_A$  is itself a class variable. The theorem does not give a set code for every  $A$ , nor a class function whose set-valued arguments enumerate all classes. A third sort may contain all these traces as objects, but then the sort and its axioms must be explicitly introduced. Inside GBC, each encoding or decoding is a schema uniform in one supplied class parameter.

Indeed, an exhaustive uniform enumeration of all global enumerations is impossible. Suppose a single class graph  $F(\xi, \eta)$  gave global bijections  $F_\xi$  for every ordinal  $\xi$  and covered every available global bijection. Define a bit class by

$$a(\xi) = 1 \iff F_\xi(2 \cdot \xi) \neq b(2 \cdot \xi + 1).$$

The associated pair-swap enumeration  $e_a$  differs from  $F_\xi$  at position  $2 \cdot \xi$ : when  $a(\xi) = 1$  it outputs the unequal upper baseline label; when  $a(\xi) = 0$  it outputs the lower label instead of the equal upper one. Thus  $e_a$  is missing from the family. This is an elementary diagonal argument, and it coexists with [theorem 102.3](#) because the latter never supplies such a set-indexed exhaustive family.

[merge] The pair-swap enumeration  $e_A$  and the decoder of [theorem 102.2](#) are source 17's construction in the proof of [theorem 48.4](#); [theorem 102.3](#) turns that construction into a complete invariant. The diagonal paragraph above is [theorem 19.37](#) in pair-swap form.

## 102.2 Source 27: the marked core detects the admitted classes of a model

The same first-order set universe can support different collections of admitted classes. Their unmarked external order types may conceal that difference. Marking the common bounded-support core pointwise gives a much more rigid invariant.

### 102.2.1 Reconstruction from a trace uses only set quantifiers

For a class injection  $E : \text{Ord} \rightarrow \mathbf{No}$ , define its lower trace on the core by

$$L_E = \{d \in \mathcal{P}_s(b) : E_d <_{\text{lex}} E\}.$$

For an injective set prefix  $p$ , let  $C_p = \{d \in \mathcal{P}_s(b) : E_d \text{ extends } p\}$ . Call  $p$  *straddling* if  $C_p$  meets both  $L_E$  and its complement.

The prefix  $E \upharpoonright \alpha$  straddles at every set length  $\alpha$ : append fresh letters on both sides of  $E(\alpha)$  and complete to core codes. No other prefix at that length straddles, since the cylinders at a fixed level are linearly arranged and a lower cut cannot cross two of them. Consequently the graph of  $E$  is recovered by

$$E(\alpha) = x \iff \exists p [\text{dom } p = \alpha + 1, p(\alpha) = x, C_p \cap L_E \neq \emptyset, C_p \setminus L_E \neq \emptyset]. \quad (\text{S27.17})$$

Every quantified prefix and every witness code is a set. This is the elementary part of the repository's more general represented-cut recognition theorem ([theorem 45.1](#)). We need this formula, rather than just an abstract appeal to density, when classes from different models are compared externally.

### 102.2.2 An embedding criterion for two class realizations

Let  $(M, \mathcal{X})$  and  $(M, \mathcal{Y})$  be set-sized models of GBC with the same first-order set structure. They need not be transitive, and neither class part is assumed contained in the other. Suppose they share a baseline  $b : \text{Ord}^M \rightarrow \mathbf{No}^M$ . Let  $H_{\mathcal{X}}$  and  $H_{\mathcal{Y}}$  be their *external* orders of admitted set-like enumerations, and identify the evaluated canonical core codes as distinguished elements of both orders.

*Note 102.5* (Source 27, Theorem 9.1, “Embeddings fixing the core”). *There exists an external order embedding*

$$J : H_{\mathcal{X}} \longrightarrow H_{\mathcal{Y}}$$

*fixing every common core element if and only if  $\mathcal{X} \subseteq \mathcal{Y}$ . Whenever such an embedding exists, it is the literal inclusion on enumeration graphs. In particular, an isomorphism fixing the core pointwise exists exactly when  $\mathcal{X} = \mathcal{Y}$ . This is source 22’s [theorem 102.3](#) in another form. Source 27 shares only the baseline  $b$  (its decoder  $d : \mathbf{No} \rightarrow V$  uses Mostowski collapses instead of a class bijection  $g$ ), assumes no inclusion between the realizations, and states the criterion for order embeddings  $H_{\mathcal{X}} \rightarrow H_{\mathcal{Y}}$  fixing the core, which must then be the inclusion. Source 22 fixes  $b$  and  $g$  and states inclusions of trace collections.*

*Source 27’s proof.* If  $J$  fixes the core, then for every  $d \in \mathcal{P}_s(b)$  and  $E \in H_{\mathcal{X}}$ ,

$$E_d < E \iff E_d < J(E).$$

The two lower traces are the same external subset of the common set-code domain. Formula ([S27.17](#)), evaluated in the same first-order structure with the same predicates  $L_E, b$ , therefore reconstructs the same graph in both expansions. Hence  $J(E) = E$  and  $H_{\mathcal{X}} \subseteq H_{\mathcal{Y}}$ .

To recover arbitrary admitted classes of sets, use a fixed definable surjection  $d : \mathbf{No} \rightarrow V$ , available in set theory with Choice. Here is its coding construction. A surreal sign word can encode an ordinal  $\alpha$ , a distinguished  $i < \alpha$ , and a binary relation on  $\alpha$ ; unary sign headers and an ordinal-length binary table give such a code. If the relation is well-founded and extensional, return the image of  $i$  under its Mostowski collapse; otherwise return  $\emptyset$ . Every set has a code by well-ordering the transitive closure of its singleton. No simultaneous choice of a code for every set is made. The decoding map  $d$  is the same elementary definition in both class realizations.

For  $C \in \mathcal{X}$ , let  $Z_C = \{\alpha : d(b(\alpha)) \in C\}$ . Swap baseline positions  $2 \cdot \alpha$  and  $2 \cdot \alpha + 1$  exactly when  $\alpha \in Z_C$ . The resulting enumeration  $E_C$  belongs to  $H_{\mathcal{X}}$ , hence also to  $H_{\mathcal{Y}}$ . Its pair orientations, together with  $b$ , recover  $Z_C$  by elementary comprehension. Surjectivity of  $d \circ b$  then recovers

$$C = \{x : \exists \alpha [d(b(\alpha)) = x \text{ and } \alpha \in Z_C]\}.$$

Thus  $C \in \mathcal{Y}$ , proving  $\mathcal{X} \subseteq \mathcal{Y}$ .

Conversely, class inclusion includes each admitted enumeration, and the same elementary first-disagreement formula preserves its order. This inclusion fixes the common core. The first part of the proof already establishes its uniqueness.  $\square$

The use of ([S27.17](#)) is substantive. Two classes from incomparable realizations need not coexist in any common class model. If  $M$  is nonstandard, their external disagreement set need not have a first element in its internal ordinal order. The proof does not assume one: it transfers an elementary reconstruction formula with shared parameters instead.

If  $(M, \mathcal{X})$  is externally countable,  $H_{\mathcal{X}}$  is countable, dense, and without endpoints. The usual back-and-forth argument makes it isomorphic to  $\mathbb{Q}$ . Hence an unmarked countable order can forget the class realization entirely, while fixing the embedded core pointwise forces exactly class inclusion. The marking is additional mathematical data, not a property extracted from the pure order.

**Corollary 102.6** (The raw-order existence criterion). *Under the same hypotheses, a core-fixing external embedding of the raw global well-order comparisons exists exactly when  $\mathcal{X} \subseteq \mathcal{Y}$ . Such an embedding fixes every old set-like enumeration. No uniqueness is asserted on non-set-like fibers.*

*Proof.* A raw well-order has the same core trace as its initial Ord block. If that trace is the trace of an exhaustive enumeration  $E$ , formula (S27.17) makes its initial block equal to  $E$ ; no labels remain for a tail. Thus  $E$  is the unique raw realization of that trace. A core-fixing embedding therefore fixes every set-like  $E$ , and the pair-code argument gives class inclusion.

For the converse, a shared relation's internal well-foundedness is absolute between same-set GBC expansions: it is equivalent to absence of a set-coded descending  $\omega$ -sequence. Class inclusion therefore includes the old raw well-orders, and elementary labelled comparison preserves their order. It fixes the core.  $\square$

[merge] The remark before [corollary 102.6](#) that a countable  $H_{\mathcal{X}}$  is  $\mathbb{Q}$  is source 13's [proposition 55.5](#) (Part IX) and source 21's [theorem 102.13](#) below.

### 102.3 Source 21: model dependence and preservation

Changing the admitted classes can change the collection of global enumerations even when every set remains fixed. Nevertheless, the abstract external order can forget much of this change. In particular, every externally countable GBC model gives the same abstract set-like enumeration order, namely  $\mathbb{Q}$ . Naming a common dense core reveals a much finer distinction. We prove these statements after separating the relevant notions of well-foundedness and preservation.

#### 102.3.1 Shared relations and well-foundedness

We use two standard facts from second-order set theory: realizations with the same sets agree about well-foundedness of shared class relations, and well-foundedness is preserved from a transitive submodel with the same ordinals. See [35, Observations 4.12–4.13]. Their elementary proofs explain exactly why they apply here.

*Note 102.7* (Source 21, Lemma 11.1, “A set witness to ill-foundedness”). *In GBC, a class relation  $R$  is ill-founded if and only if there is a set function  $f : \omega \rightarrow \text{dom}(R)$  such that*

$$f(n+1) R f(n) \quad (n \in \omega).$$

*Consequently, well-foundedness of a fixed class relation is expressible with only set quantifiers and the class parameter  $R$ .* This is the scope statement printed in [section 5.6](#) (the Hilbert's-tenth review's patch) and in source 11's [section 20](#), and the equivalence of [note 57.5](#) (Part IX); source 25 states it in [section 104](#).

*Source 21's proof.* The range of a descending sequence is a nonempty class with no  $R$ -minimal element. Conversely, suppose that a nonempty class  $A$  has no  $R$ -minimal element. Fix  $a_0 \in A$ , and use a set-like global well-order to select an  $R$ -predecessor in  $A$  at each subsequent step. Every nonempty class of possible predecessors has a first point in that global order. Ordinary recursion with the displayed class parameters produces the sequence, and Class Replacement makes its restriction to  $\omega$  a set.  $\square$

**Proposition 102.8** (Changing classes while keeping the sets). *Let  $(M, \mathcal{X})$  and  $(M, \mathcal{Y})$  be GBC realizations of the same first-order model. They agree about well-foundedness of every relation in  $\mathcal{X} \cap \mathcal{Y}$ . They also agree about the labeled lexicographic comparison of any shared class well-orders of a fixed shared carrier.*

*Proof.* The first assertion follows from [note 102.7](#): the possible set sequences and their membership relations are identical. For the second, the largest common labeled prefix and the two first residual labels have elementary definitions in the shared carrier and relations. Those definitions quantify over the same set domain and therefore have the same interpretation. For set-like enumerations, one can equivalently use their least ordinal of disagreement.  $\square$

No transitivity or external well-foundedness assumption is needed for this agreement statement. Both models can agree about a relation that is externally ill-founded. The assertion concerns their common interpretation, not its correctness in a larger metatheory.

**Proposition 102.9** (Preservation with the same ordinals). *Suppose  $(M, \mathcal{X}) \subseteq (N, \mathcal{Y})$  are transitive GBC models with  $\text{Ord}^M = \text{Ord}^N$ , and old classes are retained as the same relations on old elements. Every old class relation that  $(M, \mathcal{X})$  regards as well-founded remains well-founded in  $(N, \mathcal{Y})$ .*

*On a fixed old carrier, inclusion therefore preserves the old labeled lexicographic well-order space and its comparisons.*

*Proof.* Suppose that  $N$  has a descending  $\omega$ -sequence through an old relation  $R$ . In  $N$ , the ranks of its entries are bounded by some ordinal  $\beta$ . This ordinal belongs to  $M$ , since the models have the same ordinals. All the entries lie in the ground set  $A = \text{dom}(R) \cap V_\beta^M$ , increasing  $\beta$  if necessary. By Class Separation,  $R \cap (A \times A)$  is a set relation in  $M$ . The ground model regards it as well-founded and constructs its rank function into an ordinal. Transitivity makes that same rank function a witness to well-foundedness in  $N$ , contradicting the descending sequence.

For an old fixed carrier, the numerical labels and the two relation graphs have not changed. Their common labeled prefix and first residual labels are consequently unchanged. Thus the same first discrepancy gives the same lexicographic comparison.  $\square$

This applies to ordinary set-forcing extensions and, more generally, to class-forcing extensions satisfying the stated hypotheses. It does not assert the preservation of every second-order axiom, the existence of a uniform forcing relation for arbitrary class forcing, or that every *new* abstract class-well-order type was already present. Those are separate questions with stronger hypotheses and genuine recursion issues [\[24, 27\]](#).

**Proposition 102.10** (A sufficient condition for external correctness). *Let  $(M, \mathcal{X})$  be a transitive GBC model, and let  $\theta = \text{Ord}^M$  be its ordinal height in the metatheory. If  $\text{cf}(\theta) > \omega$ , every internally well-founded class relation is externally well-founded.*

*Proof.* An external descending  $\omega$ -sequence would have its entries' ranks bounded below  $\theta$ , by the cofinality hypothesis. Restrict the relation to a ground rank segment containing those entries. This is a well-founded set relation in the transitive model  $M$ , so its ground ordinal rank function also witnesses external well-foundedness. This contradicts the sequence.  $\square$

The rank-cut case is the familiar sufficient condition in [\[35, Observation 1.14\]](#). For height of countable cofinality, the rank bound can fail. A transitive model is correct about its well-founded *set* relations, but transitivity alone does not ensure correctness about all admitted class relations. A transitive realization with this additional correctness property is called a  $\beta$ -model.

### 102.3.2 The carrier also changes under forcing

There is an essential qualification to any claimed inclusion between surreal well-order spaces in different universes. If a forcing extension adds a new subset  $r \subseteq \omega$ , it adds the new surreal sign sequence of length  $\omega$  whose positive signs occur exactly at positions in  $r$ . Hence  $\mathbf{No}^M \subsetneq \mathbf{No}^N$ . An

old enumeration  $E : \text{Ord} \rightarrow \mathbf{No}^M$  is no longer onto  $\mathbf{No}^N$ , so it is not literally a point of the new  $\mathfrak{W}_{\text{sl}}(\mathbf{No}^N)$ .

After choosing auxiliary enumerations, there are straightforward comparison embeddings. For unrestricted class well-orders, fix a class well-order  $T$  of  $D = \mathbf{No}^N \setminus \mathbf{No}^M$  and send  $R$  to  $R + T$ . Every old label precedes every new one, so the first labeled discrepancy of two old orders remains their first discrepancy after extension.

For set-like orders, this sum generally has a proper-class initial segment. Instead choose a set-like enumeration  $d$  of  $D$ , indexed by  $\text{Ord}$  when  $D$  is proper or by a set ordinal when it is a set. Interleave  $E(\alpha)$  at slot  $(\alpha, 0)$  and, where defined,  $d(\alpha)$  at slot  $(\alpha, 1)$ , with  $\alpha$  the primary coordinate. Every initial segment is a set, so the resulting well-order is set-like and has type  $\text{Ord}$ . At the first old discrepancy all preceding new-label slots agree; thus lexicographic comparisons are preserved. These constructions require the stated auxiliary data. They should not be mistaken for a canonical inclusion or a functorial choice independent of that data.

### 102.3.3 Proper expansions of the class realization

Now fix the sets. Let

$$(M, \mathcal{X}) \subseteq (M, \mathcal{Y}), \quad b \in \mathcal{X},$$

be GBC realizations, and use the same normalized core  $\mathcal{P}_{\text{bd}}(b)$  in both. Its codes and evaluations are identical because the set part and the baseline are identical. Write  $H_{\mathcal{X}}$  and  $H_{\mathcal{Y}}$  for the externally interpreted collections of admitted set-like global enumerations. For set-sized two-sorted models, these collections are ordinary sets in the metatheory.

**Theorem 102.11** (A class expansion as an extension by cuts). *The following hold.*

- (i)  $H_{\mathcal{X}}$  is an order-dense suborder of  $H_{\mathcal{Y}}$ .
- (ii)  $H_{\mathcal{X}} = H_{\mathcal{Y}}$  if and only if  $\mathcal{X} = \mathcal{Y}$ .
- (iii) For  $E \in H_{\mathcal{Y}}$ , its lower cut  $L_E$  in the common core belongs to  $\mathcal{X}$  if and only if its enumeration graph  $E$  belongs to  $\mathcal{X}$ .

*Proof.* Both orders contain  $\mathcal{P}_{\text{bd}}(b)$ , which is dense in  $H_{\mathcal{Y}}$ . Old comparisons are unchanged by [proposition 102.8](#); this proves (i).

For (ii), choose a class bijection  $v : \text{Ord}^M \rightarrow M$  in  $\mathcal{X}$ , using Global Choice. Given any  $A \in \mathcal{Y}$ , define a class subset of the internal ordinals by

$$B_A = \{\alpha : v(\alpha) \in A\}.$$

Encode  $B_A$  by swapping the  $\alpha$ -th adjacent pair of  $b$  exactly when  $\alpha \in B_A$ . Denote the resulting enumeration by  $E_A$ . This is an element of  $H_{\mathcal{Y}}$ . If its graph belonged to  $\mathcal{X}$ , the orientations of its pairs, together with  $b$  and  $v$ , would recover  $A$  by elementary comprehension. Thus a new class supplies a new admitted enumeration. The converse is immediate since enumeration graphs are classes.

For (iii), an admitted  $E$  defines  $L_E$  by elementary comprehension. Conversely, if  $L_E \in \mathcal{X}$ , apply the elementary reconstruction formula of [note 97.10](#) inside  $(M, \mathcal{X})$ . Its set quantifiers have the same domain as in  $(M, \mathcal{Y})$ , so its resulting class graph is exactly  $E$ . Hence  $E \in \mathcal{X}$ .  $\square$

**Corollary 102.12** (Rigidity when the core is fixed pointwise). *If  $\mathcal{X} \subsetneq \mathcal{Y}$ , there is no weakly increasing map  $H_{\mathcal{Y}} \rightarrow H_{\mathcal{X}}$  fixing every point of the common core. In particular there is no such isomorphism or monotone retraction.*

*Proof.* Suppose  $r$  is such a map. If  $r(E) > E$ , choose a core point  $E_d$  strictly between them. Monotonicity gives  $r(E) \leq r(E_d) = E_d$ , a contradiction. If  $r(E) < E$ , choose a core point between them and use  $r(E_d) \leq r(E)$ , again a contradiction. Thus  $r(E) = E$  for every input, which is impossible for a point in  $H_Y \setminus H_X$ .  $\square$

The core therefore detects a proper expansion through newly represented cuts, provided its individual points are identified. This does not imply that the abstract unmarked enumeration order detects the expansion.

### 102.3.4 The external countable order is always rational

**Theorem 102.13** (External size and countable classification). *For every set-sized two-sorted GBC model  $(M, \mathcal{X})$ , the metatheory has*

$$|H_{\mathcal{X}}| = |\mathcal{X}|.$$

*If the entire two-sorted model is externally countable, then*

$$(H_{\mathcal{X}}, <_{\text{lex}}) \cong (\mathbb{Q}, <).$$

*Neither assertion requires transitivity,  $\beta$ -correctness, or  $\omega$ -standardness.*

*Proof.* The inequality  $|H_{\mathcal{X}}| \leq |\mathcal{X}|$  follows because the enumeration graphs are members of  $\mathcal{X}$ . Fix internal bijections  $v : \text{Ord}^M \rightarrow M$  and  $b : \text{Ord}^M \rightarrow \mathbf{No}^M$ . The binary pair construction in [theorem 102.11](#) gives an external injection  $A \mapsto E_A$  from  $\mathcal{X}$  into  $H_{\mathcal{X}}$ , since the graph of  $E_A$  determines  $A$ . Cantor–Bernstein proves the cardinal equality.

In the countable case, the GBC theorems that  $\mathfrak{W}_{\text{sl}}$  is a linear order, is dense, and has no endpoints hold in the model. Their class quantifiers range over exactly the externally admitted class objects in  $\mathcal{X}$ . Thus they say precisely that the external relation on  $H_{\mathcal{X}}$  is a countable dense linear order without endpoints. The usual back-and-forth for countable orders identifies it with  $\mathbb{Q}$ .  $\square$

There is no conflict with the internal statement that no uniformly set-indexed family is cofinal in  $\mathfrak{W}_{\text{sl}}$ . An external countable listing of all its admitted points need not be encoded by a uniform family inside the model. Nor is there a conflict with the diagonal obstruction to an internal exhaustive class list: an external list is not an internal decoder.

This theorem gives a concrete limitation on attempts to recover truth resources or class-comprehension strength from the unmarked order. Whenever the relevant two-sorted models are externally countable, their set-like enumeration orders are all isomorphic to  $\mathbb{Q}$ , even though their admitted class collections can differ. The named dense core retains finer information through [theorem 102.11](#).

Finally,  $\omega$ -standardness plays a different role in the unrestricted order. The preceding rational classification transfers internally proved density directly to the admitted class objects. By contrast, an interval that the model regards as finite can have externally infinitely many points when its claimed size is a nonstandard natural number. Statements about external finite-tail condensation must therefore be read with their separate standardness hypotheses. The distinction between Global Choice and selection of class witnesses is likewise unaffected: our cut reconstructions are explicit and unique, and do not use a Class Choice principle [\[66\]](#).

*Note 102.14* ([\[merge\]](#); overlaps in source 21’s Section 11). [Proposition 102.8](#) combines [note 102.7](#) with the elementarity of labelled comparison used in [theorem 48.1](#). In [theorem 102.11](#), item (iii) is source 17’s [theorem 48.4](#) and item (ii) its last clause; item (i) and [corollary 102.12](#) are new. In [theorem 102.13](#), the second assertion is source 13’s [proposition 55.5](#) (Part IX); the first,  $|H_{\mathcal{X}}| = |\mathcal{X}|$ , is new, and source 30 proves it again ([note 102.17](#)).

## 102.4 Source 30: what labelled enumeration spaces remember about their class universe

[merge] Source 30's Section 9, printed whole; source 30 cites none of sources 13–29. Its class realizations  $\mathcal{C}, \mathcal{D}$  are printed  $\mathcal{X}, \mathcal{Y}$  and its core  $\mathcal{B}_b$  is printed  $\mathcal{P}_s(b)$  (as a family of enumeration graphs). Its Proposition 9.1, Theorem 9.2 and Corollaries 9.3 and 9.4 are results of sources 22 and 21 and are printed as notes with source 30's proofs. [Proposition 102.19](#) (1), [proposition 102.20](#), [theorem 102.21](#) and [corollary 102.22](#) are new against the repository; source 30 calls the last two “applications of known class-theoretic machinery”.

The repository proves that enlarging the available classes, while keeping the sets and a baseline fixed, necessarily adds a new global enumeration ([theorem 48.4](#)). There is a stronger converse formulation: inclusion of the available *labelled* enumeration families detects inclusion of the entire class collections. In fact, the much narrower family obtained by independently swapping fixed adjacent pairs already contains all this information. This observation gives a precise positive answer to the reconstruction question with labels retained. It also explains why reconstruction from the pure external linear order is a substantially different problem.

The arguments in this section use two distinct levels of language. Within GB, each subset of the ordinals and each enumeration is one class variable, and the constructions below are elementary formulas in those variables. When comparing class realizations, we work externally with a fixed *set-sized* model  $M$  and collections  $\mathcal{X}, \mathcal{Y} \subseteq \mathcal{P}(M)$ . The external collection of their class graphs is then an ordinary set in the metatheory. No internal class whose elements are proper classes is introduced.

### 102.4.1 An elementary coding by pair orientations

Fix a class bijection

$$b : \text{Ord} \longrightarrow \text{No.}$$

Its existence already entails Global Choice, by the repository's theorem over the choiceless GB base ([theorem 13.1](#)). For each ordinal  $\alpha$ , sort the two labels  $b(2 \cdot \alpha), b(2 \cdot \alpha + 1)$  numerically:

$$u_\alpha = \min\{b(2 \cdot \alpha), b(2 \cdot \alpha + 1)\}, \quad v_\alpha = \max\{b(2 \cdot \alpha), b(2 \cdot \alpha + 1)\}.$$

Thus  $u_\alpha < v_\alpha$ . Define the pair-normalized baseline  $c$  by

$$c(2 \cdot \alpha) = u_\alpha, \quad c(2 \cdot \alpha + 1) = v_\alpha.$$

Here multiplication is ordinal multiplication, with the finite ordinal on the left. The intervals  $[2 \cdot \alpha, 2 \cdot \alpha + 2)$  partition  $\text{Ord}$ . All of these definitions are elementary in the original baseline.

For a class  $A \subseteq \text{Ord}$ , let  $E_A$  be the enumeration obtained by reversing exactly the pairs indexed by  $A$ :

$$\begin{aligned} E_A(2 \cdot \alpha) &= \begin{cases} v_\alpha, & \alpha \in A, \\ u_\alpha, & \alpha \notin A, \end{cases} \\ E_A(2 \cdot \alpha + 1) &= \begin{cases} u_\alpha, & \alpha \in A, \\ v_\alpha, & \alpha \notin A. \end{cases} \end{aligned} \tag{S30.9.1}$$

Each pair is still used once and distinct pairs are disjoint, so every  $E_A$  is a class bijection. Conversely, the elementary predicate  $\text{Pair}_c(E)$  says that  $E$  is a function on the ordinals and, for every  $\alpha$ ,

$$(E(2 \cdot \alpha), E(2 \cdot \alpha + 1)) \in \{(u_\alpha, v_\alpha), (v_\alpha, u_\alpha)\}. \tag{S30.9.2}$$

This predicate itself guarantees that  $E$  is a global bijection. Its unique orientation class is

$$A_E = \{\alpha \in \text{Ord} : E(2 \cdot \alpha) = v_\alpha\}. \quad (\text{S30.9.3})$$

*Note 102.15* (Source 30, Proposition 9.1, “Pair coding with an elementary inverse”). *In GB with the displayed baseline, the transformations  $A \mapsto E_A$  and  $E \mapsto A_E$  are mutually inverse, uniformly elementary transformations between ordinal classes and classes satisfying  $\text{Pair}_c$ . If  $A \neq B$  and  $\delta = \min(A \triangle B)$ , then*

$$E_A <_{\text{lex}} E_B \iff \delta \in B.$$

This is source 22’s [proposition 102.1](#) with its decoder [theorem 102.2](#), with the baseline pair-normalized; the Boolean structure below is source 30’s.

*Source 30’s proof.* The inverse assertions follow directly from (S30.9.1)–(S30.9.3). A nonempty ordinal class has a least member: after choosing any witness, minimize within the set of ordinals below that witness. Before position  $2 \cdot \delta$ , the two enumerations agree. At that position the enumeration whose orientation bit is zero has value  $u_\delta$ , and the other has value  $v_\delta > u_\delta$ . This proves the comparison formula.  $\square$

The coding also retains Boolean operations. Associate to  $A$  the class permutation of surreal labels

$$T_A = E_A \circ c^{-1}.$$

It either fixes both labels of a pair or exchanges them. Therefore

$$T_A^2 = \text{id}, \quad T_A \circ T_B = T_{A \triangle B}, \quad T_{\text{Ord} \setminus A} = T_{\text{Ord}} \circ T_A. \quad (\text{S30.9.4})$$

Intersection is recovered by the elementary operation that exchanges a pair precisely when both input permutations exchange that pair. Thus the orientation family records the Boolean algebra of available ordinal classes, including symmetric difference as actual permutation composition. Boolean operations alone do not characterize which families form a model of class theory: comprehension and Class Replacement impose additional requirements.

#### 102.4.2 A faithful invariant of class realization

Let  $(M, \mathcal{X})$  and  $(M, \mathcal{Y})$  be models of GBC with exactly the same first-order structure. They need not be transitive, and neither class collection is initially assumed to contain the other. Write

$$\mathcal{E}(\mathcal{X}) = \{E \in \mathcal{X} : (M, \mathcal{X}) \models E : \text{Ord} \xrightarrow{\sim} \mathbf{No}\}.$$

This is external notation for a collection of graphs. Internal ordinal arithmetic, surreal labels, and coded ordered pairs are all interpreted in  $M$ . If a baseline  $c$  is common to the two realizations, write

$$\mathcal{K}_c(\mathcal{X}) = \{E \in \mathcal{X} : (M, \mathcal{X}) \models \text{Pair}_c(E)\}.$$

*Note 102.16* (Source 30, Theorem 9.2, “Reconstruction from labelled enumeration availability”). *For any two such realizations,*

$$\mathcal{X} \subseteq \mathcal{Y} \iff \mathcal{E}(\mathcal{X}) \subseteq \mathcal{E}(\mathcal{Y}). \quad (\text{S30.9.5})$$

*If a pair-normalized baseline  $c$  belongs to both realizations, these conditions are also equivalent to*

$$\mathcal{K}_c(\mathcal{X}) \subseteq \mathcal{K}_c(\mathcal{Y}).$$

*In particular, equality of either labelled availability family implies equality of the complete class collections.* This is source 22’s [theorem 102.3](#) (and source 27’s [note 102.5](#)). Source 30 needs no baseline given in advance: it takes one from the assumed inclusion of enumeration families, and the class bijection  $g$  from that baseline.

*Source 30’s proof.* The forward implications use elementary comprehension and the fact that being a bijection between the displayed classes is a first-order assertion with set quantifiers and the specified class graph. Its truth is unchanged when the first-order structure and graph are unchanged.

Suppose now that  $\mathcal{E}(\mathcal{X}) \subseteq \mathcal{E}(\mathcal{Y})$ . Choose  $b \in \mathcal{E}(\mathcal{X})$ . The assumption makes it a common baseline, and pair normalization gives a common  $c$ . The standard coding proof of the baseline–Global Choice equivalence supplies a class bijection

$$g : \text{Ord}^M \longrightarrow M$$

uniformly definable from  $b$ ; hence the same  $g$  is available in both realizations. One can instead use a common class surjection, obtained by decoding ordinal presentations of rooted well-founded extensional relations, since injectivity is not needed below.

Take any class  $X \in \mathcal{X}$ , and form its ordinal code

$$A_X = \{\alpha \in \text{Ord}^M : g(\alpha) \in X\}.$$

Elementary comprehension in  $(M, \mathcal{X})$  gives  $A_X$ , and then  $E_{A_X} \in \mathcal{K}_c(\mathcal{X})$ . The assumed enumeration inclusion puts  $E_{A_X}$  in  $\mathcal{Y}$ . Applying the elementary inverse ([S30.9.3](#)) in the latter model recovers  $A_X$ , and the formula

$$x \in X \iff \exists \alpha \in \text{Ord}^M (g(\alpha) = x \wedge E_{A_X}(2 \cdot \alpha) = v_\alpha) \quad (\text{S30.9.6})$$

recovers  $X$ . Consequently  $X \in \mathcal{Y}$ , proving  $\mathcal{X} \subseteq \mathcal{Y}$ .

If the common baseline is given at the outset, the same proof uses only the inclusion of  $\mathcal{K}_c$ . Every quantifier in the reconstruction formula ranges over sets of  $M$ ; no quantification over an exhaustive family of classes is hidden in the construction.  $\square$

*Note 102.17* (Source 30, Corollary 9.3, “External size”). *For any set-sized GBC model  $(M, \mathcal{X})$  and a baseline  $c \in \mathcal{X}$ , the external sets  $\mathcal{X}$ ,  $\mathcal{E}(\mathcal{X})$ , and  $\mathcal{K}_c(\mathcal{X})$  are equinumerous.* This is the first assertion of source 21’s [theorem 102.13](#), with  $\mathcal{K}_c(\mathcal{X})$  added.

*Source 30’s proof.* The map  $X \mapsto E_{A_X}$  in the preceding proof injects all of  $\mathcal{X}$  into  $\mathcal{K}_c(\mathcal{X})$ , while  $\mathcal{K}_c(\mathcal{X}) \subseteq \mathcal{E}(\mathcal{X}) \subseteq \mathcal{X}$ . Apply Cantor–Bernstein externally.  $\square$

The reconstruction conclusion of [Note 102.16](#) also holds when the recorded objects are the labelled set-like well-order relations rather than their enumeration graphs. The transformations in both directions are elementary: transport ordinal order along the enumeration, or assign to each label the ordinal order type of its predecessor set. It also holds for the availability family of *all* labelled class well-orders. For the latter statement one uses the standard first-order characterization of internal class well-foundedness; see [64, Section 2]. Indeed, a nonempty ill-founded subclass yields a nonempty ill-founded *set* of labels: start with one label, and at each finite stage adjoin all predecessors within the given ill-founded subclass of least possible rank; then take the union. This construction uses ordinary set-valued recursion. Therefore two GB realizations with the same sets agree about the well-foundedness of a class relation they share. This is an internal absoluteness statement, and does not assert external well-foundedness.

*Note 102.18* (Source 30, Corollary 9.4, “The represented-cut version”). *Fix a common baseline and its set-coded support core. If two realizations have the same available represented trace cuts of that core, then they have the same classes. Inclusion of those represented-cut families likewise reflects inclusion of the class realizations.* This is the trace form of source 22’s [theorem 102.3](#).

*Source 30’s proof.* The repository’s recognition theorem ([theorem 45.1](#)) constructs the unique enumeration from its represented core cut by an elementary formula. Conversely, the cut is elementary in the enumeration. These operations are absolute between realizations with the same sets and baseline. Apply [Note 102.16](#).  $\square$

Thus a formalization may safely use the pair predicate and its elementary decoder as a small interface to arbitrary classes. The statement is uniform in any individually supplied class, or in a supplied uniform family. It does not furnish a same-level class of all pair-swap enumerations: the repository’s diagonal theorem ([theorem 19.37](#)) still rules out an exhaustive class-indexed evaluator. The positive reconstruction and the negative enumeration theorem describe different operations.

### 102.4.3 Why the pure external linear order loses this information

For an externally countable model of GBC, its admitted enumeration family is externally countable. Its lexicographic order is dense without endpoints. To see density, take the first disagreement of two enumerations, retain their common set prefix, choose an unused numerical label strictly between the two disagreeing labels, and complete the extended prefix to a global enumeration. The surreal set-cut property supplies the fresh label, and the baseline supplies the completion. Choosing a smaller or larger first label gives the absence of endpoints. Cantor’s classification of countable dense linear orders therefore makes this external order isomorphic to  $(\mathbb{Q}, <)$ .

**Proposition 102.19** (A core preserved setwise and a core fixed pointwise). *Let  $(M, \mathcal{X})$  and  $(M, \mathcal{Y})$  be externally countable GBC models with the same sets and a common baseline  $b$ . Let  $\mathcal{P}_s(b)$  be the common family of its internally set-supported permutations, viewed as enumeration graphs.*

1. *The core  $\mathcal{P}_s(b)$  and its complement are dense in each enumeration order. There is an external order isomorphism  $F : \mathcal{E}(\mathcal{X}) \longrightarrow \mathcal{E}(\mathcal{Y})$  with  $F[\mathcal{P}_s(b)] = \mathcal{P}_s(b)$  and  $F(b) = b$ .*
2. *If such an order isomorphism fixes every member of  $\mathcal{P}_s(b)$  pointwise, then  $\mathcal{X} = \mathcal{Y}$ , and the isomorphism is the identity on enumeration graphs.*

*Proof.* Core density is the repository’s prefix-completion theorem ([lemma 19.4](#) and [theorem 19.10](#)). For complement density, choose a prefix cylinder inside any prescribed open interval, and a core enumeration  $q = b \circ \sigma$  in that cylinder. Choose an ordinal bound beyond the prefix length and the support of  $\sigma$ . Define a class permutation  $\tau$  that fixes positions below a sufficiently large such bound and exchanges every later adjacent pair. Then  $q \circ \tau$  still lies in the cylinder. Beyond the bound,  $\sigma$  is the identity and  $\sigma \circ \tau$  moves every point of a proper-class tail. Thus  $q \circ \tau \notin \mathcal{P}_s(b)$ . All these constructions are elementary from the baseline and set parameters and work in each realization.

Each enumeration order is therefore a countable dense linear order with two dense colors: membership and nonmembership in the core. The usual back-and-forth proof of Cantor’s theorem applies with colors preserved. Start with the one-point partial map  $b \mapsto b$ , and extend alternately through countable external lists of the two domains; every required open interval contains an unused point of the required color. This proves the first assertion.

For the second, let  $E \in \mathcal{E}(\mathcal{X})$ . An isomorphism fixing the core pointwise makes  $E$  and  $F(E)$  determine the same cut of the common core. The repository’s elementary uniqueness theorem for represented cuts ([theorem 45.1](#)) implies that their labelled enumeration graphs are identical. This

uniqueness also follows directly by taking a set prefix through a disagreement and placing a common core enumeration strictly between the resulting two prefixes. Consequently the two enumeration families coincide. [Note 102.16](#) yields  $\mathcal{X} = \mathcal{Y}$ .  $\square$

Thus even a distinguished baseline point and a unary predicate for the support core are insufficient to reconstruct a countable class realization. The stronger requirement that the embedding of that core be fixed pointwise retains precisely the represented-cut information. The same back-and-forth may begin with any finite common suborder of the core fixed pointwise, so naming finitely many additional core points does not remove this loss of information.

**Proposition 102.20** (Pure order does not detect truth or ETR). *Suppose  $(M, \mathcal{Y})$  is an externally countable model of  $\text{GBC} + \text{ETR}$ , and  $M$  has a parametrically definable global well-order. Put  $\mathcal{X} = \text{Def}(M)$ , allowing set parameters in definitions. Then*

$$(M, \mathcal{X}) \models \text{GBC} + \neg\text{ETR}, \quad \mathcal{E}(\mathcal{X}) \cong \mathcal{E}(\mathcal{Y}) \cong (\mathbb{Q}, <)$$

*as external pure linear orders, while  $\mathcal{E}(\mathcal{X}) \subsetneq \mathcal{E}(\mathcal{Y})$  as labelled graph families. Moreover, relative to a common definable baseline, the external isomorphism can preserve the support core setwise and fix the baseline point.*

*Proof.* The definable classes of a first-order model satisfy GB, and the definable global well-order supplies Global Choice. Every class in  $\text{Def}(M)$  belongs to  $\mathcal{Y}$  by elementary comprehension. Elementary transfinite recursion constructs a truth predicate for the set universe, including satisfaction with set assignments, by recursion on formula complexity; this is a standard consequence of **ETR** [22]. Tarski's undefinability theorem excludes such a full satisfaction predicate from  $\text{Def}(M)$ , even with a set parameter. Hence the smaller realization fails ETR and is properly contained in the larger one. [Note 102.16](#) gives strict inclusion of their labelled spectra. Both pure orders are countable, dense, and have no endpoints, giving their external isomorphisms with  $\mathbb{Q}$ . [Proposition 102.19](#) supplies the additional preservation assertions.  $\square$

This proposition is conditional on the displayed model hypothesis; it does not derive the consistency of  $\text{GBC} + \text{ETR}$  from ZFC. The separation between definable-class models and truth extensions is standard [65]; its application here pinpoints the information discarded by forgetting coordinates. No claim that the external isomorphism is available internally is needed.

#### 102.4.4 Exactly when a definable baseline exists

Global Choice and a definable global choice function are different requirements. Fix one set parameter  $p$ , and let  $\text{HOD}_p$  mean the sets whose transitive closures consist of sets definable from ordinal parameters and the *single named parameter*  $p$ . This convention is explicit because notation such as  $\text{HOD}(p)$  is also used with other parameter conventions.

**Theorem 102.21** (Definability threshold). *Over ZF, the following are equivalent for classes definable by first-order formulas from the fixed set parameter  $p$ :*

1. *there is such a class well-order of  $\mathbf{No}$ ;*
2. *there is such a set-like class well-order of  $\mathbf{No}$ ;*
3. *there is such a bijection  $\text{Ord} \rightarrow \mathbf{No}$ ;*
4.  $V = \text{HOD}_p$ .

*The formulation of existence of a definable class is metatheoretic; for any specified definition, the constructions produce specified definitions of the other objects. In particular, parameter-free definability has threshold  $V = \text{HOD}$ .*

*Proof.* Apply the repository's bare-GB choice proof (theorem 13.1) to the given definable relation. Its operations use elementary comprehension and ordinary set-valued recursion, so every resulting class remains definable from  $p$ . In particular it gives a  $p$ -definable global well-order of  $V$ ; refining by rank makes it set-like. Each set is then the unique object at some ordinal position of this order, and so is definable from that ordinal and  $p$ . Every set, including every member of its transitive closure, is consequently ordinal-definable from  $p$ . Thus  $V = \text{HOD}_p$ .

Conversely, the canonical ordinal-definition codes give a  $p$ -definable well-order of  $\text{HOD}_p$ . Concretely, a code records a rank  $\theta$ , a formula number, and a finite tuple of ordinals, and asserts that the formula defines one object in the set structure  $V_\theta$  with parameter  $p$ . Order the codes first by a bound containing their ranks and ordinal parameters, and then by canonical well-orders within that set of codes; assign each object its least defining code. Satisfaction for the set  $V_\theta$  is uniformly definable in ZF. This construction therefore uses no truth predicate for  $V$ . If  $V = \text{HOD}_p$ , it well-orders all sets; birthday or rank refinement and restriction then give the required set-like surreal well-order and enumeration. The remaining implications are the usual transport and collapse of a set-like well-order.  $\square$

The parameter-free surreal statement is explicitly discussed by Hamkins [18]. The parameter-relative formulation makes precise what is required when a formal development proposes to replace an explicit class baseline by a definition in the language of sets. For a set model  $M$ , it follows that

$$\mathcal{E}(\text{Def}(M)) \neq \emptyset \iff M \models \exists p [V = \text{HOD}_p]. \quad (\text{S30.9.7})$$

Allowing arbitrary set parameters in  $\text{Def}(M)$  is essential to the quantifier on the right.

#### 102.4.5 A common baseline across all class realizations

The preceding reconstruction transfers precise existence results about class realizations to availability of global surreal enumerations. Williams proves that a countable  $M \models \text{ZFC}$  has a *minimum* GBC-realization exactly when it has a parametrically definable global well-order [64, Main Theorem 1]. Here minimum means contained in every realization; it is stronger than merely having no smaller one.

**Corollary 102.22** (Universal availability is definable availability). *Let  $M \models \text{ZFC}$  be countable and GBC-realizable. With the intersection taken externally over all its GBC-realizations,*

$$\bigcap_{\mathcal{X}: (M, \mathcal{X}) \models \text{GBC}} \mathcal{E}(\mathcal{X}) = \mathcal{E}(\text{Def}(M)).$$

*Consequently there is a global surreal enumeration admitted by every realization exactly when  $M \models \exists p [V = \text{HOD}_p]$ .*

*Proof.* A definable enumeration belongs to every realization. Conversely, suppose that one enumeration  $b$  belongs to them all. The classes definable from  $b$  and set parameters form  $\text{Def}(M; b)$ . This is a GB-realization, since it is contained in a given GBC-realization and its defining operations and Class Replacement are inherited there. It has Global Choice because it contains  $b$ . Since every realization contains  $b$  and is closed under elementary definitions,  $\text{Def}(M; b)$  is contained in every realization. It is therefore a minimum GBC-realization.

Williams’s theorem implies that  $M$  has a parametrically definable global well-order. Hence  $\text{Def}(M)$  itself is a GBC-realization. The assumed universal availability of  $b$  now puts  $b$  in  $\text{Def}(M)$ , proving the reverse inclusion. Equation (S30.9.7) gives the final equivalence.  $\square$

The countability hypothesis enters through the cited minimum-realization theorem and should not be silently removed. This corollary and [Note 102.16](#) are applications of known class-theoretic machinery and the elementary pair construction; they are not claims to new consistency theorems. They sharpen the repository’s class-extension analysis ([theorems 48.1](#) and [48.4](#)) in two ways: even a narrow labelled subfamily detects the whole class collection, and the existence of a baseline common to all realizations has an exact definability criterion. Equivalently, every nondefinable global surreal enumeration admitted by one realization of a countable set model can be omitted by another GBC-realization of those same sets.

[merge] [Proposition 102.19](#) (1) refines source 13’s [proposition 55.5](#) and source 21’s [theorem 102.13](#) by a back-and-forth with two dense colours fixing the baseline; item (2) is the isomorphism case of source 27’s [note 102.5](#). Together with [proposition 102.20](#) it answers [research question 113.18](#) for externally countable models: the bare order, even with the core named as a set and the baseline as a point, detects neither the class realization nor ETR.

## 103 Unrestricted class well-orders and other readings (source 25)

[merge] Source 25’s Section 13, on the scope of its theorems. Its Proposition 13.1 is [theorem 14.2](#) and is printed as a note.

The main homogeneity theorem concerns injective Ord-words and their exhaustive subclass. It must not be silently applied to non-set-like well-orders, arbitrary repeated words, or numerically increasing words. We now state how those interpretations fit around it.

### 103.1 Direct comparison without ordinal enumeration

Let  $R, S$  be class well-orders of the same labelled class  $X \subseteq \mathbf{No}$ , where well-order means that every nonempty admitted subclass has a least element. Write  $\text{Pred}_R(x)$  for the class of strict  $R$ -predecessors of  $x$ . Define  $I(R, S)$  to consist of those  $x$  for which

$$\text{Pred}_R(x) = \text{Pred}_S(x)$$

and the restrictions of  $R, S$  to that common predecessor class agree. This is an elementary formula with the supplied class parameters. No quantification over possible initial-segment classes is needed.

*Note 103.1* (Source 25, Proposition 13.1, “Largest common labelled prefix”). *The class  $I(R, S)$  is initial in both orders, and  $R, S$  agree on it. If  $R \neq S$ , its complement has distinct least elements  $u$  under  $R$  and  $v$  under  $S$ . The rule*

$$R <_{\text{lex}} S \iff u < v$$

*using the numerical order of the labels defines a strict linear comparison on supplied class well-orders of  $X$ . For set-like global well-orders, it agrees with first-disagreement comparison of their Ord-enumerations. This is [theorem 14.2](#) (source 12’s [theorem 14.7](#)); source 25 recalls it with its proof.*

*Source 25’s proof.* If  $x \in I(R, S)$  and  $yRx$ , then  $y$  is in the common predecessor class of  $x$ . Agreement on that class shows that  $y$  has the same predecessors in the two orders and that their restrictions

agree there. Thus  $y \in I(R, S)$ . The same argument works for  $S$ , proving initiality. For two points in  $I(R, S)$ , comparison with their predecessor classes shows agreement of the orders.

If  $I(R, S) = X$ , the orders coincide. Otherwise the class well-order property gives the two least points outside it. They cannot be the same point  $w$ : then the predecessor class of  $w$  in both orders would be exactly  $I(R, S)$ , with identical restrictions, putting  $w$  in  $I(R, S)$  after all.

For transitivity, compare  $I(R, S)$  and  $I(S, T)$  as initial segments of  $S$ . They are nested. If the first is properly shorter,  $S$  and  $T$  still agree at the next point where  $R$  separates from  $S$ ; hence the comparison of  $R$  with  $T$  is that of  $R$  with  $S$ . The symmetric argument applies if the second is shorter. If they coincide and  $R <_{\text{lex}} S <_{\text{lex}} T$ , their next labels satisfy  $u < v < w$ . Thus the distinct next labels  $u, w$  decide  $R <_{\text{lex}} T$  as well. Trichotomy and asymmetry are immediate from distinct next labels.

For exhaustive set-length words or full Ord-enumerations, the labels before the first unequal coordinate form exactly this common prefix. Hence the two definitions agree.  $\square$

This direct comparison is part of the maintained report ([theorem 14.2](#)). Its important foundational feature is that a proper-class common prefix causes no recursion problem. One compares the supplied relations directly rather than first trying to assign them class ordinal types.

### 103.2 Set-like is a genuine restriction

A class well-order is *set-like* when each point has only a set of predecessors. A proper-class set-like well-order has type Ord in GBC; the rank of each point is the set ordinal determined by its predecessor set, and these ranks exhaust Ord. This gives the enumeration interpretation used for  $\mathfrak{W}_{\text{sl}}$ .

Unrestricted well-orders may have a proper-class initial block followed by further elements: Ord + 1, Ord + Ord, and more elaborate supplied class well-orders are examples of possible types. They have no enumeration by Ord. Global choice provides enough coding to transport such orders to the carrier **No**, but does not turn them into set-like orders.

Numerically well-ordered subclasses also need not be set-like. [Note 86.2](#) embeds a supplied class order of type Ord + Ord into the numerical surreal line. Its range, with inherited numerical order, has that same non-set-like type. A claim that every increasing proper-class word has a set-like range would therefore require an additional hypothesis; a full injective Ord-word has a set-like range in its *enumeration* order, which need not coincide with the numerical order.

### 103.3 Termination, arbitrary words, and increasing subsets

When comparing exhaustive well-orders on one fixed carrier, a word cannot be a proper prefix of another exhaustive word. The position of a termination marker is irrelevant there. It becomes important for varying ranges, arbitrary words, and injective words of different lengths. An end-first convention places a proper prefix before all its extensions; a central marker places some next letters below and others above termination. These can produce different local characters and saturation behavior, as studied in the earlier reports ([part VII](#); sources 13 and 23).

The prefix geometry used here avoids that ambiguity. Nodes are ordered by extension, siblings by their numerical next labels, and full branches are compared at a genuine first disagreement. The new theorems therefore do not depend on selecting a termination marker for the entire node set.

The family of numerically increasing words is not preserved by our automorphisms, as [Section 91](#) shows. Nor is the injective extension lemma automatically valid after imposing monotonicity on each word: the next label must then be above all earlier labels, which adds cross-coordinate restrictions absent from its proof. Arbitrary repeated words remove the injectivity restriction but no longer

literally enumerate well-orders of their ranges. Each variation warrants its own theorem rather than a notational substitution.

### 103.4 Relation codes, order types, and quotients

One can fix a well-ordering of label pairs and compare characteristic functions of relations at their first unequal bit. In a set-like class pair order, a nonempty difference class has a least coordinate. This yields a valid code-dependent comparison, but generally not the common-prefix comparison in [Note 103.1](#). It orders the *bits describing the relations*, not the next labels in their enumerations.

Passing to unlabelled isomorphism types changes the problem again. Set-sized well-order types have canonical representatives in Ord, but a type-then-label ordering deliberately prioritizes length or type and need not preserve enumeration lexicography. For class well-orders, one must not form an ordinary class of proper-class equivalence classes. Work with supplied representatives and a definable equivalence relation, a higher sort, or an explicitly larger universe. The label relation of [Section 93](#) avoids this issue by representing each label class with its unique root edge.

## 104 A size and recursion audit (source 25)

### 104.1 Four different levels that should not be collapsed

For clarity, the objects in this article occupy the following levels.

| Object                                        | Legitimate representation in the global argument                                           |
|-----------------------------------------------|--------------------------------------------------------------------------------------------|
| One prefix or support code                    | A set, hence an element of an ordinary class                                               |
| The core and prefix tree                      | Ordinary classes of such sets; their incidence is a class relation                         |
| One full enumeration or raw order             | A supplied class relation, not an element of the core unless represented by a support code |
| All full enumerations, automorphisms, or cuts | Predicates on class variables; a literal collection requires a higher-level interpretation |

Kelley–Morse theory strengthens class comprehension, but its classes still have sets as elements. It does not authorize a same-level class whose members are all classes. A higher sort or a universe shift is needed when such a collection is to become an object.

### 104.2 Why the back-and-forth does not need ETR

The homogeneity proof uses the following operations, all at the indicated sizes.

| Operation                     | Size and principle used                                                                  |
|-------------------------------|------------------------------------------------------------------------------------------|
| Collect disagreement ordinals | Class replacement on a set of indices produces a set of ordinals                         |
| Build the forced prefix       | A set-length function; values are specified by elementary formulas with class parameters |
| Choose a core completion      | A set support code; global choice selects the least successful code                      |
| One back-and-forth history    | A set partial map between set codes at each set stage                                    |
| Take a limit history          | A union over a set ordinal of set partial maps                                           |
| Take the final automorphism   | Elementary comprehension of the union of the set-valued recursion                        |
| Transform one supplied branch | Formula ( <a href="#">S25.1</a> ), with the branch as a class parameter                  |

A set-valued recursion with an elementary class parameter can be expressed by saying that a value occurs in a set-sized correct initial history. Uniqueness of the histories follows by ordinary set

transfinite induction, and their existence by set recursion with the fixed parameters. Elementary comprehension then collects the compatible stages into a class. The stage value is never a new arbitrary class.

By contrast, a recursion assigning an entire class to each stage, such as an iterated truth predicate of class length, falls under materially stronger recursion principles. The class-game and class-forcing literature makes these distinctions precise [63, 22, 24]. The present proof does not infer a class-valued recursion theorem merely from the availability of  $\text{Ord}$  as an index class.

### 104.3 No uniform enumeration of all global enumerations

*Note 104.1* (Source 25, Proposition 14.1, “Diagonal obstruction to exhaustive class coding”). *No uniformly class-indexed family of global enumerations, with its index an ordinary class of sets, contains every member of  $\mathfrak{W}_{\text{sl}}$ .* This is [theorem 19.37](#) (source 12’s [theorem 19.38](#)), proved with a guard step at odd positions instead of a pair swap.

*Source 25’s proof.* By global choice it suffices to treat a uniform family  $(e_\alpha)_{\alpha \in \text{Ord}}$ , allowing repetitions and padding a smaller family if necessary. Construct an injective word  $d$  in two-position blocks. At position  $2 \cdot \alpha$ , choose an unused label different from  $e_\alpha(2 \cdot \alpha)$ . At position  $2 \cdot \alpha + 1$ , choose the least-indexed still unused label in the baseline enumeration  $b$ .

At each set stage the used labels form a set, so both choices exist. This is set-valued recursion. The second choice guarantees exhaustiveness. Indeed, for any  $\beta$ , the labels  $b(\gamma)$  with  $\gamma < \beta$  have all been used by some set-ordinal stage once they have each been used; a supremum of those set-many stages exists. At the next guard step,  $b(\beta)$  is used unless it has already appeared. Transfinite induction on  $\beta$  proves that every baseline label eventually occurs. Finally,  $d$  disagrees with  $e_\alpha$  at coordinate  $2 \cdot \alpha$  for each  $\alpha$ .  $\square$

This earlier diagonal mechanism ([theorem 19.37](#)) explains why the class of support codes can be dense without representing every global enumeration. The availability of a dense coded core is not an exhaustive coding theorem.

### 104.4 Cuts and the Burali–Forti boundary

The small-cut property used in [Note 86.3](#) allows only set-sized option families. An unrestricted rule filling every proper-class cut would already demand a surreal strictly greater than every surreal, by taking all of **No** on the left and nothing on the right. This is impossible. Similarly, the proper class  $\text{Ord}$  must not be treated as one of its own set ordinals. The proper-class scope of the enumeration domain is not a license to use it as a set-length prefix.

A cut of  $\mathcal{P}_s(b)$  is one supplied class of core codes. The totality of all such class cuts is not an ordinary class of sets. The trace decoder in [Note 92.1](#) acts on one supplied cut, and its uniform variants act on a supplied class-indexed family. This is enough for the results proved here.

### 104.5 Class realizations and external models

For a model  $(M, \mathcal{X})$  of GBC, the words and automorphisms in the global theorems are those admitted by its class realization  $\mathcal{X}$ . The homogeneity construction from admitted uniform parameters yields an admitted class map. Its statement does not refer to every externally imaginable subset of  $M$ .

With an inaccessible cardinal  $\kappa$  in an ambient set theory, the full-class interpretation  $(V_\kappa, \mathcal{P}(V_\kappa))$  makes the collection of internal classes an ordinary set in the ambient universe. All its internal full words can then be collected externally, and ordinary external maps between them can be discussed.

This is a legitimate larger-universe interpretation, not a proof that GBC internally has a class of all classes. Inaccessible cardinals are not required for the regular set theorem of [Section 94](#).

For fixed class relations in GBC, well-foundedness is equivalent to the absence of a set-coded descending  $\omega$ -sequence. In the nontrivial direction, a nonempty class with no minimal element lets global choice select a descending sequence by set recursion. Consequently, enlarging the class realization while keeping the set universe and a fixed relation unchanged does not change that relation's well-foundedness. What can change is which class relations and full branches are available. This scope distinction is also recorded in the repository's review notes (this report's README, "Other discrepancies", and [section 5.6](#)).

Finally, "all definable classes" requires an explicit metatheoretic or syntactic interpretation. Formula codes alone do not supply an unrestricted internal truth predicate. Restricting to a stated formula family, supplying the relevant satisfaction relation, or working externally over a fixed model avoids conflating definability with a same-level exhaustive class coding.

## 105 What this Part answers

[merge] Dated notes, 3 October 2026, in the form of [section 50](#); where Part VIII's notes or the question index of [section 113](#) say otherwise, these notes supersede them. Questions of sources 13–30 are cited by their labels in this report (`swo:sub:nnumber` for unlabelled ones).

- (a) *Which extra predicates make the reconstruction unique* (Part VIII's item (c) and Part IX's item (f), [section 60](#); source 11's [research question 113.4](#); source 14's "Minimal enrichment for exhaustiveness", [research question 113.34](#); source 13's "Minimal extra structure for recognizing branches", [research question 113.20](#); source 22's "Eliminating label data", [research question 113.135](#)): source 14's question is **answered**, the others **in part**. Unranked cylinder inclusion recovers every prefix height ([theorem 87.1](#)) and, with label occurrence, recognizes represented and exhaustive cuts ([theorem 87.4](#) and [corollary 87.5](#)). Without labels it does not: the core with all its cylinders and the order of children does not recognize exhaustive branches, even after naming any set of core points and nodes ([theorems 91.1](#) and [91.2](#) and [corollary 91.3](#)); nor does the ordered prefix tree without the core ([corollary 96.3](#) and [note 96.8](#)). Equality of labels on different extension edges suffices ([proposition 93.4](#)) and makes the core-and-cylinder structure rigid ([theorem 93.3](#); source 27's [note 96.5](#)). Open: whether a strictly weaker enrichment recognizes exhaustiveness while leaving nontrivial automorphisms (source 25's [research question 113.166](#)), and whether a support filtration recovers part of the labels ([research question 113.167](#)).
- (b) *The stabilizer of the exhaustive cuts* (Part VIII's item (c); source 14's "The exhaustive-trace stabilizer", [research question 113.33](#); source 17's "The extendible automorphism group", [research question 113.73](#); source 20's [research question 113.107](#); source 21's [research question 113.119](#)): **in part**. Not every cylinder-preserving automorphism belongs to it ([theorem 92.2](#)), even among those fixing a given set of core points and nodes ([theorem 91.2](#)); in the bare order, not every automorphism fixing a given set of core points and supported in one interval belongs to it ([theorem 97.7](#)); every automorphism of the ordered prefix tree agrees through any set height with one that preserves exhaustion ([corollary 96.12](#)), and explicit families preserve it ([theorem 96.4](#), source 27's antichain transformations, [proposition 96.11](#)). The structure of the stabilizer remains open (source 25's [research question 113.165](#)).
- (c) *Automorphism extension across residual fibres* (source 15's "Automorphism extension", [research question 113.51](#); source 14's "Automorphisms of raw trace fibers", [research question 113.39](#);

- source 20's [research question 113.108](#); source 21's [research question 113.120](#)): **answered** in an external set-sized model: a core automorphism extends to the raw order exactly when it preserves the isomorphism types of all residual fibres, with a split exact sequence ([theorem 98.5](#)). A uniform internal version is not given.
- (d) *Completion with residual data* (source 15's question, [research question 113.50](#)): **answered** in an external set-sized formulation ([theorem 98.2](#)); over residual alphabets traces merge at most two initial words ([proposition 99.2](#)), with an explicit example and interior completion point ([propositions 99.4](#) and [99.5](#)).
- (e) *Baselines* (source 11's [research question 113.5](#), Part VIII's item (d); source 17's "Changing baselines", [research question 113.74](#)): **further in part**. Relabelled cores are disjoint ([proposition 97.9](#)), and two cores coincide exactly when their baselines eventually agree, being otherwise disjoint (source 25's remark to [research question 113.170](#)). The general case remains open.
- (f) *Dependence on the class realization* (Part VIII's item (e) and Part IX's item (e); source 11's [research question 113.8](#); source 12's [research question 113.18](#); source 08's question 12; source 17's "Recovering a class realization", [research question 113.75](#); source 14's "Which new cuts can a class extension add?", [research question 113.43](#)): source 17's question is **answered**: the labelled core with its admitted represented cuts recovers the whole class realization ([theorem 102.3](#), with  $b$  and  $g$  fixed; [note 102.5](#), with  $b$  only; [note 102.16](#), with no baseline given), and pair-swap traces already suffice. Source 12's [research question 113.18](#) is **answered for externally countable models**: the external order is  $\mathbb{Q}$ , stays so with the core named and the baseline fixed, and detects neither the class part nor ETR ([theorem 102.13](#) and [propositions 102.19](#) and [102.20](#)); fixing the core pointwise recovers everything ([note 102.5](#) and [corollary 102.12](#)). In general the external order remembers at least the cardinality of the class part ([theorem 102.13](#)); what more it remembers for uncountable models is open. Source 22's "Reconstruction without fixed coding parameters" ([research question 113.136](#)) is answered by [notes 102.5](#) and [102.16](#); a definable common baseline exists exactly when  $V = \text{HOD}_p$  for some  $p$  ([theorem 102.21](#) and [corollary 102.22](#)). Source 18's "The expanded countable model" ([research question 113.88](#)) asks what depends on the countable class realization once the label evaluation is added: all of it, by [note 102.16](#); the classification of the expanded structure is open.
- (g) *Ordinal support bounds* (Part VIII's item (f); source 17's "Ordinal and birthday optima for supported completion", [research question 113.78](#); source 09's direction "Sharp birthday and support bounds" and source 08's question 13): the ordinal half is **answered**: the least ordinal  $\beta$  with a completing permutation supported in  $\beta$  is  $\max(\delta_S, \delta_T)$  ([theorem 101.2](#)). Birthday bounds and the forced-prefix length remain open, as source 27 says. Source 17's sentence after [corollary 49.10](#) ("It does not assert a minimum ordinal support bound") remains true of source 17's theorem; source 27 supplies the bound.
- (h) *Stale claims kept as provenance*. Source 20's opening of its Section 5 and source 21's opening of its Section 9 say they answer the repository's extension question negatively; at their pins that was new, and at this report's present state it is a second route to Part VIII's item (c) ([section 97](#)). Source 22's sentence "We have not shown that this label information can be discarded" is answered by source 25 ([note 87.6](#)).

## Part XIV

# Unrestricted class well-orders II: local size, condensation histories and external models

[merge] (3 October 2026.) The sequel to Part IX on unrestricted class well-orders of  $\mathbf{No}$ , and the last Part of the batch-83 addition. Part IX (part IX) printed what batch-81 sources 13–18 prove about them: direct comparison by the largest common labelled prefix, the canonical decomposition of one class well-order into Ord-blocks (theorem 52.3), explicit condensation histories of every prescribed class length (theorem 53.4), finite components (theorem 54.4), products, a  $\Sigma_1^1$  comprehension bound, and source 18’s classification of the full external order in countable  $\omega$ -standard models (theorem 58.6). This Part prints what seven batch-83 manuscripts add on the same objects. It is “II” relative to Part IX: every result printed there is cited by its Part IX label, and the batch-83 re-proofs of it are notes.

- [Section 106](#): source 23’s Sections 9–10, its re-proofs of direct comparison and of the canonical set-interval blocks, with the iteration of condensation by explicit witnesses (limits as unions of equivalences).
- [Section 107](#): local size inside the unrestricted order. Source 20’s Section 6 (the maximal final set tail, an exact local coding dichotomy, the convex blocks of locally set-sized intervals and their dense quotient with an unfilled countable cut, and the external cardinal form in a full model) and source 27’s Section 7 (every uniform class-indexed family misses a whole convex copy of  $\mathfrak{W}_{\text{all}}(\mathbf{No})$ ; the set analogue at every birthday cutoff).
- [Section 108](#): complete condensation histories. Source 20’s Section 7 (termination by the input order; exact heights  $\min\{\alpha : \theta \leq \kappa^\alpha\}$  in full models), source 23’s Section 11 (a second route to source 15’s polynomial histories, in the union-of-equivalences convention), source 29’s Section 11 (floor maps, finite normal forms, and the theorem that over GBC the existence of canonical condensation histories is equivalent to strong comparability of class well-orders), and source 23’s Section 12 (copies of polynomial orders of any prescribed hierarchy inside every interval between two distinct set-like global enumerations).
- [Section 109](#): countable class models. Source 18’s question on  $\omega$ -nonstandard models ([research question 113.89](#)) is answered three times independently, by source 19’s Section 12, source 20’s Section 8 and source 21’s Section 10. Source 19 is printed first and is the base: its [theorem 109.9](#) gives one complete theory for the pure order of *every* externally set-sized GBC model, the strongest of the three answers. Sources 20 and 21 follow as routes, each whole; what only they prove is printed as theorems (source 20’s external finite-condensation blocks and decidability of the common theory, source 21’s automorphism group of the nonstandard order and the first Cantor–Bendixson derivative). Source 30’s compactness observation closes the section.
- [Section 110](#): source 27’s Section 10 (foundations, full rank semantics, internal and external well-foundedness, and its ledger).
- [Section 112](#): what the Part answers.

The rules of [section 1.2](#) apply: a result proved in an earlier Part, or twice in this one, is printed once and every other copy is a numbered note quoting the statement, carrying the copy’s own label, followed by its own proof when the argument differs or the source adds a point.

*Provenance and what each source saw.* Sources 19 and 20 are pinned to d5bd4a67b, sources 21 and 23 to 109aaca15, sources 27, 29 and 30 to 7ff7736ec; none of these revisions contains Part IX.

Source 19 read batch-81 sources 15, 16 and 18 as supplied manuscripts, source 20 read source 18, and source 23 read drafts of sources 13, 14 and 17; source 29 read sources 19, 20 and 21; sources 21, 27 and 30 cite none of these manuscripts. Their overlaps with Part IX and with one another are therefore independent re-proofs unless a note says otherwise.

*Notation in this Part* (the batch-83 notation addendum, [section 1.3.2](#), lists every renaming).  $\mathfrak{W}_{\text{all}}(\mathbf{No})$ ,  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  as in [section 1.3](#); for a set-sized two-sorted model  $\mathcal{M}$ ,  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  and  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}}$  are the external sets of its admitted class well-orders and of its admitted set-like ones, as in Part IX (source 19's  $H_{\text{all}}^{\mathcal{M}}$ ,  $H_{\text{sl}}^{\mathcal{M}}$  and source 20's  $H^{\mathcal{M}}$ ; source 21's  $L^{\mathcal{M}}$  is kept, being defined in its text).  $\sigma(\mathcal{A})$  is the dense shuffle, as in [section 58](#);  $\mathcal{F} = \{n! : n \in \omega\}$  (source 19's  $\mathcal{D}$ ); the nonstandard interval type  $\omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*$  is  $I_{\infty}$  in all three countable-model sources (source 20's symbol; source 19's  $K$  and source 21's  $H$  are renamed, since  $K_R$  and  $H$  name a final set tail and a history here).  $P(\Gamma)$  is the class of finite-support ordinal-coefficient polynomials compared at their greatest disagreement, source 15's  $P(J)$  of [definition 53.1](#) (source 23's  $P(\Gamma)$  and source 29's  $\mathcal{P}(\Gamma)$  are renamed;  $\mathcal{P}(V_{\kappa})$  remains a power set). Source 20's common-prefix carrier  $P(R, S)$  is printed  $C(R, S)$ , this report's common prefix. Source 20's  $K_R$  is the largest final set segment of  $R$ , source 16's  $A_R$  ([corollary 52.7](#)). *False reading*: it is not the  $K_R$  of source 18's “Uniform removal through ordinary ordinal stages” in Part IX, which is an initial set-like part of a block index order. Source 27's  $\kappa = |X|$  is printed  $\mu$  and its  $S_{<\theta}$  is  $\mathbf{No}_{<\theta}$ ; its core  $\mathcal{D}_b$  is  $\mathcal{P}_s(b)$ ; source 23's  $\mathfrak{E}$  and  $\mathfrak{W}$  are  $\mathfrak{W}_{\text{sl}}$  and  $\mathfrak{W}_{\text{all}}$ . Displayed equations keep their source numbers as (SNN.n).

## 106 Direct comparison and set-interval condensation once more (source 23)

[merge] Source 23's Sections 9–10 recall the direct comparison of class well-orders and the canonical decomposition into set-interval blocks before its new constructions ([section 108](#)). Both are earlier results, printed as notes; the text around them is kept, including the warnings on what the raw order adds to the set-like one, and the iteration of condensation by explicit set witnesses.

### 106.1 Source 23: direct comparison beyond ordinal-class enumerations

A set-like well-order on  $\mathbf{No}$  has a class enumeration of order type  $\text{Ord}$ . A raw class well-order need not: examples include copies of  $\text{Ord} + \text{Ord}$  and lexicographic products of ordinal classes. Simply asking for the first *ordinal coordinate* of disagreement can miss an entire proper-class common prefix.

The repository gives a direct comparison ([theorems 14.2](#) and [14.7](#)). Here is the mechanism, with its foundational boundary made explicit.

*Note 106.1* (Source 23, Proposition 9.1, “Largest common labelled initial part”). *For two class well-orders  $H, K$  of the same labelled class  $X$ , there is an elementarily definable largest common initial part on which the two relations agree. If  $H \neq K$ , let  $a$  and  $b$  be the first remaining labels in  $H$  and  $K$ . Then  $a \neq b$ , and the rule*

$$H <_{\text{lex}} K \iff a <_X b$$

*defines a strict linear comparison on raw well-orders, when  $X$  has a fixed linear label order. No elementary transfinite recursion axiom is required.* This is [theorem 14.2](#) (source 12's [theorem 14.7](#)) with the same proof; Part IX prints the five batch-81 proofs ([section 51](#)).

*Source 23's proof.* Declare  $x$  to belong to  $P$  when its predecessor classes in  $H$  and  $K$  are equal and the two relations agree on that predecessor class. This is an elementary formula with class

parameters: equality of predecessor classes and agreement of relations use only quantification over set objects. If  $x \in P$ , every predecessor of  $x$  belongs to  $P$ ; the relations agree on  $P$ . Any common labelled initial part has this property and is contained in  $P$ .

If  $P = X$ , the orders agree. Otherwise the nonempty complement has an  $H$ -least point  $a$  and a  $K$ -least point  $b$ . Were  $a = b$ , its predecessor class would be  $P$  in both orders and it would belong to  $P$ , a contradiction.

For transitivity, compare the common parts  $P_{H,K}$  and  $P_{K,M}$  as initial segments of  $K$ . They are comparable by inclusion. If one is properly smaller, the first disagreement with the third order is the same as the earlier disagreement. If they are equal, the three next labels satisfy the transitive numerical comparison. This proves transitivity; trichotomy and asymmetry follow directly.  $\square$

The proposition remains a predicate-level statement about a fixed finite number of class relations. It does not collect every such relation into an ordinary class.

### 106.1.1 Why the raw order has phenomena absent from the set-like part

A raw order can have a proper-class common prefix with only two labels  $a < b$  left over. The two orders ending respectively in  $(a, b)$  and  $(b, a)$  are adjacent in the outer lexicographic order: there is no third permutation of the remaining carrier. This construction uses a well-order of  $\mathbf{No} \setminus \{a, b\}$  as the common prefix. The repository gives the more general exact finite-tail adjacency analysis (theorem 16.2; source 17's theorem 54.4).

By contrast, if two exhaustive Ord-enumerations differ after a set prefix, fresh surreal labels between the differing values remain available. Their interval contains many further enumerations and, as Section 108.4 will show, raw orders of arbitrarily prescribed condensation complexity.

## 106.2 Source 23: set-interval condensation without classes as elements

The classical finite condensation of a linear order identifies points with a finite interval between them; see, for example, Brown and Suárez [68]. We use a size-relative analogue for class well-orders: replace “finite” by “a set.” These are not the same operation, and finite-condensation theorems are not invoked as proofs of the class claims below.

**Definition 106.2.** For a class well-order  $H = (X, <_H)$ , put

$$x \sim_H y \iff [\min_H(x, y), \max_H(x, y)]_H \text{ is a set.}$$

Let  $B_H$  be the subclass of points that are least in their  $\sim_H$ -class. The *set-interval condensation* of  $H$  is  $D(H) = H \upharpoonright B_H$ .

Saying that the displayed interval is a set means that there exists a set whose members are exactly the points satisfying the interval formula. No powerclass is required.

*Note 106.3* (Source 23, Theorem 10.2, “Canonical block decomposition”). *The relation  $\sim_H$  is a convex equivalence relation. Every block has a least point, and  $B_H$  represents the quotient as a class well-order. Every block is either a set ordinal order or a copy of Ord. Every nonfinal block is a copy of Ord; a set-sized block can occur only as the final block.* This is source 15's theorem 52.3 (Part IX), proved there and by source 16 (theorem 52.6 with corollary 52.7) and source 18 (theorem 52.11) by the same rank argument; source 29's note 108.9 below is a fifth copy.

*Source 23's proof.* Reflexivity and symmetry are immediate. If  $x \sim_H y$  and  $y \sim_H z$ , the interval from  $x$  to  $z$  is contained in the union of the two given set intervals; Separation makes it a set.

Convexity follows by the same argument. Each block is an admitted nonempty subclass and has an  $H$ -least point  $b$ .

For  $x$  in this block, the interval  $[b, x)_H$  is a set well-order. Assign to  $x$  its ordinal order type. This is a class order isomorphism from the block onto an initial segment of  $\text{Ord}$ . If the block is a set, the range is a set ordinal. If the block is proper, the range cannot be a set, by Class Replacement applied to the inverse; hence the range is all of  $\text{Ord}$ .

Suppose a block  $C$  is a set and some point lies after it. The class of points strictly after every member of  $C$  has a least element  $d$ . For  $c \in C$ , the interval  $[c, d]_H$  is contained in  $C \cup \{d\}$ : a point between them outside  $C$  would be strictly after the whole convex block and contradict minimality of  $d$ . Thus  $c \sim_H d$ , impossible. Therefore a set block must be final.

The representative of a block is an ordinary set object. Restricting  $H$  to these representatives supplies the quotient order without ever using a proper block as an element of a class.  $\square$

In particular, every raw well-order is canonically a lexicographic sum of  $\text{Ord}$  blocks, possibly with one final set-ordinal block. The index order of those blocks can itself be a complicated raw well-order. This is a structural decomposition, not a claim that every raw order has only a set number of blocks.

### 106.2.1 Iteration with explicit witnesses

To keep every stage on the original domain, start with equality  $E_0$ . Given a convex equivalence relation  $E$ , define its condensation successor by

$$x D(E) y \iff \exists S \text{ a set } \forall z \in [x, y]_H \exists s \in S (zEs), \quad (\text{S23.3})$$

where the interval is written with its endpoints in increasing order. Thus a set of representatives meets all  $E$ -classes in the interval. At a limit stage take the union of earlier equivalences.

The witness in (S23.3) can be converted into a set of least representatives using Class Replacement. Accordingly it says exactly that the interval in the represented quotient is a set. This formula is elementary once  $E$  is a class parameter.

For a general raw order, asserting a uniform hierarchy of class-valued relations along an arbitrary class well-order is a genuine recursion principle.  $\text{GBC} + \text{ETR}$  is a sufficient setting; elementary transfinite recursion has strength beyond  $\text{GBC}$  [22, 24]. We make no claim here that full  $\text{ETR}$  is necessary for this particular operator. The next section avoids the issue for a large explicit family by writing down every stage simultaneously.

[merge] Source 23's successor rule (S23.3) with unions at limits is the convention of equivalence relations; sources 15, 20 and 29 iterate nested classes of least representatives and intersect them at limits (sections 53.1 and 108.1 and definition 108.10). Source 29's corollary 108.14 shows that the two conventions define the same history. Whether  $\text{ETR}$  is needed for general inputs is settled in the form of an equivalence by source 29's theorem 108.19, not by  $\text{ETR}$  itself (section 112).

## 107 Local size of intervals in the unrestricted order (sources 20 and 27)

[merge] Source 11's diagonal theorem (theorem 19.37) says that no uniform class of set codes exhausts the set-like order. Source 20 localizes it to intervals of the unrestricted order and finds an exact dichotomy: an interval  $[R, S]$  has a set-indexed exhaustive coding exactly when the residual carrier  $Y(R, S)$  after the common prefix is a set, and otherwise no uniform family indexed by any

class of sets exhausts even the open interval. The resulting equivalence  $\equiv_{\text{set}}$  has convex blocks  $\mathcal{W}(K_R)$ , and its quotient is dense but not set-cut-filling. Source 27 proves the stronger omission: a uniform family misses a whole convex copy of  $\mathfrak{W}_{\text{all}}(\mathbf{No})$ , so no uniform family is dense in the raw comparison. Both are new against the repository.

### 107.1 Source 20: A local size dichotomy for the unrestricted lexicographic order

The global failure of exhaustive set coding has a sharper local form. An interval can have an ordinary set of codes, or it can defeat every uniform family indexed by a class of sets. The distinction is determined by exactly one geometric feature: how many labels remain after the endpoints' common prefix. Throughout this section we work in GBC. Several of the structural lemmas only use GB once the displayed well-orders have been supplied.

We use the elementary comparison of labelled class well-orders established in this report (theorems 14.2 and 14.7) and source 18 (theorem 51.16). If  $R \neq S$  are class well-orders of  $\mathbf{No}$ , their maximal common labelled prefix has carrier  $C(R, S)$ . The first labels after this prefix are distinct; their numerical comparison decides  $R <_{\text{lex}} S$ . We put  $C(R, R) = \mathbf{No}$  and write

$$Y(R, S) = \mathbf{No} \setminus C(R, S).$$

The common prefix carries a relation as well as a carrier. Thus equality of prefix carriers below always includes agreement of their induced orders when that agreement is needed.

A labelled class prefix  $p$  consists of a class  $A_p \subseteq \mathbf{No}$  with a specified class well-order. Its cylinder

$$\text{Cyl}(p) = \{R : R \text{ extends } p \text{ as a labelled initial segment}\}$$

is notation for a predicate on class relations. It is convex under the native lexicographic comparison. In particular, its members need not have set codes, and the braces do not assert that these members form an ordinary GB class. Whenever  $\mathbf{No} \setminus A_p$  is nonempty, a completion exists: append a fixed global well-order of the remaining labels.

#### 107.1.1 Final set tails and interior cylinders

For a class well-order  $R$  of  $\mathbf{No}$ , put

$$K_R = \{x \in \mathbf{No} : \{y \in \mathbf{No} : xRy\} \text{ is a set}\}.$$

This definition uses only set quantifiers with  $R$  as a class parameter.

*Note 107.1* (Source 20, Lemma 6.1, “The maximal final set tail”). *The class  $K_R$  is either empty or a set. It is final in  $R$  and is the unique maximal final subset of  $R$  that is a set. If it is nonempty, it is the final set block in the canonical set-interval decomposition of  $R$ .* This is source 16’s corollary 52.7 (Part IX), whose  $A_R$  is the present  $K_R$ , with the same argument; the uniqueness and maximality clauses are explicit here.

*Source 20’s proof.* Finality follows because a tail after a later point is contained in the tail after an earlier point. If  $K_R$  is nonempty, let  $k$  be its  $R$ -least member. Then

$$K_R = \{k\} \cup \{y : kRy\},$$

which is a set by the definition of  $k$ . Every final set  $T$  lies in  $K_R$ : for  $x \in T$ , the tail after  $x$  is contained in  $T$ .

For the block assertion, recall that two labels lie in one canonical block precisely when the closed interval between them is a set (theorem 52.3; source 18's theorem 52.11). All of  $K_R$  lies in one such block. If  $zRk$  belonged to that block, the union of  $[z, k]_R$  and the set tail after  $k$  would make the tail after  $z$  a set, contradicting the minimality of  $k$ . Conversely every point of a final set block has a set tail. Thus the two descriptions agree.  $\square$

The next lemma is the main local argument. It is useful because the unused numerical alphabet can be a very thin proper subclass of  $\mathbf{No}$ ; one cannot assume that it contains a numerical separator between two specified labels.

**Lemma 107.2** (An interior cylinder with a proper residual alphabet). *Suppose  $R <_{\text{lex}} S$  and  $Y(R, S)$  is a proper class. There exists a labelled class prefix  $p$  such that*

$$\emptyset \neq \text{Cyl}(p) \subseteq (R, S), \quad \mathbf{No} \setminus A_p \text{ is a proper class.}$$

*This conclusion uses only GB and the supplied class well-orders, apart from the use of Global Choice to choose an arbitrary completion of the resulting prefix.*

*Proof.* Let  $C = C(R, S)$ , let  $Y = \mathbf{No} \setminus C$ , and let  $a < b$  be the first labels of  $R, S$  respectively after  $C$ . Consider an ascent in the  $R$ -tail,

$$aRxRy, \quad x < y, \quad \{z : xRz\} \text{ a proper class.} \quad (\text{A})$$

If such a pair exists, transpose the labels  $x, y$  in  $R$  to obtain an order  $T$ . At the first changed position,  $R$  has label  $x$  and  $T$  has label  $y > x$ , so  $R < T$ . Both still start with  $a$  immediately after  $C$ , whereas  $S$  starts with  $b > a$ , so  $T < S$ .

Take for  $p$  the prefix whose labels are  $\{z : zRx\}$ , in their  $R$ -order, followed by  $y$ . Every completion of  $p$  has the same two strict comparisons just described. Its residual carrier is

$$\mathbf{No} \setminus A_p = \{x\} \cup (\{z : xRz\} \setminus \{y\}),$$

which is proper. This supplies the desired cylinder. Dually, a descent

$$bSxSy, \quad x > y, \quad \{z : xSz\} \text{ a proper class} \quad (\text{D})$$

gives a cylinder inside  $(R, S)$  by transposing  $x, y$  in  $S$ .

Suppose neither (A) nor (D) exists. By note 107.1, the class

$$Z = Y \setminus (K_R \cup K_S \cup \{a, b\})$$

is proper. If  $uRv$  are in  $Z$ , then  $aRu$ , the tail after  $u$  is proper, and failure of (A) implies  $u > v$  numerically. Hence  $R$  on  $Z$  is strictly numerically decreasing. Failure of (D) similarly implies that  $S$  on  $Z$  is strictly numerically increasing.

The restriction of each relation to  $Z$  is a class well-order. Recursively take the first  $\omega$  elements of  $(Z, S)$ : at every finite stage the complement of the finitely many selected elements is nonempty, and its  $S$ -least member is uniquely specified. Ordinary set-valued recursion with class parameters yields a set sequence  $(z_n)_{n < \omega}$ . Its entries strictly increase numerically, so  $z_{n+1}Rz_n$  for every  $n$ . Its range is a nonempty available subclass with no  $R$ -least element, a contradiction. Thus (A) or (D) exists, completing the proof.  $\square$

[merge] Source 18's lemma 58.4 (Part IX) finds, by the same ascent–descent alternative, a cylinder with *infinite* residual carrier inside an interval joining two finite-condensation blocks; the lemma above is its proper-class analogue, with the final set tails  $K_R, K_S$  in place of the maximal finite tails.

### 107.1.2 Uniform coding and its diagonal obstruction

For precision, a *uniform  $I$ -indexed family* of class well-orders means a single class relation  $F \subseteq I \times \mathbf{No} \times \mathbf{No}$ , where  $I$  is a class of sets and the section

$$F_i = \{(x, y) : (i, x, y) \in F\}$$

is a class well-order for each  $i \in I$ . A predicate on class well-orders has an exhaustive such coding if every available well-order satisfying it is one of these sections. This last condition is an assertion with class quantifiers; it is not an application of elementary comprehension to a collection of classes. Set-indexed coding means that  $I$  is a set.

**Lemma 107.3** (A diagonal inside every proper-residual cylinder). *If  $\mathbf{No} \setminus A_p$  is proper, no uniform family indexed by any class of sets exhausts  $\text{Cyl}(p)$ . More strongly, for every uniform class-indexed family  $(R_i)_{i \in I}$  of well-orders of  $\mathbf{No}$ , some member of  $\text{Cyl}(p)$  differs from every  $R_i$ .*

*Proof.* Put  $Y = \mathbf{No} \setminus A_p$ . Global Choice supplies a class bijection from  $\text{Ord} \times \{0, 1\}$  to  $Y$ . Thus  $Y$  is partitioned into disjoint pairs  $\{u_\xi, v_\xi\}$  for  $\xi \in \text{Ord}$ ; name their labels so that  $u_\xi < v_\xi$  numerically. Global Choice also supplies a class injection  $\sigma : I \rightarrow \text{Ord}$ .

Define an ordered pair at every ordinal  $\xi$ . If  $\xi = \sigma(i)$ , put  $u_\xi, v_\xi$  in the opposite order to their order in  $R_i$ . The index  $i$  is unique. At other coordinates use the order  $(u_\xi, v_\xi)$ . This rule is elementary in the given class parameters. Append these pairs, in increasing ordinal order, after the prefix  $p$ . The result  $T$  is a class well-order of  $\mathbf{No}$ : a nonempty subclass either has a least member in the prefix, or has a least pair index and then a least member of that finite pair. It belongs to  $\text{Cyl}(p)$ .

For each  $i$ , the two labels in pair  $\sigma(i)$  occur in the opposite relative order in  $T$  and  $R_i$ . Hence  $T \neq R_i$ . The construction has produced one ordinary class relation from the given uniform family, without enumerating any collection of classes.  $\square$

[merge] The pair-swap diagonal is the one of source 11's [theorem 19.37](#) and source 12's [theorem 19.38](#), run inside a cylinder; source 27's [theorem 107.8](#) ([section 107.2](#)) strengthens the conclusion from one omitted order to a whole omitted convex copy of  $\mathfrak{W}_{\text{all}}(\mathbf{No})$ .

**Theorem 107.4** (Exact local coding dichotomy). *For two distinct class well-orders  $R <_{\text{lex}} S$  of  $\mathbf{No}$ , the following are equivalent:*

1.  $Y(R, S)$  is a set;
2. the closed interval  $[R, S]$  has a uniform set-indexed exhaustive coding;
3. the open interval  $(R, S)$  has a uniform exhaustive coding indexed by a class of sets.

*If these conditions fail, every proposed uniform class-indexed family omits a well-order strictly between  $R$  and  $S$ .*

*Proof.* Suppose  $Y = Y(R, S)$  is a set and let  $p$  be the common labelled prefix. The cylinder of  $p$  consists precisely of the orders obtained by appending a well-order of  $Y$ . All such well-orders form the ordinary set  $\mathcal{W}(Y) \subseteq \mathcal{P}(Y \times Y)$ . Concatenation gives a uniform family of class relations indexed by this set. Every order in  $[R, S]$  extends  $p$  by prefix convexity. Filter the index set by the elementary native comparisons  $R \leq F_i \leq S$ . Separation with the supplied class parameters gives a set of indices coding exactly the closed interval. Filtering with strict comparisons gives the open interval, proving  $(1) \Rightarrow (2) \Rightarrow (3)$ .

If  $Y$  is proper, [lemma 107.2](#) gives a proper-residual cylinder inside  $(R, S)$ . [Lemma 107.3](#) constructs within that cylinder a well-order omitted by any proposed class-indexed family. This contradicts (3), and proves both the remaining implication and the last assertion.  $\square$

This is a sharper conclusion than an estimate of cardinality. In GB there is no ordinary cardinal assigned to the collection of all class well-orders. The theorem instead gives a precise dichotomy in terms of legitimate uniform presentations. In particular, for these intervals, allowing a proper class of set indices does not enlarge the family of intervals that can be exhaustively presented.

### 107.1.3 The convex blocks of locally set-sized intervals

Define

$$R \equiv_{\text{set}} S \iff Y(R, S) \text{ is a set.}$$

Equality satisfies this convention because  $Y(R, R) = \emptyset$ .

**Theorem 107.5** (Canonical local-size blocks). *The relation  $\equiv_{\text{set}}$  is a convex equivalence relation on the predicate of class well-orders of  $\mathbf{No}$ . The block containing  $R$  consists exactly of the orders obtained by keeping the labelled prefix on  $\mathbf{No} \setminus K_R$  and replacing the final well-order of the set  $K_R$  arbitrarily. Consequently its native lexicographic order is represented by the ordinary set order  $\mathcal{W}(K_R)$ .*

*Proof.* Symmetry and reflexivity are immediate. For transitivity, the common prefixes of  $(R, S)$  and  $(S, T)$  are initial segments of the same order  $S$ , so one is contained in the other. The shorter is a common labelled prefix of  $R, T$ . If both original residuals are sets, so is the residual after this shorter prefix, and hence so is  $Y(R, T)$ . Convexity follows from prefix convexity: an order between  $R, S$  extends their common prefix, so its common-prefix residual with either endpoint is a subset of  $Y(R, S)$ .

Suppose  $R \neq S$  and  $Y(R, S)$  is a set. Let  $a$  be the first  $R$ -label outside their common prefix. Its strict  $R$ -tail is a subset of  $Y(R, S)$ , so  $a \in K_R$ . Hence the common prefix already contains every label of  $\mathbf{No} \setminus K_R$ , in its original  $R$ -order. Conversely, if  $S$  keeps that prefix and appends any well-order of  $K_R$ , then  $R, S$  share that prefix and their first-disagreement residual, if any, is contained in the set  $K_R$ . This proves the block description. The numerical first difference inside the common set tail is exactly the usual comparison on  $\mathcal{W}(K_R)$ .  $\square$

If  $K_R = \emptyset$  or  $|K_R| = 1$ , the block is a singleton. If  $|K_R| = n < \omega$ , its size is  $n!$ . If  $K_R$  is infinite of cardinality  $\mu$ , its size is  $2^\mu$ : the upper bound follows from coding a relation by a subset of  $K_R^2$ , and independent orientations of  $\mu$  disjoint pairs give the lower bound. The ordered structure for an infinite tail depends on its numerical alphabet, so cardinality alone does not classify these blocks. Every set alphabet  $K \subseteq \mathbf{No}$  occurs as such a final tail: well-order  $\mathbf{No} \setminus K$  in type Ord and append a well-order of  $K$ .

We may discuss a quotient comparison using representatives and  $\equiv_{\text{set}}$ . The notation  $[R]$  in the next statement is only an abbreviation for this equivalence relation. It does not make an equivalence class of class relations into a set or an ordinary class element.

**Theorem 107.6** (A dense quotient that does not fill countable cuts). *The quotient comparison by  $\equiv_{\text{set}}$  is dense and has no endpoints. Nevertheless there are two uniformly coded countable families whose quotient classes form an unfilled cut of character  $(\omega, \omega)$ . Thus deleting all locally set-sized blocks does not produce a surreal-like set-cut-filling order.*

*Proof.* Let  $R < S$  belong to different blocks. Their residual is proper, so lemma 107.2 gives a proper-residual cylinder inside  $(R, S)$ . Choose three different labels from its residual, sort them numerically, and form completions  $T_0 < T_1 < T_2$  beginning with these respective labels after the

prefix. Their first disagreements leave the entire proper residual unused, so the three completions lie in three different blocks. Convexity of the blocks gives

$$[R] < [T_1] < [S].$$

To obtain blocks on both sides of any  $R$ , choose first labels numerically below and above the first label of  $R$ , and complete them. Their disagreement with  $R$  occurs before any common label, leaving the proper residual **No**.

For the countable gap, use the proper numerical alphabet

$$Y = (\mathbb{Q} \setminus \{0\}) \cup \{\alpha : \alpha \in \text{Ord}, \alpha \geq \omega\} \cup \{-\alpha : \alpha \in \text{Ord}, \alpha \geq \omega\} \subseteq \mathbf{No}.$$

Its complement is proper as well: for example, the labels  $\alpha + \frac{1}{2}$  for infinite ordinals  $\alpha$  are in that complement and are pairwise distinct. Choose one class well-order  $p$  of  $\mathbf{No} \setminus Y$  and use it as a prefix. For each positive integer  $n$ , let  $R_n$  extend  $p$  with first remaining label  $-1/n$ , and let  $S_n$  extend it with first remaining label  $1/n$ . Append a fixed global order of the unused labels in each case. These constructions are uniform in  $n$ , and

$$[R_n] < [R_{n+1}] < [S_{m+1}] < [S_m] \quad (n, m \geq 1).$$

All the displayed classes are distinct because different first labels after  $p$  leave the proper residual  $Y$ .

Suppose a class  $[T]$  lies above every  $[R_n]$  and below every  $[S_n]$ . In particular,  $R_1 < T < S_1$ , so prefix convexity forces  $T$  to extend  $p$ . Let  $y \in Y$  be its first remaining label. The inequalities imply

$$-1/n \leq y \leq 1/n \quad (n \geq 1).$$

No member of  $Y$  satisfies these inequalities: a nonzero rational fails one of them by the Archimedean property of  $\mathbb{Q}$ , and an ordinal or negative ordinal of magnitude at least  $\omega$  fails already for  $n = 1$ . This is a contradiction.

The downward closure of the  $[R_n]$  and the upward closure of the  $[S_n]$  therefore partition the quotient comparison. The first family is cofinal on the lower side, and the second is coinital on the upper side. Neither side has an endpoint because the displayed sequences are strictly monotone. No finite family can be cofinal or coinital on the respective side, proving the exact character  $(\omega, \omega)$ . These closures are again predicates on representatives; the proof does not collect quotient objects.  $\square$

**Corollary 107.7** (The external cardinal form of the local dichotomy). *Let  $\kappa$  be strongly inaccessible in an ambient ZFC universe and interpret classes using  $(V_\kappa, \mathcal{P}(V_\kappa))$ . The raw order of all internal class well-orders of the internal surreal carrier is then an ordinary ambient set order. For any two distinct members  $R < S$ , its open and closed intervals satisfy*

$$\begin{aligned} |(R, S)| &\leq |[R, S]| < \kappa, & \text{if } Y(R, S) \text{ is an internal set,} \\ |(R, S)| &= |[R, S]| = 2^\kappa, & \text{if } Y(R, S) \text{ is internally proper.} \end{aligned}$$

*Thus  $\equiv_{\text{set}}$  is exactly the external condensation relation defined by  $|[R, S]| < \kappa$ . Its quotient has  $2^\kappa$  points, and every open quotient interval with distinct bounds has  $2^\kappa$  points.*

*Proof.* The full-model size check, proved again in [corollary 108.3](#), identifies internal sets with ambient subsets of cardinality less than  $\kappa$ . The surreal carrier has ambient cardinality  $\kappa$ . If  $Y(R, S)$  is an internal set of cardinality  $\mu < \kappa$ , the common-prefix cylinder is coded by a subset of  $\mathcal{P}(Y(R, S)^2)$ . Its cardinality is less than  $\kappa$  by the strong-limit property, proving the first case.

If the residual is internally proper, its ambient size is  $\kappa$ . By lemma 107.2, the open interval contains a cylinder whose residual also has size  $\kappa$ . Independent orientations of  $\kappa$  disjoint pairs in that residual give  $2^\kappa$  distinct completions in the cylinder. All are available because this is the full-class model. Conversely every raw well-order is a relation on a carrier of size  $\kappa$ , so there are at most  $2^\kappa$  such orders. This proves the second case and the condensation characterization.

The whole raw order has  $2^\kappa$  elements, again by pair coding and the relation-coding upper bound. Each equivalence block has fewer than  $\kappa$  elements by theorem 107.5 and the strong-limit property. Hence there are  $2^\kappa$  blocks: fewer blocks, even allowing  $\kappa$  elements per block, could not cover  $2^\kappa$  elements. Finally, for  $[R] < [S]$  the raw interval  $(R, S)$  has  $2^\kappa$  elements. Discarding the two endpoint blocks removes fewer than  $\kappa$  elements. Grouping the remaining elements into blocks of size less than  $\kappa$  still leaves  $2^\kappa$  distinct blocks strictly between  $[R]$  and  $[S]$ .  $\square$

[merge] Source 20's Section 10 uses the same full model to re-prove source 11's nonembedding theorem 20.1, by counting  $2^\kappa$  disjoint six-point blocks against a dense subset of size  $\kappa$ ; that passage is printed with source 20's foundations.

Two condensation operations have now appeared and must be kept separate. In corollary 107.7 the points being condensed are *whole well-orders*, and the retained blocks describe local interval sizes in their lexicographic order. The next section condenses intervals *inside one supplied well-order*, whose points are surreal labels. The common set/class boundary does not identify these different orders or their quotients.

## 107.2 Source 27: uniform families miss whole convex copies of the raw order

The bounded-support core is a dense ordinary class of set codes for the set-like interpretation. Could a more elaborate ordinary class of codes be dense in the raw comparison? The answer is negative. A diagonal argument leaves enough unused labels to retain a convex copy of the entire raw order, rather than just producing one omitted object.

### 107.2.1 The diagonal construction

**Theorem 107.8** (An omitted convex copy). *Work in GBC. Let  $I$  be any ordinary class, and let  $\mathcal{R}(i, x, y)$  be a uniform family of binary relations on  $\mathbf{No}$ . There is a convex family of raw class well-orders, described by explicit operations on class variables, that is order-isomorphic to  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  and contains none of the relations  $R_i$ .*

*In particular, no uniformly class-indexed family of raw well-orders meets every nonempty open interval of the raw comparison.*

*Proof.* Reserve  $A = (0, 1) \subseteq \mathbf{No}$  and put  $B = \mathbf{No} \setminus A$ . The map that prefixes the signs  $(+, -)$  is a numerical order isomorphism  $\varphi : \mathbf{No} \rightarrow A$ . The complement  $B$  is a proper class. Global Choice provides a bijection  $c : \text{Ord} \rightarrow B$  and an injection  $j : I \rightarrow \text{Ord}$ .

The ordinal pairs

$$\{2 \cdot \alpha, 2 \cdot \alpha + 1\}, \quad \alpha \in \text{Ord},$$

partition  $\text{Ord}$ . Here  $2 \cdot \alpha$  is left ordinal multiplication. Write  $x_\alpha = c(2 \cdot \alpha)$  and  $y_\alpha = c(2 \cdot \alpha + 1)$ . List these pairs in order of  $\alpha$ . Within pair  $\alpha = j(i)$ , choose its orientation opposite to the truth value of  $R_i(x_\alpha, y_\alpha)$ : put  $x_\alpha$  before  $y_\alpha$  exactly when that truth value is false. There is at most one such  $i$  because  $j$  is injective. Orient all unassigned pairs by a fixed default. This elementary definition gives a class bijection  $h : \text{Ord} \rightarrow B$  and its induced well-order  $P_h$ .

For every class well-order  $Q$  of  $A$ , form  $h + Q$ , placing all of  $B$  first in the order  $P_h$ , then all of  $A$  in order  $Q$ . Its initial set-like block is exactly  $h$ , since every point of  $A$  has the proper class

$B$  before it. Thus these orders constitute the convex fiber (S27.2) (source 11's [proposition 15.3](#)). Restriction to  $A$  and concatenation with  $h$  identify its raw comparison with  $\mathfrak{W}_{\text{all}}(A)$ ; conjugation by  $\varphi$  identifies the latter with  $\mathfrak{W}_{\text{all}}(\mathbf{No})$ .

Every member of this fiber differs from  $R_i$  on the ordered pair  $(x_{j(i)}, y_{j(i)})$ . Therefore the whole fiber is omitted, even though the input sections were not assumed to be well-orders.

For the final claim choose  $a_0 < a_1 < a_2$  in  $A$  and well-orders  $Q_0, Q_1, Q_2$  of  $A$  beginning with these respective labels. Global Choice completes the residual carriers. Then  $h + Q_0 < h + Q_1 < h + Q_2$ . Convexity puts the nonempty ambient interval  $(h + Q_0, h + Q_2)$  inside the omitted fiber.  $\square$

The conclusion is stronger than failure of exhaustive coding. A uniform family might omit many points and still be dense; this theorem rules that out for the raw comparison. It does not rule out cofinal or cointial uniform families: varying the first numerical label through  $\mathbf{No}$  gives such families immediately. It also does not contradict density of  $\mathcal{P}_s(b)$  in  $\mathfrak{W}_{\text{sl}}$ , because the fiber used above has a proper-class tail and contains no set-like global well-order.

The reference to a “convex family” is shorthand for a predicate on class variables together with the transformations  $Q \mapsto h + Q$  and restriction to  $A$ . It is not a claim that this family is a class of sets. Every step in the proof is elementary comprehension with class parameters, supplemented by Global Choice for the two enumerations.

### 107.2.2 The set analogue at birthday cutoffs

The same mechanism has a useful set version, where ordinary counting can replace class diagonalization.

**Theorem 107.9** (Many disjoint convex copies). *Let  $X$  be an infinite linearly ordered set of cardinality  $\mu$ . Suppose a convex subset  $A \subseteq X$  is order-isomorphic to  $X$  and  $B = X \setminus A$  has cardinality  $\mu$ . Then  $\mathcal{W}(X)$ , with enumeration lexicography, contains  $2^\mu$  pairwise disjoint convex copies of itself. Every subset of size less than  $2^\mu$  misses one such copy, and its order-topological density and cellularity both equal  $2^\mu$ .*

*Proof.* There are  $2^\mu$  bijections  $h : \mu \rightarrow B$ : independent pair swaps give the lower bound, while  $\mu^\mu = 2^\mu$  gives the upper bound. For each such  $h$ , consider the completions  $h + Q$  with  $Q \in \mathcal{W}(A)$ . They are a prefix cylinder and therefore convex. Restriction identifies the cylinder with  $\mathcal{W}(A) \cong \mathcal{W}(X)$ . Distinct bijections have distinct length- $\mu$  prefixes, so their cylinders are disjoint.

Each cylinder contains three points in increasing order, hence a nonempty ambient open interval. Selecting one such interval per cylinder gives  $2^\mu$  disjoint nonempty open intervals. Every dense subset must meet all of them. Since  $|\mathcal{W}(X)| = 2^\mu$ , both bounds are exact. A set of fewer than  $2^\mu$  points meets fewer than that many disjoint cylinders, proving the stronger omitted-copy assertion.  $\square$

For every infinite ordinal  $\theta$ , this theorem applies to  $X = \mathbf{No}_{<\theta}$ . The cone  $A = (0, 1) \cap \mathbf{No}_{<\theta}$  consists precisely of  $(+, -) \frown s$  for  $s \in \mathbf{No}_{<\theta}$  and is isomorphic to  $X$ . Finite prefixing preserves every infinite birthday cutoff: for finite  $\alpha$  the new length is finite, while for infinite  $\alpha$  one has  $2 + \alpha = \alpha$ . The complement contains the whole negative-sign cone, also isomorphic to  $X$ , and therefore has the same cardinality. No inaccessible-cardinal assumption enters this statement about a fixed set of sign sequences.

The exact density formula overlaps the earlier corpus (source 16's [theorem 27.2](#), its “Moreover” clause). The point of the argument here is its stronger geometric form: small subsets miss an entire convex self-copy. The class theorem replaces the unavailable hypercardinality count by an explicit diagonal on a uniform family.

*Note 107.10* ([merge]; how the omission results compare). Four uniform-coding obstructions are now printed. Source 11's [theorem 19.37](#) and source 12's [theorem 19.38](#) produce one global enumeration omitted by a given uniform family; source 20's [lemma 107.3](#) produces one omitted order inside every cylinder with proper residual carrier, hence inside every interval whose residual  $Y(R, S)$  is proper ([theorem 107.4](#)); source 27's [theorem 107.8](#) omits an entire convex fibre isomorphic to  $\mathfrak{W}_{\text{all}}(\mathbf{No})$ , so a uniform family is not even dense in the raw comparison. Source 27's theorem does not decide the local question of source 20's dichotomy (its omitted fibre is chosen by the diagonal, not inside a prescribed interval), and it does not contradict density of the core in the set-like order: its fibre has a proper-class tail and contains no set-like order, as source 27 says.

## 108 Complete condensation histories (sources 20, 23 and 29)

[merge] Part IX printed source 15's explicit histories: for every class well-order  $J$ , the polynomial order  $P(J)$  has an elementary history indexed by  $J + 1$  whose stages are proper and whose appended last stage is a singleton ([theorem 53.4](#)). Three batch-83 sources go further. Source 20 proves that a *supplied* nested history of an arbitrary class well-order  $W$  terminates by the stage  $W + 1$ , names ETR as a sufficient existence principle, and computes the exact heights in full models. Source 23 re-proves source 15's polynomial histories in the equivalence-relation convention and places copies of them inside every interval between two distinct set-like global enumerations. Source 29 gives each point of a well-order with a terminating history a finite polynomial address, and proves over GBC that the existence of canonical histories for all inputs is equivalent to strong comparability of class well-orders. All three take the same nested-representative operator  $D_W$  and the same limit convention, up to source 29's [corollary 108.14](#), which identifies source 23's union of equivalences with the intersection of representatives used by sources 15, 20 and 29.

### 108.1 Source 20: complete condensation histories: a bound and an exact model

The canonical set-interval decomposition is elementary. A supplied uniform history of successive decompositions can also be analysed elementarily. The issue of obtaining that history for an arbitrary input is separate. The preceding continuation realized arbitrary class well-orders as first-level block-index orders, analysed removal of initial blocks through ordinary ordinal stages, and supplied a polynomial example isomorphic to its own first condensation (source 18; [theorem 52.14](#) and [proposition 52.15](#)). Those results do not by themselves supply a uniform history of iterated quotients for every input. Here we prove that a complete history always terminates when it is run long enough, specify one sufficient recursion hypothesis, and calculate its exact height in full-class models.

#### 108.1.1 A precise limit convention

Let  $(X, W)$  be a nonempty class well-order. For a nonempty subclass  $A \subseteq X$  containing  $m = \min_W X$ , define  $D_W(A)$  to be the least representatives of the equivalence relation

$$x \sim_A y \iff \{z \in A : \min_W(x, y) \leq_W z \leq_W \max_W(x, y)\} \text{ is a set.}$$

Thus  $D_W(A) \subseteq A$  and it contains  $m$ . This is an elementary operator on classes with  $W$  as parameter. In particular, if  $A \neq \{m\}$  and  $s$  is the least member of  $A \setminus \{m\}$ , then  $s \notin D_W(A)$ , because  $[m, s]_{W \upharpoonright A} = \{m, s\}$ .

A *nested representative history* uses  $A$  itself as the carrier at each stage, rather than replacing it by an unspecified isomorphic copy. At successor stages apply  $D_W$ , and at nonzero limit stages

intersect all earlier retained subclasses. The limit convention is essential: abstract order isomorphism types alone do not retain the information needed to form these intersections.

**Theorem 108.1** (Termination by the input order). *Work in GB. Suppose a single class relation uniformly codes a nested representative history  $(H_i)_{i \in (X, W) + 1}$ , with*

$$H_m = X,$$

*successor stages given by  $D_W$ , and nonzero limit stages given by intersection. Here one fresh final stage  $*$  has been appended to the index order  $(X, W)$ . Then*

$$H_* = \{m\}.$$

*More precisely, for every  $x \in X$ ,*

$$H_x \subseteq \{m\} \cup \{y \in X : x \leq_W y\}. \quad (\text{S20.1})$$

*For arbitrary  $W$ , elementary transfinite recursion along  $(X, W) + 1$  is a sufficient hypothesis for the required uniform history to exist. No necessity or reverse-mathematical equivalence is asserted.*

*Proof.* The recursion rules imply that the retained classes are decreasing and all contain  $m$ . Transfinite induction along  $W$  is available in GB for formulas with the supplied history as a class parameter: a nonempty class of counterexamples would have a least member. We prove (S20.1) by that induction.

At the first stage  $x = m$ , the assertion is immediate. Suppose  $x$  is the immediate successor of  $t$ . By induction, no member of  $H_t$  lies strictly below  $t$  except possibly  $m$ . If  $t \neq m$  and  $t \in H_t$ , it is therefore the immediate successor of  $m$  in the induced order on  $H_t$ , and is deleted by  $D_W$ . All earlier members other than  $m$  have already disappeared. If  $t = m$ , there are no earlier nonminimal members to delete. In either case  $H_x = D_W(H_t)$  contains no  $y <_W x$  except  $m$ , as required.

If  $x$  is a nonzero limit point of the index order, take  $m \neq y <_W x$ . There is  $t$  with  $y <_W t <_W x$ ; the inductive bound excludes  $y$  from  $H_t$ , hence from  $H_x = \bigcap_{t <_W x} H_t$ . This proves the bound at limit stages.

If  $W$  has a greatest element  $\ell$ , the bound at  $\ell$  gives  $H_\ell \subseteq \{m, \ell\}$ . Its condensation is  $\{m\}$ , which is the appended successor stage. If  $W$  has no greatest element, every  $y \neq m$  has some index  $x >_W y$ , and the bound at that stage excludes it from the final intersection. The final stage is again  $\{m\}$ .

Finally, the rule for  $H_i$  is elementary in the earlier part of the history: one tests whether the index is first, a successor, or a limit, and then applies the corresponding displayed rule. The principle of elementary transfinite recursion along  $(X, W) + 1$  therefore supplies a class coding the history. This uses the standard meaning of ETR, whose stages may themselves be classes; its distinction from ordinary set-valued recursion is discussed in the primary literature on class recursion [24, 22]. The termination proof itself needed only GB and the already supplied history.  $\square$

The theorem does not contradict an isomorphism  $W \cong D_W(X)$ . The retained subclasses decrease even when their abstract order types repeat. In particular, no nontrivial retained class is literally a fixed point of  $D_W$ : its second member is always deleted at the next stage. A purported nonterminating history that keeps replacing a quotient by an arbitrary isomorphic copy has changed the specified limit convention.

### 108.1.2 The exact ordinal calculation

An external set theorem gives a completely explicit calculation. Let  $\kappa$  be any infinite initial cardinal and let  $\theta > 0$  be an ordinal. On a suborder of  $\theta$ , condense intervals of cardinality less than  $\kappa$ , retain least representatives, and intersect retained carriers at limits. Write  $H_\alpha(\theta)$  for the resulting ordinary transfinite history. Exponentiation in the next theorem is *ordinal exponentiation*.

**Theorem 108.2** (Multiples of ordinal powers). *For every ordinal  $\alpha$ ,*

$$H_\alpha(\theta) = \{\kappa^\alpha \cdot \beta : \kappa^\alpha \cdot \beta < \theta\}. \quad (\text{S20.2})$$

*Consequently the first singleton stage has exact height*

$$h_\kappa(\theta) = \min\{\alpha : \theta \leq \kappa^\alpha\}. \quad (\text{S20.3})$$

*Proof.* First observe that, on an ordinal  $\gamma$ , condensation by intervals of cardinality less than  $\kappa$  keeps exactly the points  $\kappa \cdot \delta < \gamma$ . Indeed, ordinary left division by  $\kappa$  writes each point uniquely as  $\kappa \cdot \delta + \rho$ , with  $\rho < \kappa$ . Within one  $\kappa$ -segment every closed interval has size less than  $\kappa$ . An interval meeting two different segments contains a final segment of the earlier  $\kappa$ -segment and therefore has size at least  $\kappa$ . This argument does not require regularity of  $\kappa$ .

At  $\alpha = 0$ , equation (S20.2) simply says that the retained carrier is all of  $\theta$ . If it holds at  $\alpha$ , the map  $\beta \mapsto \kappa^\alpha \cdot \beta$  order-isomorphically identifies an initial ordinal segment with  $H_\alpha(\theta)$ . Applying the preceding division observation to this induced order keeps precisely the indices  $\beta = \kappa \cdot \delta$ . Their images are

$$\kappa^\alpha \cdot (\kappa \cdot \delta) = \kappa^{\alpha+1} \cdot \delta,$$

proving the successor step.

Let  $\lambda$  be a nonzero limit ordinal. Every multiple of  $\kappa^\lambda$  is a multiple of  $\kappa^\alpha$  for  $\alpha < \lambda$ : write  $\lambda = \alpha + \delta$  and use  $\kappa^\lambda = \kappa^\alpha \cdot \kappa^\delta$ . For the converse, suppose  $x$  is a multiple of every  $\kappa^\alpha$  for  $\alpha < \lambda$ . Divide it by  $\kappa^\lambda$ :

$$x = \kappa^\lambda \cdot q + r, \quad r < \kappa^\lambda.$$

Continuity of ordinal exponentiation gives an  $\alpha < \lambda$  with  $r < \kappa^\alpha$ . The term  $\kappa^\lambda \cdot q$  is itself a multiple of  $\kappa^\alpha$ . Thus the displayed expression is the left division of  $x$  by  $\kappa^\alpha$ , with remainder  $r$ . Since  $x$  was a multiple of that power, uniqueness of division implies  $r = 0$ . This proves that the intersection of all earlier retained classes consists exactly of the multiples of  $\kappa^\lambda$ , establishing the limit step.

The right side of (S20.2) always contains 0 and contains another point exactly when  $\kappa^\alpha < \theta$ . This proves (S20.3). The set in that minimum is nonempty, since  $\alpha \mapsto \kappa^\alpha$  is increasing and  $\kappa^\theta \geq \theta$ .  $\square$

For example,

$$h_\kappa(\kappa) = 1, \quad h_\kappa(\kappa + 1) = 2, \quad h_\kappa(\kappa^\omega) = \omega, \quad h_\kappa(\kappa^\omega + 1) = \omega + 1.$$

The last pair makes the role of an appended terminal point especially clear: the class-limit intersection may retain that point as well as the minimum, requiring one more condensation.

**Corollary 108.3** (Exact heights in a full-class model). *Let  $\kappa$  be strongly inaccessible in an ambient ZFC universe, and use the full two-sorted model  $(V_\kappa, \mathcal{P}(V_\kappa))$ . If an internal class well-order of its surreal carrier has ambient ordinal type  $\theta$ , then  $|\theta| = \kappa$ , and its canonical nested condensation history has ambient height  $h_\kappa(\theta)$  from (S20.3). The possible heights are exactly*

$$0 < \alpha < \kappa^+.$$

*There is no single internal class-well-order schedule that bounds the heights of all such input orders. The bound by the input order in theorem 108.1 can be attained.*

*Proof.* In this full model, a subclass of  $V_\kappa$  is an internal set exactly when its ambient cardinality is less than  $\kappa$ . Inaccessibility bounds the cardinality of every  $V_\beta$  for  $\beta < \kappa$ ; conversely, regularity bounds the ranks of fewer than  $\kappa$  many elements of  $V_\kappa$ . This is the standard full-model size check used in the earlier continuation (source 18; [section 57.5](#)). All ambient subsets are available as classes, so internal class well-orders are actual well-orders externally. The surreal carrier has ambient cardinality  $\kappa$ . Its order type therefore satisfies  $\kappa \leq \theta < \kappa^+$ , and the condensation is exactly the one computed in [theorem 108.2](#).

The bound  $h_\kappa(\theta) \leq \theta < \kappa^+$  gives one inclusion for the height spectrum. Conversely, if  $0 < \alpha < \kappa^+$ , the ordinal  $\theta = \kappa^\alpha$  has cardinality  $\kappa$  and has height exactly  $\alpha$ , because ordinal exponentiation with base  $\kappa > 1$  is strictly increasing. For completeness, the cardinality assertion follows by induction: ordinal multiplication at a successor stage preserves cardinality  $\kappa$ , and at a limit below  $\kappa^+$  the union has at most  $\kappa$  terms, each of size at most  $\kappa$ . A bijection transfers this ordinal order to the surreal carrier, giving an available internal class relation.

Any internal class well-order schedule has an ambient order type less than  $\kappa^+$ . The displayed spectrum contains a larger height, proving the absence of a universal schedule in this model. For attainment of the input-order bound, take an ordinal fixed point

$$\theta = \kappa^\theta$$

of cardinality  $\kappa$ . One exists by starting with  $\theta_0 = \kappa$ , setting  $\theta_{n+1} = \kappa^{\theta_n}$ , and taking  $\theta = \sup_{n < \omega} \theta_n$ . Each stage and the supremum have cardinality  $\kappa$ , and continuity gives the fixed point. Strict increase of exponentiation shows  $\kappa^\alpha < \theta$  for every  $\alpha < \theta$ , so  $h_\kappa(\theta) = \theta$ . Such an input retains more than one point at every earlier stage and first becomes a singleton at its appended final stage.  $\square$

The last corollary is an external classification in a specified full-class model. It is not a claim that a GB universe contains the ordinal  $\kappa$  naming its own height, nor that it can collect all class well-orders and their histories into one class-valued object. The remaining foundational question is sharp: which fragment, if any, of elementary transfinite recursion is necessary for every supplied class well-order to admit the nested history? The termination theorem answers what happens to a history once it exists; it does not settle that existence principle over GB or GBC.

*Note 108.4* ([merge]; the existence question is answered over GBC). Source 29 answers this question, which source 20 also asks as its [research question 113.111](#), over GBC: the principle CTH that every class well-order admits its history on the schedule  $W + 1$  is equivalent to strong comparability CWO of class well-orders ([theorem 108.19](#)). Since ETR implies CWO (Hamkins–Woodin), ETR remains sufficient; whether it is necessary is not settled: source 29 leaves Hamkins and Woodin’s Question 7, on converses among these principles, open. Source 29 does not treat the question over GB without global choice. Source 20’s [theorem 108.1](#) is source 29’s [note 108.11](#), and its height formula is recovered there from finite normal forms (“A concrete full-model check in [section 108.3](#)).

[merge] (4 October 2026, batch 96.) Answered over GB as well. Sources 34 and 35 (Part XVI) prove independently that CTH, CWO and the two polynomial forms are equivalent over GB with ZF sets and no form of choice ([theorem XVI.5.8](#) and [note XVI.5.19](#)); source 29’s only use of global choice, the well-foundedness of  $P(\Gamma)$  ([note 108.15](#)), is replaced by a choice-free proof ([theorem XVI.4.2](#) and [note XVI.4.4](#); [note XVI.5.10](#)). Whether ETR is necessary remains open.

*Note 108.5* ([merge]; the polynomial orders in four sources). Source 15’s  $P(J)$  ([definition 53.1](#)), source 18’s  $(\mathcal{P}, \triangleleft)$  for  $J = \omega$  ([proposition 52.15](#)), source 23’s  $P(\Gamma)$  and source 29’s  $\mathcal{P}(\Gamma)$  are one class: finite partial functions from the exponent order to the nonzero ordinals, compared at the greatest exponent of disagreement. They are printed  $P(\Gamma)$  here. Source 23 compares them by ([S23.4](#)); source 29 uses them as the codomain of its finite normal forms.

## 108.2 Source 23: ordinal-polynomial models of every prescribed hierarchy

Let  $\Gamma = (G, <_\Gamma)$  be a given set or class well-order. A member of  $P(\Gamma)$  is a finite partial function from  $G$  to the nonzero ordinals. Evaluation outside its finite domain is defined to be zero. Thus we may conveniently write  $p : G \rightarrow \text{Ord}$  with finite support, but *the object  $p$  is its finite graph*. For  $p \neq q$ , the finite union of their supports has a greatest point of disagreement  $\delta$ , and we define

$$p < q \iff p(\delta) < q(\delta). \quad (\text{S23.4})$$

This is reverse lexicography on finite supports, not on arbitrary infinite-support words.

*Note 108.6* (Source 23, Lemma 11.1, “Polynomial order is a class well-order”). *In GBC,  $P(\Gamma)$  with (S23.4) is a class well-order. It is proper whenever  $G$  is nonempty.* This is source 15’s lemma 53.2 (Part IX), and source 29’s note 108.15; the three proofs map a descending sequence to ordinals by a base larger than all coefficients (source 15 uses an additively indecomposable base, source 23 an infinite base, source 29 the order type  $\delta^\alpha$ ).

*Source 23’s proof.* The greatest-disagreement comparison is a linear order: in a comparison of three finite graphs, work in the finite union of their supports, where ordinary finite lexicography applies.

Suppose a nonempty admitted subclass had no least point. Global choice would recursively select a strictly descending sequence  $p_0 > p_1 > \dots$ . The sequence is a set, by set recursion and Class Replacement. The union of its supports is a set well-ordered by  $\Gamma$ , say of order type  $\alpha$ . Its coefficients form a set of ordinals, so choose an infinite ordinal base  $b$  larger than all of them. Reindex the support set by  $\alpha$ . The map

$$p_n \longmapsto \sum_{\xi \in \text{supp}(p_n)}^{\text{decreasing } \xi} b^\xi p_n(\xi)$$

is strictly order-preserving into the ordinals. Indeed, at the highest differing exponent  $\delta$ , every finite sum of lower terms is less than  $b^\delta$ ; this follows successively from coefficients being below  $b$  and the laws of ordinal exponentiation. A larger coefficient at  $\delta$  therefore dominates all lower terms. We obtain a descending sequence of ordinals, a contradiction.

For any fixed  $g \in G$ , varying the coefficient at  $g$  embeds  $\text{Ord}$ . Thus the carrier is proper when  $G$  is nonempty.  $\square$

*Note 108.7* (Source 23, Lemma 11.2, “The first block removes the least coordinate”). *Suppose  $G$  is nonempty with least point  $g_0$ . Two polynomials have a set interval between them if and only if they agree at every coordinate strictly above  $g_0$ . Consequently*

$$D(P(\Gamma)) \cong P(\Gamma \setminus \{g_0\}),$$

where the order on the remaining coordinates is inherited. This is source 15’s lemma 53.3 (Part IX), with the same proof.

*Source 23’s proof.* If they agree above  $g_0$ , all points between them agree there too. Only the coefficient at  $g_0$  varies between two fixed ordinals, giving a set interval.

Otherwise let  $\delta > g_0$  be their greatest disagreement, with  $p < q$ . Keep every coordinate of  $p$  above  $g_0$  fixed, and vary its coefficient at  $g_0$  through all ordinals greater than or equal to its original value. Every resulting polynomial lies between  $p$  and  $q$ , since the higher disagreement at  $\delta$  still places it below  $q$ . These give a proper class of points in the interval.

The least representative of a block has coefficient zero at  $g_0$ . Deleting that coordinate identifies the representative order with the stated polynomial order.  $\square$

Adjoin a formally tagged new greatest stage  $\top$  to  $\Gamma$  (using a disjoint tagged copy of its old carrier). For  $t \in G$ , let  $I_t = \{\gamma : \gamma <_\Gamma t\}$  and put  $I_\top = G$ . Define

$$pE_tq \iff \forall \gamma \in G \setminus I_t (p(\gamma) = q(\gamma)). \quad (\text{S23.5})$$

The quantifier ranges over set objects  $\gamma$ ;  $p, q$  are finite graphs. This is one elementary definition with parameter  $\Gamma$ , and defines a class family on the set-coded stages of  $\Gamma + 1$ .

*Note 108.8* (Source 23, Theorem 11.3, “Prescribed-hierarchy theorem”). *Let  $\Gamma$  be any given class well-order, including a set well-order. The family (S23.5) is its polynomial order’s set-interval condensation hierarchy. More precisely:*

- (i) *At the first stage,  $E_t$  is equality. Each  $E_t$  is a convex equivalence relation.*
- (ii) *Its represented quotient is  $P(\Gamma \setminus I_t)$ .*
- (iii) *If  $t$  has immediate predecessor  $s$  in the stage order, then  $E_t = D(E_s)$ .*
- (iv) *At every nonzero limit stage  $t$ , including a limit final stage,  $E_t = \bigcup_{s < t} E_s$ .*
- (v)  *$E_\top$  is universal, and every  $E_t$  for  $t \in G$  is nonuniversal. In particular, collapse occurs exactly at the final stage.*

*These particular hierarchies are available in GBC without ETR.* This is source 15’s [theorem 53.4](#) (Part IX), stated for the equivalence relations  $E_t$  with unions at limits instead of nested classes of representatives with intersections; the two conventions agree by source 29’s [corollary 108.14](#). Source 23’s form adds the explicit quotient  $P(\Gamma \setminus I_t)$  at every stage and allows  $\Gamma$  to be a set well-order. Source 29’s [note 108.15](#) is a third copy.

*Source 23’s proof.* For each initial segment  $I_t$ , equivalence means equality on the remaining tail. This is a convex equivalence, and its least representative is obtained by deleting all coefficients in  $I_t$ . Its quotient therefore has exactly the stated polynomial order.

At a successor stage the remaining tail loses its least coordinate. [Note 108.7](#) proves precisely the successor clause, including when  $I_s$  is a proper class. At the first stage no coordinate has been removed, so equality is obtained.

At a limit stage, if  $pE_tq$ , their finite set of differing coordinates is contained in  $I_t$ . A finite subset of this initial segment is already contained in some  $I_s$  with  $s < t$ : take a stage strictly above its greatest member, which exists because  $t$  is not a successor. Thus  $pE_sq$ . The reverse inclusion is immediate. If there are no differing coordinates, any earlier stage suffices. The same proof applies when the predecessor segment of  $t$  is proper.

At the final stage all coordinates are deleted. Before that stage, the zero polynomial and the polynomial with coefficient one at coordinate  $t$  remain inequivalent. No recursion theorem was used: the displayed formula supplies the family and the preceding arguments verify its recursive specification.  $\square$

### 108.2.1 Every set ordinal, and beyond

For  $\Gamma = \alpha$  a set ordinal, we may say that the collapse rank is exactly  $\alpha$ . Every positive set ordinal is therefore realized by a proper-class well-order. For finite  $n$ , the order is the usual finite lexicographic ordinal-class power, with the highest coordinate compared first. Its successive condensations delete one least coordinate at a time.

For  $\Gamma = \omega$ , the quotient at every finite stage  $n$  is isomorphic to  $P(\omega)$  because  $[n, \omega)$  has order type  $\omega$ . Nevertheless the union of the finite-stage equivalences is universal: two finite graphs have bounded support. This gives a particularly transparent warning against declaring a hierarchy stable

merely because its successive quotient order types are isomorphic. ([merge] Source 15’s [remark 53.5](#) and source 18’s [proposition 52.15](#) make the same point with the same order; [note 53.6](#).)

For  $\Gamma = \text{Ord}$ , the tail after any set ordinal stage is again order-isomorphic to  $\text{Ord}$ . Consequently every set-stage quotient is isomorphic to  $P(\text{Ord})$ , and no set stage collapses it. The final stage of  $\text{Ord} + 1$  does collapse it, by the same finite-support argument. The final stage has a proper class of predecessors, but its relation is explicitly defined, not obtained by an unlicensed recursion.

Taking, for example,  $\Gamma = \text{Ord} + \text{Ord}$  continues the hierarchy beyond that first class-length block. The theorem is always relativized to a *given* admitted  $\Gamma$ . It does not assert a same-level class containing the hierarchies of all class well-orders.

### 108.2.2 Transport to surreal labels

Under global choice, every proper ordinary class admits a set-like  $\text{Ord}$ -enumeration. Hence for nonempty  $\Gamma$  there is a class bijection between  $P(\Gamma)$  and  $\mathbf{No}$ , and its well-order may be transported to the surreal carrier. The transported ordering is generally unrelated to the numerical ordering of the labels.

Thus the theorem supplies actual raw well-orders of *all surreal numbers*, not just abstract orders on an unrelated large carrier. The choice of transport affects the outer lexicographic position but not the condensation hierarchy of the transported relation.

### 108.3 Source 29: the exact strength of complete condensation histories

The elementary comparison of two labelled class well-orders does not require an isomorphism between their unlabelled order types. The repository’s common-prefix construction makes this distinction explicit ([theorem 14.2](#)). Iterating the canonical set-interval decomposition of one class well-order is a different problem. The preceding continuation, source 20, proved termination conditional on a supplied uniform history, gave elementary transfinite recursion as a sufficient existence principle, and asked for the exact strength of that existence assertion ([theorem 108.1](#), [research question 113.111](#)).

We now identify it with *strong class-well-order comparability*. The central construction assigns a finite ordinal-coefficient address to every point of a well-order with a supplied terminating history. These addresses form an initial segment of a class of formal polynomials. A common history for two convex suborders therefore gives their initial-segment comparison. Conversely, comparability places any class well-order inside a polynomial order with an explicit condensation history.

All results in this section are over **GBC**, unless a weaker setting is explicitly stated. No collection of classes is treated as an ordinary class of members. A history, an embedding, or a family of maps is always one supplied class relation. Formal sums and appended endpoints use tagged copies of their carriers; an arbitrary class carrier might be the entire universe, so a “new endpoint” must not mean an untagged set outside that carrier.

#### 108.3.1 The operator, the schedule, and the existing termination bound

Let  $W = (X, <_W)$  be a nonempty class well-order and put  $m = \min_W X$ . Here “class well-order” means that every nonempty admitted subclass has a least element. Given a nonempty subclass  $A \subseteq X$ , define

$$x \sim_A y \iff \{z \in A : \min_W(x, y) \leq_W z \leq_W \max_W(x, y)\} \text{ is a set,} \quad x, y \in A. \quad (\text{S29.21})$$

Let  $D_W(A)$  be the subclass of least representatives of these equivalence classes. The assertion that a displayed interval is a set is expressed by the existence of a set with exactly its members. Thus both  $\sim_A$  and  $D_W(A)$  have elementary definitions from the supplied class parameters.

*Note 108.9* (Source 29, Lemma 11.1, “One-step block facts”). *The relation  $\sim_A$  is a convex equivalence relation. Each of its blocks has a least element and, in its induced order, is either a set ordinal or a copy of Ord. A set-sized block can only be final. In particular, a block followed by another least representative has type Ord.* This is source 15’s [theorem 52.3](#) (Part IX) for the induced order on  $A$ , and source 23’s [note 106.3](#), with the same proof.

*Source 29’s proof.* Reflexivity and symmetry are immediate. An interval between two points is contained in the union of the intervals from those points to a third point, which proves transitivity. Taking subintervals proves convexity. Each block is an admitted nonempty subclass and therefore has a least point  $a$ . For a point  $x$  in that block, its predecessors within the block are exactly the set interval  $[a, x)_W \cap A$ . Their ordinal order types give a canonical rank map whose range is an initial subclass of Ord.

If that range is bounded by a set ordinal, Class Replacement applied to the inverse rank map makes the block a set. Otherwise the range is all of Ord. This proves the order-type assertion without assigning a set ordinal to a proper class. Finally, if a set block were not final, let  $y$  be the least point after it. Adjoining  $y$  to the block would give a set interval from its minimum, contradicting the maximality of the equivalence block.  $\square$

This is the canonical set-interval decomposition already used in the project ([theorem 52.3](#); source 20’s [section 108.1](#)). Its simultaneous definition requires no history of class-valued states.

Let  $\Gamma = (I, <_\Gamma)$  be a nonempty class well-order, and append a final stage  $*$ . Every  $i \in I$  has an immediate successor in  $\Gamma + 1$ , denoted  $i^+$ . A nonzero limit stage means a stage other than the first which has no immediate predecessor; its predecessor class need not be a set.

**Definition 108.10** (Canonical history). A canonical condensation history for  $W$ , with schedule  $\Gamma + 1$ , is one class

$$H \subseteq (I \cup \{*\}) \times X$$

whose slices satisfy

$$\begin{aligned} H_{\min \Gamma} &= X, \\ H_{i^+} &= D_W(H_i) \quad (i \in I), \\ H_\lambda &= \bigcap_{i <_{\Gamma+1} \lambda} H_i \quad \text{at every nonzero limit stage } \lambda. \end{aligned}$$

The final stage is included in the successor or limit clause as appropriate. The history is *terminating* if  $H_* = \{m\}$ . The principle CTH asserts that every nonempty class well-order  $W$  has such a history with the specific schedule  $W + 1$ .

The slices are decreasing and all contain  $m$ , by elementary transfinite induction with  $H$  as a class parameter. The same kind of induction proves the following bound from the preceding continuation. We include the argument because the distinction between existence and termination is central to the equivalence.

*Note 108.11* (Source 29, Proposition 11.3, “Termination for the input-order schedule; earlier result”). *In GB, a supplied canonical history on the schedule  $W + 1$  satisfies*

$$H_x \subseteq \{m\} \cup \{y \in X : x \leq_W y\} \quad (x \in X), \tag{S29.22}$$

*and its final slice is  $\{m\}$ .* This is source 20’s [theorem 108.1](#), which source 29 credits; the proof is the same induction.

*Source 29's proof.* Induct along the supplied class well-order  $W$ . The first-stage bound is immediate. If  $x$  is the successor of  $t$ , the inductive bound has already excluded all points below  $t$  except  $m$ . If  $t \neq m$  remains in  $H_t$ , it is the immediate successor of  $m$  there. Its interval from  $m$  has two points, so  $D_W$  deletes  $t$ . This proves the bound at  $x$ ; the case  $t = m$  is immediate.

At a nonzero limit  $x$ , each  $m \neq y <_W x$  lies below some  $t <_W x$ . The inductive bound excludes  $y$  from  $H_t$  and hence from the intersection at  $x$ . If  $W$  has a greatest element  $\ell$ , the bound leaves at most  $\{m, \ell\}$  at stage  $\ell$ , and the appended successor condenses it to  $\{m\}$ . If  $W$  has no greatest element, every  $y \neq m$  is excluded at some later stage, so the final intersection is again  $\{m\}$ .  $\square$

An appropriate instance of ETR supplies the history because the displayed successor and limit rules are elementary in the earlier history. This is class-valued recursion, not merely a recursion whose values and earlier histories are sets. The standard distinction is developed in the class-recursion literature [22, 27]. The remaining arguments first work with an already supplied history.

### 108.3.2 Greatest retained predecessors and finite changes

The essential new observation concerns projections onto retained carriers. A decreasing family of arbitrary subclasses need not have the property below; the successor rule forces it.

**Lemma 108.12** (Canonical floor maps). *For every stage of a supplied canonical history and every  $x \in X$ , the greatest retained predecessor exists:*

$$p_i(x) = \max_W \{a \in H_i : a \leq_W x\}. \quad (\text{S29.23})$$

*These maps are uniformly elementary in  $H, W$ . For  $i \leq j$ ,*

$$p_j(x) \leq_W p_i(x), \quad p_j(p_i(x)) = p_j(x), \quad p_i(p_j(x)) = p_j(x). \quad (\text{S29.24})$$

*Each  $p_i$  is nondecreasing as a function of  $x$ . At every nonzero limit stage  $\lambda$ , the earlier floors of a fixed point stabilize:*

$$\exists i_0 < \lambda \forall i (i_0 \leq i < \lambda \implies p_i(x) = p_\lambda(x)). \quad (\text{S29.25})$$

*Proof.* Prove existence by elementary transfinite induction. At the first stage the floor of  $x$  is  $x$ . Given  $p_i(x) = a$ , let  $b$  be the least representative of the  $\sim_{H_i}$ -block containing  $a$ . A representative between  $b$  and  $x$  would have to lie between  $b$  and  $a$ , by the defining property of  $a$ . It would therefore lie in the same block as  $b$ , contrary to least-representative uniqueness. Thus  $p_{i+}(x) = b$ .

At a nonzero limit  $\lambda$ , the earlier floors are nonincreasing because the retained carriers are nested. The class of their values is nonempty and has a  $W$ -least value  $b$ , attained at some stage  $i_0 < \lambda$ . Every later floor below  $\lambda$  equals  $b$ . Also  $b \in H_{i_0}$ , so nesting places it in every earlier slice. It follows that  $b$  belongs to the limit intersection. Any point of that intersection below  $x$  is at most  $p_{i_0}(x) = b$ . This proves both existence and (S29.25).

The induction assertion uses only set quantifiers and the supplied classes. In particular, the class of earlier floor values is defined directly by the greatest-predecessor formula; no family of newly chosen class maps is assumed. Once existence is proved, the same formula defines all  $p_i$  in a single class relation.

Monotonicity in  $x$  is immediate. If  $i \leq j$ , every  $H_j$ -point at most  $x$  is an  $H_i$ -point and is at most  $p_i(x)$ . This proves the first composition identity. The second follows because  $p_j(x)$  itself lies in  $H_i$ .  $\square$

**Proposition 108.13** (Each point changes its floor only finitely often). *For every fixed  $x$ , only finitely many stages  $i \in I$  satisfy  $p_{i+}(x) \neq p_i(x)$ . No new floor value first appears at a limit stage.*

*Proof.* The limit assertion is (S29.25). If the class of successor changes were not finite, repeatedly taking its least next member would give increasing stages  $i_0 < i_1 < \dots$  with

$$p_{i_{n+1}}(x) \leq_W p_{i_n^+}(x) <_W p_{i_n}(x).$$

These are uniquely chosen set-valued steps. Ordinary recursion along  $\omega$ , with the supplied classes as parameters, and Class Replacement produce a set-coded descending sequence in  $W$ , a contradiction.  $\square$

The finiteness is pointwise, not a finite bound on the length of the whole history. It is also internal finiteness when the theorem is interpreted inside a nonstandard model of class theory.

There is a precise quotient interpretation of the limit convention. Put  $x E_i y$  when  $p_i(x) = p_i(y)$ . The maps  $p_i$  are monotone surjections onto  $H_i$ , so  $E_i$  is a convex equivalence relation.

**Corollary 108.14** (Continuous identification at limits). *At a nonzero limit stage,*

$$E_\lambda = \bigcup_{i < \lambda} E_i.$$

*Thus no pair of original points is first identified at a limit.*

*Proof.* An earlier identification persists by (S29.24). Conversely, if the two floors agree at  $\lambda$ , choose an earlier stage after both stabilization stages in (S29.25). Their floors already agree there.  $\square$

Consequently the limit quotient is the directed quotient limit of the earlier stages. This can be stated without collecting a category of all class orders: for any supplied class order  $Y$  and any uniform compatible family of monotone maps  $f_i : H_i \rightarrow Y$ , there is a unique map from  $H_\lambda$  through which they factor. Define it by restricting the first  $f_i$  to  $H_\lambda$ . Equation (S29.25) and compatibility verify the factorization; surjectivity of each projection gives uniqueness. This answers one natural version of the earlier question about alternative limit conventions (source 20's [research question 113.112](#)): retaining the canonical quotient maps gives exactly the nested-representative limit.

### 108.3.3 A class of formal ordinal-coefficient polynomials

For a class well-order  $\Gamma = (I, <_\Gamma)$ , let  $P(\Gamma)$  be the ordinary class of finite partial functions from  $I$  to nonzero set ordinals. Missing coefficients are read as zero. Order these functions by the coefficient at the *greatest* exponent where they differ. This is a finite-support comparison, not a claim that Ord is a set-valued base for an ordinary exponentiation operation. The empty function, denoted 0, is the least polynomial.

*Note 108.15* (Source 29, Lemma 11.7, “Polynomial well-orders and their explicit histories”). *The order  $P(\Gamma)$  is a class well-order in GBC. It has an elementary canonical terminating history on the schedule  $\Gamma + 1$ , namely*

$$K_i = \{q \in P(\Gamma) : \text{supp}(q) \subseteq \{j : i \leq_\Gamma j\}\}, \quad K_* = \{0\}. \quad (\text{S29.26})$$

This combines source 15's [lemma 53.2](#) and [theorem 53.4](#) (Part IX), and source 23's [notes 108.6](#) and [108.8](#); source 29's well-foundedness proof computes the set order type  $\delta^\alpha$  instead of mapping into an ordinal base.

*Source 29's proof.* If the polynomial order had a nonempty subclass without a least element, Global Choice would produce a descending  $\omega$ -sequence. The union of its finite exponent supports is a set  $A$ , whose induced  $\Gamma$ -order has a set ordinal type  $\alpha$ . Class Replacement also bounds all coefficients occurring in that sequence by a single set ordinal  $\delta \geq 2$ , chosen strictly above every coefficient.

The sequence would therefore lie in the set order of finite-support  $\delta$ -valued functions on  $\alpha$ , with the same greatest-difference comparison. This is a well-order of ordinary ordinal type  $\delta^\alpha$ : the successor step is an ordinal sum of  $\delta$  copies of the preceding order, and at a limit every finite support is bounded in an earlier exponent segment. Ordinary set transfinite induction proves the assertion. The descending sequence is impossible, so the class polynomial order is well-founded.

At stage  $i$ , the  $K_i$ -polynomials with the same coefficients strictly above  $i$  form exactly one small-interval block, varying their  $i$ -coefficient through Ord. Within such a block every bounded coefficient interval is a set. If two higher parts differ, arbitrarily increasing the  $i$ -coefficient of the smaller polynomial stays below the larger polynomial. Their interval therefore contains a proper class. The least representative of a block has coefficient zero at  $i$ , proving the successor clause in (S29.26). At a nonzero limit, retaining only exponents above all earlier thresholds is exactly the intersection rule. The final threshold leaves only the zero polynomial.  $\square$

All polynomial objects are sets: a polynomial has a finite domain of set-valued stage labels and finitely many set ordinal coefficients. The possibly proper-class size is in the collection of available codes and in its ordering, not in an individual code.

### 108.3.4 Finite normal forms from a supplied history

For a history with schedule  $\Gamma + 1$ , define

$$c_i(x) = \text{otp}(\{z \in H_i : p_{i+}(x) \leq_W z <_W p_i(x)\}, <_W). \quad (\text{S29.27})$$

The displayed interval is a set. Indeed, the successor construction in lemma 108.12 identifies  $p_{i+}(x)$  as the least representative of the small-interval block containing  $p_i(x)$ . The digit is zero exactly when these two floors coincide. By proposition 108.13,

$$\text{NF}_H(x) = \{(i, c_i(x)) : i \in I, c_i(x) > 0\} \in P(\Gamma). \quad (\text{S29.28})$$

This finite graph is a set, and its dependence on  $x$  is given by one elementary class formula.

**Theorem 108.16** (Canonical finite normal form). *For a supplied terminating history  $H$ , the map  $\text{NF}_H$  is a class isomorphism of  $W$  onto an initial segment of  $P(\Gamma)$ .*

*Proof.* We first record precisely how to insert a digit. Suppose  $b \in H_{i+}$ , and let  $z \in H_i$  be the point of ordinal rank  $\rho$  in the small-interval block beginning at  $b$ , whenever that point exists. Then

$$p_i(z) = z, \quad p_{i+}(z) = b.$$

For every later stage, the floors of  $z$  agree with the floors of  $b$ , by (S29.24). At every earlier stage  $j < i$ , both relevant floors of  $z$  equal  $z$ , because  $z \in H_i \subseteq H_{j+}$ . It follows that  $\text{NF}_H(z)$  has the same digits as  $\text{NF}_H(b)$  above  $i$ , has digit  $\rho$  at  $i$ , and has zero digits below  $i$ . The digits of  $b$  at and below  $i$  are themselves zero. This is an exact one-digit insertion rule.

Now fix an actual normal form. At the last stage the floor of its point is  $m$ . Read its finitely many nonzero digits in decreasing stage order, starting from that anchor. At each step the one-digit rule says to take the unique point of the indicated ordinal rank in the indicated block. For an actual code, this point exists by (S29.27). Limit stages introduce no additional changes, by (S29.25). The

successive anchors therefore reconstruct the original point. Uniqueness at each rank proves that  $\text{NF}_H$  is injective. These are finitely many uniquely specified choices of sets, not a choice of class isomorphisms.

It remains to prove order preservation and, crucially, that the image is an initial segment. Let  $q < \text{NF}_H(x)$  be any polynomial, and let  $i$  be their greatest exponent of disagreement. Their higher digits are identical. Reading those common higher digits reconstructs the same anchor

$$b = p_{i+}(x).$$

Write  $d = c_i(x)$  and  $c = q(i)$ , with a missing digit of  $q$  read as zero. The comparison says  $c < d$ . In the  $H_i$ -block beginning at  $b$ , the point  $p_i(x)$  has rank  $d$ . Hence there are points  $a, a' \in H_i$  of ranks  $c, c+1$ , respectively, with

$$a <_W a' \leq_W p_i(x) \leq_W x. \quad (\text{S29.29})$$

Taking  $a$  inserts the digit  $c$ , leaving all smaller digits zero.

Process the remaining nonzero digits of  $q$  in decreasing order. For a lower exponent  $j < i$ , both the current anchor and the fixed cap  $a'$  belong to  $H_{j+}$ . Initially this follows from  $a, a' \in H_i$ , and it remains true after each insertion because the exponents decrease. The cap is a later least representative. Therefore the  $H_j$ -block beginning at the current anchor is nonfinal and has type Ord, by [note 108.9](#). Every requested set ordinal digit is available inside that block, and its point is still strictly below  $a'$ . The one-digit insertion rule proves that the step changes exactly the requested digit and preserves the previously inserted higher digits. After the finitely many steps, the resulting point  $y$  satisfies

$$\text{NF}_H(y) = q, \quad y <_W a' \leq_W x.$$

Thus every polynomial below an actual code is itself an actual code, and its decoded point is smaller. When  $q$  is the normal form of another given point, injectivity identifies that point with the constructed  $y$ . The two linear orders therefore have exactly the same comparisons. The same argument for arbitrary  $q$  proves initiality of the image.  $\square$

The initiality conclusion is stronger than an order embedding. It is the step that will give *strong* comparability, rather than merely an embedding as an arbitrary suborder. The cap in [\(S29.29\)](#) guarantees that every finite collection of lower digits can be filled without leaving the input order.

The theorem also explains how a history can have very large height while every point has a finite address. The exponents themselves are labels in a supplied class well-order, and may have proper classes of predecessors. They have not been replaced by set ordinals. Only the coefficients and the finite address are sets.

### 108.3.5 Restricting a history to a convex suborder

To compare two input orders, we need their histories on the same schedule. The following restriction rule supplies them from a single history of their sum.

**Lemma 108.17** (Anchored convex restriction). *Let  $Y$  be a nonempty convex subclass of  $W$ , and put  $a = \min_W Y$ . From a canonical history  $H$  on  $W$  define, on the same schedule,*

$$J_i = \{a\} \cup \{y \in H_i \cap Y : a <_W y\}. \quad (\text{S29.30})$$

*Then  $J$  is the canonical history of the induced order on  $Y$ . If  $H$  terminates, so does  $J$ .*

*Proof.* The first-stage clause is immediate, and intersecting the displayed subclasses at a limit gives the same formula at that limit. For the successor clause, fix  $x \in H_i \cap Y$  with  $a <_W x$ , and put  $u = p_i(a)$ . By the greatest-predecessor property, the global and local intervals from their respective anchors are

$$\begin{aligned} [u, x]_W \cap H_i &= \{u\} \cup \{z \in H_i : a <_W z \leq_W x\}, \\ [a, x]_W \cap J_i &= \{a\} \cup \{z \in H_i : a <_W z \leq_W x\}. \end{aligned}$$

Convexity of  $Y$  ensures that the tails displayed on the two lines coincide. The two intervals are sets simultaneously.

A witness above  $a$  that  $x$  is not a least representative is a witness in both orders. A global witness below  $a$  gives a local set interval by restricting its tail and inserting  $a$ . Conversely, a local witness equal to  $a$  can be replaced by  $u$ , using the displayed equality of tails. Consequently the retained representatives strictly above  $a$  agree exactly. The point  $a$  is the local minimum and is always retained. This proves the successor clause.

At the final stage, a singleton global carrier contributes either the same minimum or no point above  $a$ . Formula (S29.30) therefore gives  $\{a\}$ .  $\square$

Bare intersection with a noninitial convex interval is insufficient: it can discard the interval's own minimum. The anchor in (S29.30) is the necessary correction. For an initial segment, the anchor already is the global minimum, so ordinary restriction is enough.

**Corollary 108.18** (The exact criterion for a fixed schedule). *For nonempty class well-orders  $W$  and  $\Gamma$ , the following are equivalent:*

1.  $W$  has a supplied canonical terminating history on  $\Gamma + 1$ ;
2.  $W$  is class-isomorphic to an initial segment of  $P(\Gamma)$ .

*Proof.* The forward implication is theorem 108.16. For the reverse implication, restrict the explicit history (S29.26) to the given initial segment and pull it back through the supplied isomorphism. Initiality and lemma 108.17 verify the recursion clauses. The zero polynomial belongs to every nonempty initial segment, so the pulled-back history terminates at its minimum.  $\square$

This criterion uses an actual initial-segment embedding as its witness. It does not invoke a class of order types or compare unspecified cardinalities of class histories.

### 108.3.6 Equivalence with strong class-well-order comparability

Write CWO for the assertion that, for every two class well-orders, one is class-isomorphic to an initial segment of the other, allowing the whole order as an initial segment.

**Theorem 108.19** (Exact strength of canonical histories). *Over GBC, the following principles are equivalent:*

1. CWO: strong class-well-order comparability;
2. CTH: every nonempty class well-order  $W$  admits its canonical history on the input-order schedule  $W + 1$ ;
3. every nonempty class well-order admits a uniformly coded canonical terminating history on some class-well-order schedule  $\Gamma + 1$ ;
4. every nonempty class well-order  $W$  is class-isomorphic to an initial segment of  $P(W)$ .

*Proof.* (2) *implies* (3). This is [note 108.11](#): the specified input-order history terminates at its appended last stage.

(3) *implies* (1). Let  $R, S$  be two nonempty class well-orders on disjoint tagged carriers, and form their ordered sum  $T = R + S$ . Apply (3) once, to  $T$ , obtaining a terminating history with some schedule  $\Gamma + 1$ . Its two anchored convex restrictions give terminating histories for  $R$  and  $S$  on that same schedule. By [theorem 108.16](#), both are isomorphic to initial subclasses of  $P(\Gamma)$ .

Two initial subclasses of the same linear order are comparable by inclusion: if neither included the other, choosing a point in each set difference would contradict initiality in one direction or the other. Composing the map onto the smaller polynomial range with the inverse map on the larger range gives the required initial-segment isomorphism. The maps and their ranges are elementary classes defined from the one supplied history. There is no choice of a class witness for each member of a proper collection. An empty input order is handled separately and trivially.

(1) *implies* (4). We give an explicit argument that avoids assigning ordinals to class well-orders. First observe that every class order embedding  $f : W \rightarrow W$  satisfies  $x \leq_W f(x)$  for all  $x$ . Otherwise choose the least counterexample  $x$ . Since  $f(x) <_W x$ , order preservation gives  $f(f(x)) <_W f(x)$ , making  $f(x)$  an earlier counterexample. Consequently there is no class order embedding  $W + 1 \rightarrow W$ : if  $a$  were the image of the appended last point, the restriction to  $W$  would give

$$a \leq_W f(a) <_W f(*) = a.$$

Let  $\Gamma = W + 1$ . The polynomial order  $P(\Gamma)$  is a class well-order. It contains an embedded copy of  $W + 1$ , sending each exponent  $t$  to its coefficient-one monomial  $e_t$ . Comparability between  $W$  and  $P(\Gamma)$  cannot give an initial embedding of the latter into  $W$ , since composition would embed  $W + 1$  into  $W$ . Thus it supplies an initial-segment embedding

$$f : W \longrightarrow P(\Gamma).$$

Its range lies strictly below  $e_*$ . If a polynomial at least  $e_*$  lay in the range, initiality would put  $e_*$  and every  $e_x$ , for  $x \in X$ , into the range. Applying  $f^{-1}$  to these monomials would again embed  $W + 1$  into  $W$ . The polynomials strictly below  $e_*$  are exactly those supported on the original  $W$ -exponents, namely  $P(W)$ . Hence  $f$  gives (4).

(4) *implies* (2). Apply [corollary 108.18](#) with  $\Gamma = W$ . Concretely, if  $f$  is the supplied initial-segment isomorphism, define

$$H_i = \{x \in X : \text{supp}(f(x)) \subseteq \{j : i \leq_W j\}\}, \quad H_* = f^{-1}[\{0\}].$$

This is one elementary class relation. The polynomial history, initial restriction, and pullback prove all the required clauses.  $\square$

**Corollary 108.20** (The surreal carrier alone suffices). *In [theorem 108.19](#), the history principle (2) is unchanged if it is asserted only for class well-orders of the whole surreal carrier **No**.*

*Proof.* Under Global Choice, a proper class with the restriction of a set-like global well-order has type Ord. Therefore every proper class carrier has a class bijection with **No**. Transporting a supplied order through that bijection, applying the surreal-carrier history principle, and transporting both the label and stage coordinates back gives the input-order history on the original proper carrier. For a nonempty set carrier, every interval is a set, so the first successor stage is already its singleton minimum and all later stages remain there. Thus set carriers add no further requirement.  $\square$

### 108.3.7 What the equivalence settles, and what it leaves separate

The result identifies the exact condensation-history existence principle with a familiar class-theoretic comparison principle:

$$\text{GBC} \vdash \text{CTH} \longleftrightarrow \text{CWO}, \quad \text{GBC} + \text{ETR} \vdash \text{CTH}.$$

Hamkins–Woodin prove that ETR implies strong class-well-order comparability and explicitly ask about converses among the relevant ranking and comparison principles [27, Theorem 6 and Question 7]. Their Question 7 is not settled here. In particular, the presence of class-valued stages does not by itself prove that ETR is necessary. Our theorem provides an exact equivalence to CWO, without claiming an equivalence to arbitrary elementary transfinite recursion.

It also preserves the distinction with native labelled lexicography. The largest common labelled prefix of two supplied relations is elementarily definable, and their next labels can be compared without CWO or a condensation history (theorem 14.2). The stronger principle arises when all the iterated quotient information is required uniformly through a complete schedule. These are different tasks.

**Uniqueness and changes of the class collection.** Two histories for the same input and schedule agree wherever both are defined. A least stage of disagreement is impossible: the first, successor, and limit clauses all determine the slice from earlier slices. This is elementary induction with the two histories supplied as parameters. Consequently an extension of a GBC class collection with the same sets may supply a previously unavailable history, but cannot change an already available one. The recursion clauses, set-interval tests, and finite normal forms are elementary in the shared classes and sets. This is a uniqueness statement about individual histories, not a class-valued choice function assigning a history to every well-order.

**A concrete full-model check.** In a full inaccessible-universe interpretation  $(V_\kappa, \mathcal{P}(V_\kappa))$ , the polynomial order  $P(\Gamma)$  has ambient ordinal type  $\kappa^\alpha$  when  $\Gamma$  has ambient type  $\alpha$ . Its coefficients range over the internal ordinals, externally  $\kappa$ , and its supports are finite. Thus corollary 108.18 becomes exactly

$$\theta \leq \kappa^\alpha,$$

where  $\theta$  is the ambient type of the input order. This recovers the earlier exact height formula  $\min\{\alpha : \theta \leq \kappa^\alpha\}$  for the relevant nontrivial histories (source 20’s theorem 108.2 and corollary 108.3). The present proof explains that calculation through canonical finite normal forms, while remaining meaningful in arbitrary GBC realizations where external ordinal types are not available internally.

**Formalization boundary.** A direct formalization can separate four interfaces: a class well-order on set labels; a supplied history relation; the set-sized interval-rank operation; and elementary comprehension and Class Replacement. The floor-map and normal-form theorems then require no new recursion axiom. The finite polynomial codes belong to the set sort, and their comparison uses only a finite support and the supplied stage order. The existence theorem is a separate equivalence between two second-order assertions, CTH and CWO.

In a universe-relative type-theoretic implementation, the same proof can be expressed with explicit smallness and an enclosing universe. In a formalized two-sorted model, all claims of well-foundedness, finiteness, and set-sized intervals must retain that model’s interpretation. Neither approach permits forming an ordinary class whose members are all class well-orders, all histories, or all of their isomorphism classes.

*Note 108.21* ([merge]; one height calculation, five times). In the full model  $(V_\kappa, \mathcal{P}(V_\kappa))$  at an inaccessible  $\kappa$ , internal set-interval condensation is condensation by intervals of ambient cardinality below  $\kappa$ . Source 15's full-universe check (section 53.1) and source 18's (note 53.6) identify one condensation with left division by  $\kappa$ ; source 20's theorem 108.2 and corollary 108.3 iterate it to the history  $\{\kappa^\alpha \cdot \beta < \theta\}$  and the height  $\min\{\alpha : \theta \leq \kappa^\alpha\}$ , with every height  $0 < \alpha < \kappa^+$  attained and no universal schedule; source 23's universes section (proposition 111.24) computes that  $P(\Gamma)$  has type  $\kappa^\beta$  when  $\Gamma$  has type  $\beta$ , and source 29's "concrete full-model check" above turns corollary 108.18 into  $\theta \leq \kappa^\alpha$ . These agree. Source 20's corollary is the only one to state the height spectrum and the attainment of the input-order bound.

[merge] Source 23's Section 12 transports these polynomial orders into the lexicographic order of all class well-orders of **No**. Its theorem 108.23 is new against the repository and against Part IX: it follows from the convexity of the fibres over a fixed set-like head (source 11's proposition 15.3) and source 15's polynomial histories, but neither is stated with it.

#### 108.4 Source 23: arbitrary raw complexity inside global lexicographic intervals

Let  $\mathfrak{W}_{\text{sl}}$  be the virtual order of exhaustive class bijections  $e : \text{Ord} \rightarrow \mathbf{No}$ , and let  $\mathfrak{W}_{\text{all}}$  be the virtual order of all raw well-orders on **No**, both compared by the numerical label order.

**Lemma 108.22** (A set prefix is absorbed). *For every set ordinal  $\sigma$  and every nonempty class well-order  $\Gamma$ ,*

$$\sigma + P(\Gamma) \cong P(\Gamma)$$

*as class well-orders.*

*Proof.* The first set-interval block of  $P(\Gamma)$  is  $\text{Ord}$ , obtained by varying only the least coordinate. The order  $\sigma + \text{Ord}$  is isomorphic to  $\text{Ord}$ : map the first block identically onto the ordinals below  $\sigma$  and the following ordinal  $\xi$  onto  $\sigma + \xi$ . The latter enumerates the ordinal tail beginning at  $\sigma$ . Replace the first block by this isomorphism and leave the rest unchanged.  $\square$

**Theorem 108.23** (Dense realization of prescribed raw hierarchies). *In GBC, let  $e < f$  be two distinct members of  $\mathfrak{W}_{\text{sl}}$ , and let  $\Gamma$  be any nonempty admitted class well-order. There exists a raw well-order  $H$  on **No** such that*

$$e <_{\text{lex}} H <_{\text{lex}} f, \quad H \cong P(\Gamma).$$

*In particular, every such interval realizes every positive set-ordinal collapse rank and every prescribed class-indexed hierarchy of Note 108.8.*

*Proof.* Let  $\delta$  be the first ordinal where  $e$  and  $f$  disagree, and let  $p = e \upharpoonright \delta = f \upharpoonright \delta$ . This is a set prefix. Choose a fresh surreal  $c$  with

$$e(\delta) < c < f(\delta), \quad c \notin \text{ran } p,$$

using Note 81.2. The remaining label class  $Y = \mathbf{No} \setminus (\text{ran } p \cup \{c\})$  is proper. Transport the well-order  $P(\Gamma)$  to  $Y$  by a class bijection and place it after the prefix  $p \frown (c)$ .

The first disagreement with each endpoint occurs at the label  $c$ , so  $e < H < f$  regardless of the order chosen on  $Y$ . Its internal order type is  $(\delta + 1) + P(\Gamma)$ , which is  $P(\Gamma)$  by Lemma 108.22. The hierarchy is invariant under this isomorphism.  $\square$

*Remark 108.24* (The precise density assertion). The theorem concerns intervals whose endpoints are set-like exhaustive enumerations. It does not assert the same statement for every nonempty interval of  $\mathfrak{W}_{\text{all}}$ : finite residual intervals and adjacent pairs are counterexamples. Nor does it identify the condensation rank as an invariant definable from the outer lexicographic order alone. The extra structure is the relation encoded by an outer-order point.

A useful consequence is that a research program restricted to the canonical first set-like head cannot capture all internal order types appearing locally in the raw enlargement. Beyond that head one encounters hierarchies of any prescribed admitted well-ordered length. Nevertheless, all the witnesses in the theorem are constructed by one fresh-letter choice followed by a specified tail; the proof does not require a simultaneous choice of tails for all possible class parameters.

## 109 Countable class models: two external order types and one theory (sources 19, 20, 21 and 30)

[merge] Part IX printed source 18's classification of the external order  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  of an externally countable  $\omega$ -standard model of GBC as the factorial shuffle ([theorem 58.6](#)), its remark that the classification fails without  $\omega$ -standardness ([remark 58.8](#)), and its question on the  $\omega$ -nonstandard case ([research question 113.89](#)). Sources 19, 20 and 21 answer that question independently and identically: the order is the shuffle  $\sigma(\mathcal{F} \cup \{I_\infty\})$ , not isomorphic to the standard one but elementarily equivalent to it. Source 19 is printed first and is the base, because its [theorem 109.9](#) proves that the pure order of every externally set-sized model of GBC has the theory of the standard shuffle; its [proposition 109.7](#), [corollary 109.11](#) and [theorem 109.12](#) are proved only there. Sources 20 and 21 follow whole as routes. Their shared lemmas (maximal finite tail, permutation blocks, density of every tail length, the nonstandard interval, the Ehrenfeucht–Fraïssé threshold  $2^r - 1$ ) are notes pointing to the first printed copy; what only they prove is printed as theorems: source 20's external finite-condensation blocks ([corollary 109.18](#)) and the decidability of the common theory ([corollary 109.22](#)), and source 21's automorphism group of the nonstandard order and the first derivative ([theorem 109.36](#)). The lemmas on terminal tails, permutation blocks and dense tail lengths were proved first by sources 17 and 18 in Part IX ([theorem 54.4](#), [lemmas 58.1](#) and [58.5](#) and [proposition 58.3](#)); the three batch-83 copies are notes to those. Source 30's compactness observation, which explains why external finiteness of the blocks is not a first-order property, closes the section.

### 109.1 Source 19: the exact external spectrum in countable class models

The distinction between internal and external finiteness yields a complete answer to the countable-model question. It also reveals a useful contrast: the pure order has only two isomorphism types among countable GBC realizations, but these types have the same first-order theory, and that theory itself has the largest possible number of countable models.

Let  $\mathcal{M} = (M, \mathcal{X})$  be an externally countable two-sorted model of GBC. Its classes are the members of its admitted class sort  $\mathcal{X}$ . Write  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  for the external set of admitted class relations which  $\mathcal{M}$  regards as well-orders of its whole surreal carrier, and  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}}$  for the subset which it regards as set-like. Compare them by the labelled common-prefix lexicographic comparison computed in  $\mathcal{M}$ . This produces an actual external linear order. No external well-foundedness of the individual relations is assumed.

For a countable nonempty collection  $\mathcal{A}$  of nonempty order types, let  $\sigma(\mathcal{A})$  denote the shuffle obtained by densely colouring the rational order with those types and replacing each rational by the

corresponding chain. Put

$$\mathcal{F} = \{n! : n \in \mathbb{N}\} = \{1, 2, 6, 24, 120, \dots\}, \quad I_\infty = \omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*.$$

Here  $\mathbb{N}$  is the external standard set of natural numbers, and  $\mathbb{Z}$  denotes its usual order. The order  $I_\infty$  has a first and a last element. Its external finite-distance components are an initial  $\omega$ , a final  $\omega^*$ , and copies of  $\mathbb{Z}$  densely indexed between them.

**Theorem 109.1** (Exactly two countable GBC order types). *For an externally countable model  $\mathcal{M}$  of GBC,*

$$\mathfrak{W}_{\text{all}}^{\mathcal{M}} \cong \begin{cases} \sigma(\mathcal{F}), & \mathcal{M} \text{ is } \omega\text{-standard}, \\ \sigma(\mathcal{F} \cup \{I_\infty\}), & \mathcal{M} \text{ is } \omega\text{-nonstandard}. \end{cases}$$

*In both cases  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}} \cong \mathbb{Q}$ . The two unrestricted orders are nonisomorphic but elementarily equivalent in the pure language of linear orders.*

The assertion concerns two possible types among GBC realizations, conditional on the existence of the respective kinds of model. It does not say that their common first-order theory has only two countable models. We prove the classification first, and then give the stronger first-order comparison.

*Note 109.2* ([merge]; which clauses are earlier, and the two other proofs). Two clauses of [theorem 109.1](#) are in Part IX: the  $\omega$ -standard formula is source 18’s [theorem 58.6](#), and  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}} \cong \mathbb{Q}$  is source 13’s [proposition 55.5](#) (the second clause of source 18’s theorem), both by the proofs repeated below. The  $\omega$ -nonstandard formula, the nonisomorphism and the elementary equivalence are new against the repository and answer source 18’s [research question 113.89](#). Source 20 proves the same three clauses ([note 109.13](#)) and source 21 as well ([notes 109.33](#) and [109.35](#)); the three proofs use the same nonstandard-interval lemma and the same finite-game threshold. Source 19 obtains the elementary equivalence from the stronger [theorem 109.9](#), which needs no countability.

### 109.1.1 The internal finite-tail partition

The next constructions are first carried out internally in GBC. They apply to an infinite linearly ordered class whenever well-order completions are available; for the surreal carrier, Global Choice supplies them. They are parameterwise constructions of individual classes, not an internal collection containing all class orders.

*Note 109.3* (Source 19, Lemma 12.2, “The maximal finite terminal tail”). *Every class well-order  $R$  on an infinite carrier  $X$  has a unique finite terminal segment  $T_R$  such that  $R$  restricted to  $X \setminus T_R$  has no greatest element. Every finite terminal segment of  $R$  is contained in  $T_R$ . Write  $n(R) = |T_R| \in \omega^{\mathcal{M}}$ . This is source 18’s [lemma 58.1](#) (Part IX), with the same proof; source 19 adds that in an  $\omega$ -nonstandard model the stopping value may be nonstandard (the paragraph after the proof). Sources 20 and 21 repeat it ([notes 109.14](#) and [109.24](#)).*

*Source 19’s proof.* If  $R$  has no greatest element, take the empty tail. Otherwise remove the greatest element and repeatedly remove the greatest remaining element while one exists. If the process did not stop at an internal finite stage, ordinary set-valued recursion with class parameter  $R$  would produce an internal descending  $\omega$ -sequence. Class Replacement makes its range a set, contradicting well-foundedness. At the stopping stage the selected finite set is terminal and its complement has no greatest element. Each last-element or predecessor step was unique, so the tail is unique, and every finite terminal segment is among its initial sequence of removals.  $\square$

In an  $\omega$ -nonstandard model the stopping value  $n(R)$  may be nonstandard. The lemma is an internal assertion and does not claim that an external iteration through the standard natural numbers stops.

Let  $B_R$  be the cylinder obtained by keeping  $R$  unchanged on  $X \setminus T_R$  and permuting its  $n(R)$  terminal labels. These cylinders partition the admitted orders: every member has the same maximal terminal set and the same preceding prefix. Each cylinder is convex and has first and last elements. Internally it is a finite chain of size  $n(R)!$ . More explicitly, the finite set of permutations of  $T_R$  belongs to  $M$ , and each permutation defines a class relation by elementary comprehension. Sorting the terminal labels in their ambient order identifies their lexicographic permutations with the internal finite linear order of size  $n(R)!$ . Every admitted order in the cylinder arises in this manner. *Note 109.4* (Source 19, Lemma 12.3, “Adjacency has finite residual carrier”). *If  $R < S$  are adjacent, their residual carrier after the first common labelled prefix is finite. In particular, an adjacency step cannot leave the cylinder  $B_R$ .* This is source 18’s lemma 58.2 (Part IX) with the same proof, and the finite-residual half of source 11’s adjacency criterion theorem 16.2.

*Source 19’s proof.* Let  $C$  be the common prefix,  $Y = X \setminus C$ , and let the first unequal labels be  $a < b$ . Keeping  $C$  and the next label  $a$  fixed, the rest of the  $R$ -order must be the largest possible completion: a larger completion would lie between  $R$  and  $S$ . Consequently each successive label is the greatest unused label, so the reverse ambient order well-orders  $Y \setminus \{a\}$ . Dually, the ambient order well-orders  $Y \setminus \{b\}$ . Thus on  $Z = Y \setminus \{a, b\}$  both an order and its reverse are well-orders. This forces  $Z$  to be finite. Otherwise successively taking the least unused label would give an internal ascending  $\omega$ -sequence in one order, hence a descending sequence in the other. Therefore  $Y$  is finite. It is a finite terminal segment of  $R$ , and so is contained in  $T_R$  by Note 109.3.  $\square$

*Note 109.5* (Source 19, Lemma 12.4, “Every prescribed internal tail occurs densely”). *Between two distinct cylinders there is a cylinder with  $n(R) = n$ , for every prescribed  $n \in \omega^M$ .* This is source 18’s lemma 58.4 followed by lemma 58.5 (Part IX), with the same two-change argument, now read internally so that  $n$  may be nonstandard; source 20’s note 109.16 and source 21’s note 109.27 are the other copies.

*Source 19’s proof.* Take  $R < S$  in different cylinders, with common prefix  $C$ , residual carrier  $Y$ , and first unequal labels  $a < b$ . The residual  $Y$  is infinite, since otherwise the two orders would belong to one finite-tail cylinder. We first find a whole cylinder inside  $(R, S)$  with infinite residual carrier.

One possible change is to keep an  $R$ -prefix through its label  $a$ , then, at a later position outside  $T_R$ , replace the next label  $x$  by a numerically larger unused label. Its cylinder lies above  $R$  and below  $S$ , and its residual is infinite. A second possible change does the dual operation in  $S$ : after retaining its label  $b$ , replace a later label outside  $T_S$  by a smaller unused label.

At least one change is possible. Otherwise, on the infinite class

$$Z = Y \setminus (\{a, b\} \cup T_R \cup T_S),$$

every earlier  $R$ -label would be numerically greater than every later one, and every earlier  $S$ -label would be numerically smaller than every later one. The ambient order on  $Z$  and its reverse would both be well-orders, contradicting the argument in Note 109.4. The new cylinder is different from both endpoint cylinders, because its first disagreements with them occur while the residual carrier is infinite.

In that residual carrier choose an  $n$ -element set  $F$ . Well-order the remaining carrier without a greatest element: use its infinite initial cardinal if it is a set, or a set-like well-order of type Ord if it is proper. Append this order after the chosen prefix and then append the labels of  $F$ . The maximal finite terminal tail is exactly  $F$ , as required.  $\square$

For the surreal carrier the full order has no endpoints: change the first label upward or downward and complete the remaining carrier. Every cylinder has endpoints, so its quotient has no endpoints either. [Note 109.5](#) makes this quotient dense. When the class sort is externally countable the quotient is consequently a copy of  $\mathbb{Q}$ .

### 109.1.2 What a nonstandard finite interval looks like externally

**Lemma 109.6** (The external shape of a nonstandard finite interval). *In an externally countable nonstandard model of arithmetic, let  $c$  be a nonstandard natural number. The external order of the internal interval  $[0, c]$  has type*

$$I_\infty = \omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*.$$

*The arithmetic available in any GBC model suffices.*

*Proof.* Declare  $x \sim y$  when their arithmetic difference in absolute value is a standard natural number. This is precisely external finite distance in  $[0, c]$ . The component of 0 consists of its standard successors and has type  $\omega$ . The component of  $c$  consists of its standard predecessors and has type  $\omega^*$ . Every other component has arbitrary standard predecessors and successors, and all its members are obtained by those finitely iterated steps from any chosen one. It has type  $\mathbb{Z}$ .

The quotient has a first and a last component. It is dense. Indeed, if  $x < y$  belong to different components then  $y - x$  is nonstandard, and

$$z = x + \left\lfloor \frac{y - x}{2} \right\rfloor$$

is at nonstandard distance from both endpoints. A standard bound on either half would give a standard bound on  $y - x$ . Hence  $[x] < [z] < [y]$ . The open interval between the endpoint components is a countable dense order without endpoints, so is a copy of  $\mathbb{Q}$ . This gives the displayed decomposition.  $\square$

*Proof of the isomorphism assertions in [Theorem 109.1](#).* In an  $\omega$ -standard model every  $n(R)$  is standard, so every cylinder has actual finite size  $n(R)!$ . Their quotient is countable and dense without endpoints, and every factorial size occurs densely by [Note 109.5](#). Countable colour-preserving back-and-forth gives  $\sigma(\mathcal{F})$ .

In an  $\omega$ -nonstandard model the cylinders with standard tail length again have actual factorial size. If  $n(R)$  is nonstandard, then  $n(R)!$  is nonstandard, and [Lemma 109.6](#) gives external type  $I_\infty$ . These are all the possibilities. Prescribing one fixed nonstandard tail length shows that the  $I_\infty$  colour occurs densely, and each standard factorial colour is dense as before. The same coloured back-and-forth gives  $\sigma(\mathcal{F} \cup \{I_\infty\})$ .

For the set-like suborder, the first unequal ordinal position has a set-sized common prefix. Choose an unused surreal strictly between the unequal next labels and complete the prefix to a global enumeration. The surreal set-cut property permits avoidance of the set of previously used labels. This gives internal and therefore external density. Varying the first label gives no endpoints, and external countability gives  $\mathbb{Q}$ . This argument never assumes  $\omega$ -standardness.  $\square$

### 109.1.3 Recovering the cylinders from the pure order

The internal finite-tail partition is visible in the external pure order through a single first-order formula. This observation removes any dependence on a hidden choice of presentation in the comparison that follows.

Define

$$\begin{aligned} \text{Adj}(x, y) &\iff x < y \wedge \neg \exists z (x < z < y), \\ S(x) &\iff \neg \exists y \text{ Adj}(y, x) \wedge \neg \exists y \text{ Adj}(x, y), \\ E(x, y) &\iff \neg \exists z (((x < z < y) \vee (y < z < x)) \wedge S(z)). \end{aligned}$$

**Proposition 109.7** (Intrinsic cylinder equivalence). *In the external unrestricted order of any set-sized two-sorted GBC model,  $S$  picks out exactly the singleton cylinders, and  $E(x, y)$  holds exactly when  $x$  and  $y$  belong to the same finite-tail cylinder.*

*Proof.* A singleton cylinder has no immediate predecessor or successor, because the quotient is dense. In a larger internally finite cylinder every point has at least one immediate neighbour inside that cylinder, including its endpoints; the internal finite linear order gives these neighbours even when it is externally infinite. Thus these cylinders contain no  $S$ -points. Consequently  $E$  holds within a cylinder. Between distinct cylinders, [Note 109.5](#) with tail length zero gives an  $S$ -point, so  $E$  fails.  $\square$

In the standard case  $E$  is external finite condensation. In the nonstandard case a  $I_\infty$ -class contains many external finite-distance components, so  $E$  is strictly coarser. In particular the two orders in [Theorem 109.1](#) are not isomorphic: the second has infinite  $E$ -classes and the first does not. The sentence asserting that every  $E$ -class is finite can be written in  $L_{\omega_1, \omega}$ , using a countable disjunction of the finite size formulas. It is not a first-order sentence.

#### 109.1.4 One complete first-order theory for all GBC realizations

The first-order comparison does not need external countability.

**Lemma 109.8** (Finite-game threshold). *Let  $h_r = 2^r - 1$ . Two finite chains of sizes at least  $h_r$  are  $r$ -equivalent. The same conclusion holds if either chain is replaced by an infinite discrete linear order with first and last elements, in which every point other than an endpoint has its corresponding immediate predecessor and successor.*

*Proof.* Use the  $r$ -round Ehrenfeucht–Fraïssé game. With  $s$  rounds left, maintain the following invariant in each interval between matched points, including the two end intervals: either the two intervals have the same finite size below  $h_s$ , or both have at least  $h_s$  points. Initially the invariant holds.

For a short interval use its unique finite order isomorphism. In a large interval, if the newly selected point is within fewer than  $h_{s-1}$  points of one end, match that exact finite distance from the corresponding end. Otherwise choose a point leaving at least  $h_{s-1}$  points on each side. The identity  $h_s = 2h_{s-1} + 1$  guarantees enough room. Finite successor and predecessor steps are available because the intervals have endpoints and are discrete. These choices preserve the invariant with  $s - 1$  rounds left and therefore preserve the final finite order pattern.  $\square$

**Theorem 109.9** (Uniform complete theory). *For every externally set-sized two-sorted model  $\mathcal{M}$  of GBC, the pure external order  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  has the same complete first-order theory*

$$T = \text{Th}(\sigma(\mathcal{F})).$$

*In particular, the standard and nonstandard countable orders of [Theorem 109.1](#) are elementarily equivalent.*

*Proof.* Fix a quantifier rank  $r$ . Colour a cylinder by its exact finite factorial size if that size is below  $h_r$ , and merge all other cylinders into one large colour. Only finitely many colours remain. Each occurs densely in the quotient: for the large colour prescribe any standard factorial size at least  $h_r$ . The quotient has no endpoints.

In a finite game, match a newly visited quotient class to a class of the same colour in the appropriate interval between previously matched classes. Density and absence of endpoints always permit this. Corresponding small cylinders are identical finite chains. Corresponding large cylinders are  $r$ -equivalent by Lemma 109.8, since every internally finite cylinder is externally discrete with endpoints. Play a fixed  $r$ -round winning game inside each matched pair of cylinders. There are at most  $r$  moves inside any one pair, and the quotient matching preserves the order between pairs. This gives an  $r$ -round winning strategy for the whole orders. As  $r$  was arbitrary, their complete theories agree.  $\square$

**Corollary 109.10** (A proper elementary suborder and an omitted type). *In the nonstandard countable order, the union  $L_{\text{fin}}$  of its genuinely finite  $E$ -classes is a proper elementary suborder isomorphic to  $\sigma(\mathcal{F})$ . The partial type*

$$p(x) = \{\text{the } E\text{-class of } x \text{ has at least } m \text{ members} : 1 \leq m < \omega\}$$

*is nonprincipal over  $T$ . The standard shuffle omits it; every point in a  $I_\infty$ -class of the nonstandard shuffle realizes it.*

*Proof.* Deleting the  $I_\infty$ -coloured quotient points leaves a countable dense order without endpoints in which all finite factorial colours are dense. Thus  $L_{\text{fin}} \cong \sigma(\mathcal{F})$ . For elementarity fix a finite tuple from this suborder and a quantifier rank  $r$ . Repeat the preceding quotient matching while fixing its parameter classes, and use the identity within those finite parameter classes. The same finite-game argument works for every  $r$  with the tuple fixed, proving elementarity.

The type is finitely satisfiable because factorial sizes are unbounded, and its realization and omission are immediate from the class sizes. Were it isolated by a formula consistent with the complete theory  $T$ , that formula would have a realization in the standard shuffle and force a realization of  $p$  there, a contradiction.  $\square$

**Corollary 109.11** (The standard shuffle is the prime model). *The standard shuffle is a countable atomic, and hence prime, model of  $T$ .*

*Proof.* For a finite tuple, specify its partition into  $E$ -classes, the order of these classes, the finite size of each class, and the exact position of each tuple entry in its class. Each condition is first-order expressible. Their finite conjunction specifies a single automorphism orbit: apply coloured-quotient back-and-forth and the unique isomorphisms of the finite chains. Consequently it isolates the tuple's complete type, establishing atomicity.

For completeness, primeness follows by an elementary enumeration argument. Enumerate the standard shuffle and embed its elements one at a time into any model of  $T$ . At each step the isolated type of the next finite tuple is consistent with, and extends, the previously isolated tuple type; its existential realization therefore follows from that preceding type. The resulting union is an elementary embedding.  $\square$

### 109.1.5 The common theory has many other countable models

The GBC classification is more restrictive than elementary equivalence. One can make this precise without appealing to an abstract model-spectrum theorem.

**Theorem 109.12** (All countable orders occur inside countable models of  $T$ ). *For every countable linear order  $A$ , put*

$$J_A = \omega + \sum_{a \in A} \mathbb{Z} + \omega^*.$$

*There is a countable model  $L_A$  of  $T$  with exactly one infinite  $E$ -class, of type  $J_A$ . Moreover,*

$$L_A \cong L_{A'} \iff A \cong A'.$$

*Consequently  $T$  has  $2^{\aleph_0}$  pairwise nonisomorphic countable models.*

*Proof.* Start with a rational quotient densely coloured by the finite factorial sizes, choose one quotient point, and replace its chain by  $J_A$ . All other classes retain their prescribed finite chains. The order  $J_A$  is infinite, discrete, and has first and last elements. The threshold argument of [Lemma 109.8](#) therefore applies. After merging the large colours at any fixed rank, all quotient colours remain dense. The same finite-game proof gives  $L_A \models T$ .

The formula  $E$  recovers the displayed classes exactly, because the singleton classes remain dense between them. Thus an isomorphism must preserve the unique infinite class. Its external finite-distance quotient is  $1 + A + 1$ : the endpoint components are  $\omega$  and  $\omega^*$ , and the interior components are the indicated copies of  $\mathbb{Z}$ . Removing the endpoint components recovers  $A$ . Conversely an isomorphism  $A \cong A'$  extends to their  $J$ -classes, and a coloured rational back-and-forth fixing the distinguished quotient point gives  $L_A \cong L_{A'}$ .

There are  $2^{\aleph_0}$  nonisomorphic countable linear orders. For an explicit family, encode a binary sequence  $(a_n)$  by  $\sum_{n < \omega} (\mathbb{Z} + (2 + a_n))$ . Its finite-distance components alternate a copy of  $\mathbb{Z}$  and a finite chain of length 2 or 3; their quotient has type  $\omega$ , so it recovers the sequence. This gives the lower bound for models of  $T$ . The upper bound is the usual count of relations on a countable domain.  $\square$

The arithmetic midpoint in [Lemma 109.6](#) explains why these other models do not produce additional countable GBC realizations. Within an internally finite nonstandard interval, its external finite-distance quotient must be dense, forcing the interior index order to be  $\mathbb{Q}$  in a countable model. The prescribed-tail construction additionally forces such  $I_\infty$ -classes to occur densely whenever the model is nonstandard. These conditions go beyond what the pure first-order theory can express.

### 109.1.6 What the result does and does not forget

For countable GBC realizations, the pure unrestricted order remembers  $\omega$ -standardness up to isomorphism and forgets it at the level of first-order theory. Its theory is even independent of the external size of the class model. The theorem does not classify expansions by the set-like predicate, evaluation at surreal labels, birthday restrictions, named baselines, or coding and definability information. Those structures remain natural places to look for dependence on the underlying set universe and class realization.

All constructions above use elementary class comprehension, ordinary set-valued recursion with supplied class parameters, and Global Choice for completions. They require neither ETR nor an internal class of all class orders. The quotient and model-theoretic games are external set constructions, with their scope explicitly fixed at the start.

## 109.2 Source 20: two external order types for countable class models

The earlier continuation, source 18, classifies the raw lexicographic order of an externally countable,  $\omega$ -standard model of GBC as a shuffle of finite factorial chains ([theorem 58.6](#)). It asks what happens

when the model has nonstandard natural numbers ([research question 113.89](#)). We now give the exact classification in that case, including its external finite-condensation blocks and its first-order theory. The classification concerns the *pure external linear order*; it discards the labels, the class membership relation, and the predicate of set-likeness.

Let  $\mathcal{M} = (M, \mathcal{X}) \models \text{GBC}$ , with both sorts countable in the ambient metatheory. Let  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  be the external set of those  $R \in \mathcal{X}$  that  $\mathcal{M}$  regards as class well-orders of its surreal carrier. The comparison  $R < S$  means that  $\mathcal{M}$  satisfies the elementary labelled first-disagreement formula. Thus “well-order” and “finite” inside a construction below are initially *internal* notions. We never assume that  $R$  is externally well-founded. Internal linearity of the comparison nevertheless makes  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  an actual external linear order.

For a countable nonempty family  $\mathcal{A}$  of countable order types, write  $\sigma(\mathcal{A})$  for its *dense shuffle*: colour  $\mathbb{Q}$  so that every colour in  $\mathcal{A}$  is dense, and replace each rational by a copy of its colour. The usual colour-preserving back-and-forth proves uniqueness of the resulting order type. Put

$$\mathcal{F} = \{1, 2, 6, 24, 120, \dots\} = \{n! : n \in \omega\}, \quad I_{\infty} = \omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*.$$

The sum in  $I_{\infty}$  means a rationally ordered family of copies of the integer order; it does not mean an ordinal product.

*Note 109.13* (Source 20, Theorem 8.1, “Countable-model dichotomy”). *For every externally countable  $\mathcal{M} \models \text{GBC}$ ,*

$$\mathfrak{W}_{\text{all}}^{\mathcal{M}} \cong \begin{cases} \sigma(\mathcal{F}), & \mathcal{M} \text{ is } \omega\text{-standard}, \\ \sigma(\mathcal{F} \cup \{I_{\infty}\}), & \mathcal{M} \text{ is } \omega\text{-nonstandard}. \end{cases}$$

*These two orders are not isomorphic, but they are elementarily equivalent in the language containing only  $<$ . In the nonstandard case, the union of the blocks of standard finite size in the displayed shuffle is an elementary suborder isomorphic to  $\sigma(\mathcal{F})$ .* This is source 19’s [theorem 109.1](#) without its set-like clause, together with the first clause of source 19’s [corollary 109.10](#); source 20’s proof follows in the lemmas below, the proof after [note 109.17](#) and [note 109.20](#).

The proof separates an internally finite terminal permutation block from an externally finite-distance block. Conflating these two equivalence relations would give an incorrect classification.

### 109.2.1 A coarse equivalence that remains valid internally

For each admitted  $R$ , there is an internally finite terminal set  $T_R$  such that  $R$  on  $\mathbf{No}^{\mathcal{M}} \setminus T_R$  has no greatest element. Write  $n_R = |T_R|^{\mathcal{M}} \in \omega^{\mathcal{M}}$ . The following argument recalls the terminal-tail result with the nonstandard interpretation made explicit.

*Note 109.14* (Source 20, Lemma 8.2, “Internal terminal tails”). *The set  $T_R$  exists uniquely and contains every internally finite terminal segment of  $R$ .* This is source 18’s [lemma 58.1](#) (Part IX) and source 19’s [note 109.3](#), with the same proof.

*Source 20’s proof.* Work inside  $\mathcal{M}$ . If there is no greatest label, take  $T_R = \emptyset$ . Otherwise start with the greatest label and successively take its immediate predecessor whenever there is one. If this does not stop at some  $n \in \omega$ , ordinary set recursion with the class parameter  $R$  gives an  $R$ -descending sequence of length  $\omega$ . Class Replacement makes its range a set, contradicting the class well-order property. At the stopping stage the selected finite terminal segment has a remainder with no greatest element. Every finite terminal segment is obtained by finitely many of the same uniquely determined predecessor steps, proving uniqueness and maximality. In a nonstandard model the

stopping value  $n$  can be nonstandard; the argument does not assert termination after a standard finite number of external steps.  $\square$

For unequal  $R, S$ , let  $C(R, S)$  be their largest common labelled prefix. Its definition is elementary in the class parameters: a label  $x$  belongs to it exactly when the two predecessor classes of  $x$  are equal and the two relations agree on that predecessor class. Define an external relation on  $\mathfrak{M}_{\text{all}}^{\mathcal{M}}$  by

$$R E_{\mathcal{M}} S \iff R = S \text{ or } \mathcal{M} \models \text{“}\mathbf{No} \setminus C(R, S) \text{ is a finite set.”}$$

The formula on the right quantifies over a set coding the residual carrier and a natural number. It does *not* quantify over a set of class relations or assert the existence of a finite sequence whose entries are classes.

*Note 109.15* (Source 20, Lemma 8.3, “The internal permutation blocks”).  $E_{\mathcal{M}}$  is a convex equivalence relation. Its block through  $R$  consists exactly of the admitted orders that keep the prefix  $R \upharpoonright (\mathbf{No}^{\mathcal{M}} \setminus T_R)$  fixed and permute the internally finite set  $T_R$ . As an external linear order this block is isomorphic to

$$[0, n_R!)^{\mathcal{M}} = \{i \in \omega^{\mathcal{M}} : \mathcal{M} \models i < n_R!\}$$

with the model’s natural-number order. This is the internal form of source 18’s [proposition 58.3](#) (Part IX), as in source 19’s paragraph after [note 109.3](#) and source 21’s [note 109.25](#). Source 20 adds the coding argument that identifies the external block with the model’s interval  $[0, n_R!)$ , including when  $T_R$  is externally infinite.

*Source 20’s proof.* If the first-disagreement residual is internally finite, it is a terminal segment in  $R$ , hence is contained in  $T_R$  by [note 109.14](#). The two orders therefore agree on the prefix outside  $T_R$ . Conversely, two orders with that fixed prefix can first disagree only inside  $T_R$ , so they are  $E_{\mathcal{M}}$ -equivalent. Permuting  $T_R$  leaves a remainder with no greatest element, so it does not change the maximal terminal set. This proves transitivity; reflexivity and symmetry are immediate. Convexity follows because a fixed labelled prefix defines a convex lexicographic cylinder.

There is also a precise coding justification for the asserted block size. Internally let  $P$  be the set of permutations of  $T_R$ . For  $p \in P$ , elementary class comprehension defines the order  $R_p$  obtained by concatenating the fixed prefix with  $p$ . The construction can be presented as one class of triples  $(p, x, y)$  whose  $p$ -slice is  $R_p$ . Its slices are classes, not elements of a set. Conversely, the restriction of any admitted order in this cylinder to the set  $T_R$  is a set relation, by class separation, and hence is an internal permutation code in  $P$ .

Inside the model, the lexicographic order on this finite set of permutations is a chain of size  $n_R!$ , and therefore has an order isomorphism with  $[0, n_R!)$ . The external interpretations of this set isomorphism and of the slice construction give the claimed external isomorphism. In particular, when  $T_R$  is externally infinite we are using the model’s internally coded permutations, not all externally existing permutations of its external carrier.  $\square$

*Note 109.16* (Source 20, Lemma 8.4, “Every internal tail size is dense in the coarse quotient”). *The quotient  $\mathfrak{M}_{\text{all}}^{\mathcal{M}}/E_{\mathcal{M}}$  is a countable dense linear order without endpoints. For every fixed  $n \in \omega^{\mathcal{M}}$ , the blocks whose maximal terminal tail has internal size  $n$  occur densely in this quotient.* This is source 18’s [lemmas 58.4](#) and [58.5](#) (Part IX) read internally, and source 19’s [note 109.5](#), with the same argument.

*Source 20’s proof.* All constructions in this paragraph are performed inside the model. Take  $R < S$  in different  $E_{\mathcal{M}}$ -blocks. Let  $C$  be their common prefix, let  $Y = \mathbf{No} \setminus C$ , and let  $a < b$  be their

first unequal numerical labels. The residual  $Y$  is internally infinite. We first find a prefix cylinder contained in  $(R, S)$  whose residual carrier is internally infinite.

One possible construction changes, in  $R$ , a label  $x \in Y \setminus (\{a\} \cup T_R)$  to a larger unused label while retaining the prefix before  $x$ . The resulting cylinder stays above  $R$  and below  $S$ : the original next label  $a$  is retained. Because  $x$  is outside  $T_R$ , the unused carrier at that position is internally infinite, and remains so after choosing the replacement. A second possible construction changes, in  $S$ , a label  $x \in Y \setminus (\{b\} \cup T_S)$  to a smaller unused label. It has the symmetric properties.

At least one construction is possible. Otherwise, on the internally infinite class

$$Z = Y \setminus (\{a, b\} \cup T_R \cup T_S),$$

the restriction of  $R$  would equal the reverse numerical order, whereas the restriction of  $S$  would equal the numerical order. Both would be class well-orders. An infinite class cannot be well-ordered in both directions: successively choosing the least unused label in one direction produces an  $\omega$ -sequence descending in the other, again with a set range. This contradiction establishes the required cylinder. The first disagreements with both original endpoints have infinite residual carriers, so its members lie in blocks distinct from the endpoint blocks.

Let  $P$  be its fixed prefix and  $Y'$  its infinite residual carrier. Given any  $n \in \omega$ , choose an  $n$ -element set  $F \subseteq Y'$ . Well-order  $Y' \setminus F$  without a greatest element. If this carrier is a set, use an infinite initial cardinal as order type; if it is a proper class, use a set-like well-order of type  $\text{Ord}$ , available from Global Choice. Append that order after  $P$ , and then append  $F$  in any order. Its maximal finite terminal tail is exactly  $F$ . This construction works equally for a nonstandard internal  $n$ .

Returning to the metatheory, these statements give density and density of every indicated colour. Varying the first surreal label below or above a given first label gives a different coarse block, since the first residual is the entire internally infinite carrier. Thus the quotient has no endpoints. It is countable because the admitted class sort is externally countable.  $\square$

### 109.2.2 What an internally finite nonstandard interval looks like

The arithmetic ingredient is classical; compare the decomposition of countable nonstandard arithmetic models in [67]. We give the bounded-interval proof, since it identifies exactly which external blocks occur here.

*Note 109.17* (Source 20, Lemma 8.5, “The external type of a nonstandard finite interval”). *If  $N \in \omega^{\mathcal{M}}$  is nonstandard, then externally*

$$[0, N)^{\mathcal{M}} \cong I_{\infty}.$$

This is source 19’s lemma 109.6 for the half-open interval  $[0, N)$ , with the same midpoint argument; source 21’s note 109.32 is the third copy.

*Source 20’s proof.* Two points of this interval have a finite external interval between them exactly when their internal difference is a standard natural number. The block containing 0 consists of the standard natural numbers and has order type  $\omega$ . The block containing  $N - 1$  consists of

$$N - 1, N - 2, N - 3, \dots$$

and has order type  $\omega^*$ . These blocks are disjoint because  $N$  is nonstandard. A point outside them has nonstandard distance from both endpoints; adding and subtracting standard integers gives its entire finite-distance block, of type  $\mathbb{Z}$ .

The quotient of the remaining blocks is countable, dense, and has no endpoints. If  $a < b$  lie in different such blocks,  $b - a$  is nonstandard, and the model's integer midpoint  $\lfloor (a + b)/2 \rfloor$  has nonstandard distance from both. It therefore gives a strictly intermediate block. Given an interior block represented by  $a$ , the points  $\lfloor a/2 \rfloor$  and  $\lfloor (a + N - 1)/2 \rfloor$  give interior blocks respectively below and above it. Finally  $\lfloor N/2 \rfloor$  gives at least one interior block. The quotient is consequently isomorphic to  $\mathbb{Q}$ , proving the formula.  $\square$

*Source 20's proof of the isomorphism assertions in note 109.13.* If the model is  $\omega$ -standard, note 109.15 gives precisely the finite chains of sizes  $n!$ . The colours  $n = 0$  and  $n = 1$  both give the singleton type and can be merged. By note 109.16, the quotient is a densely coloured copy of  $\mathbb{Q}$ , proving the first formula.

If the model is  $\omega$ -nonstandard, standard  $n$  still give these same finite factorial chains. For every nonstandard  $n$ , the number  $n!$  is nonstandard, and note 109.17 identifies its block with  $I_\infty$ . Merge all these nonstandard colours into the one colour  $I_\infty$ . This colour is dense: choosing any one nonstandard  $n$  already gives a dense subcolour by note 109.16. The standard factorial colours remain dense. The countable colour-preserving back-and-forth now yields  $\sigma(\mathcal{F} \cup \{I_\infty\})$ .

The standard shuffle has only finite finite-distance blocks, whereas  $I_\infty$  contains an infinite such block. Thus the two external orders are not isomorphic. This conclusion needs no assumption that a class well-order in the model is externally well-founded.  $\square$

**Corollary 109.18** (External finite condensation). *In the nonstandard case, the external finite-distance blocks of  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  have exactly the following order types:*

$$1, 2, 6, 24, 120, \dots, \quad \omega, \quad \omega^*, \quad \mathbb{Z}.$$

*The uncoloured finite-condensation quotient is  $\mathbb{Q}$ . However, its block-type colours are not all dense: each coarse  $I_\infty$ -block contributes a closed quotient interval whose first point has colour  $\omega$ , whose last point has colour  $\omega^*$ , and whose interior is a rational order entirely coloured  $\mathbb{Z}$ .*

*Proof.* Inside a coarse standard block, the entire finite chain is a single finite-distance block. Inside a coarse nonstandard block, the proof of note 109.17 gives its bottom  $\omega$ -block, its top  $\omega^*$ -block, and its rationally indexed  $\mathbb{Z}$ -blocks. No finite-distance block crosses between coarse blocks: between any two distinct coarse blocks there are infinitely many others, by note 109.16. These are therefore all the possibilities.

Any two distinct points of the finite-condensation quotient either come from different coarse blocks, when coarse density supplies an intermediate point, or come from the same  $I_\infty$ -block, when note 109.17 supplies one. There are no endpoints and the quotient is countable, so it is  $\mathbb{Q}$ . The colour description follows from the same decomposition. In particular, replacing the classification in note 109.13 by a dense shuffle of the displayed finite-distance block types would be wrong.  $\square$

### 109.2.3 Elementary equivalence and an explicit elementary suborder

The new infinite block cannot be detected by a single first-order sentence because a sufficiently long finite factorial chain has the same bounded-depth order behaviour. We make this argument precise, including parameters.

*Note 109.19* (Source 20, Lemma 8.7, “The finite-chain threshold strategy”). *Put  $t_r = 2^r - 1$ . A chain of at least  $t_r$  elements that is finite externally, and an internally finite chain of at least  $t_r$  elements in  $\mathcal{M}$ , satisfy the same  $r$ -round Ehrenfeucht–Fraïssé game conditions in the pure order language. More generally, the Duplicator wins whenever every corresponding gap between previously*

*matched points has either equal size below  $t_r$ , or size at least  $t_r$  on both sides.* This is source 19's lemma 109.8, with the same strategy; source 21 uses it inside the proof of note 109.35.

*Source 20's proof.* Every nonempty gap in either chain has a least and a greatest point; for the internally finite chain this assertion holds externally because the internal endpoints are actual elements. Its size below any fixed standard finite bound is also absolute. Maintain the stated gap condition with  $r$  remaining moves. The assertion for  $r = 0$  is just preservation of the order of the selected points.

Suppose the next move divides a gap. If its size is less than  $t_r$ , the corresponding gap has exactly the same finite size, and the same-position response leaves identical gaps. Otherwise both gaps have size at least

$$t_r = 2t_{r-1} + 1.$$

If fewer than  $t_{r-1}$  unselected points lie on one side of the chosen point, match that finite distance from the corresponding endpoint. The other remaining gap is large enough on both sides. The two small-side cases cannot both occur. If neither occurs, choose a point with at least  $t_{r-1}$  unselected points on each side in the corresponding gap. Such a point exists by the displayed inequality, for example by counting  $t_{r-1}$  points from its left endpoint. The condition with  $r - 1$  remaining moves follows. Induction gives the strategy.  $\square$

*Note 109.20* (Source 20, Theorem 8.8, “An elementary standard part of the external order”).  
*Suppose  $\mathcal{M}$  is  $\omega$ -nonstandard, and let*

$$\mathfrak{W}_{\text{allstd}}^{\mathcal{M}} = \{R \in \mathfrak{W}_{\text{all}}^{\mathcal{M}} : n_R \text{ is a standard natural number}\}.$$

*This is a union of coarse blocks, and*

$$\mathfrak{W}_{\text{allstd}}^{\mathcal{M}} \cong \sigma(\mathcal{F}), \quad \mathfrak{W}_{\text{allstd}}^{\mathcal{M}} \preceq \mathfrak{W}_{\text{all}}^{\mathcal{M}}$$

*as pure linear orders. Standardness in this definition is an external condition, not a claimed internal predicate.* This is the first clause of source 19's corollary 109.10 (its  $L_{\text{fin}}$  is the present  $\mathfrak{W}_{\text{allstd}}^{\mathcal{M}}$ ), with the same quotient-matching proof; with note 109.13 it gives the countable case of source 19's theorem 109.9.

*Source 20's proof.* The standard factorial colours are dense in the coarse quotient, so restricting to them gives a densely coloured rational order. This proves the isomorphism assertion.

Fix a finite tuple of parameters in  $\mathfrak{W}_{\text{allstd}}^{\mathcal{M}}$  and a standard number  $r$  of game rounds. Pair every coarse block containing a parameter with itself, matching the whole finite chain identically. During the game maintain an order-preserving matching between the finitely many coarse blocks visited so far. Each paired pair of blocks is either two identical-size finite factorial chains, or one  $I_\infty$ -block and a finite factorial chain of size at least  $t_r$ .

If a move visits a new coarse block, choose a fresh matching block in the corresponding open interval of the other quotient, or in the corresponding ray. Every standard factorial colour is dense and unbounded there. Match a finite block by its same size. Match an  $I_\infty$ -block by any factorial size at least  $t_r$ . Start the local strategy of note 109.19 in the selected pair of blocks. If the move visits an already paired block, continue its local strategy. At most  $r$  moves occur in any one pair, and moves in different blocks are compatible because the quotient matching preserves order.

This supplies a winning strategy for every finite  $r$ , with the given parameters fixed. The Ehrenfeucht–Fraïssé criterion therefore gives the elementary inclusion. Together with the previous isomorphism results, this proves the elementary-equivalence assertion of note 109.13.  $\square$

*Note 109.21* (Source 20, Corollary 8.9, “A type that distinguishes the two countable orders”). *Let*

$$\text{Succ}(x, y) \iff x < y \wedge \neg \exists z (x < z < y).$$

*The partial one-variable type asserting that  $x$  begins a chain of  $k$  successive immediate successors, for every standard  $k$ , is finitely satisfiable but omitted in  $\sigma(\mathcal{F})$  and is realized in  $\sigma(\mathcal{F} \cup \{I_\infty\})$ .* This is the phenomenon of the second clause of source 19’s [corollary 109.10](#), with a different nonprincipal type: source 19’s type bounds the size of the class of  $x$  under its formula  $E$ , source 20’s counts immediate successors; source 20 adds the dual type and the points realizing both.

*Source 20’s proof.* Arbitrarily long finite factorial chains witness finite satisfiability. In the standard shuffle every point belongs to a finite block, and successive immediate successors cannot cross a coarse boundary, so no point realizes the whole type. In an  $I_\infty$ -block, every point of its bottom  $\omega$ -block realizes it. Dually there is a type asserting arbitrarily many successive immediate predecessors, realized in the top  $\omega^*$ -block. Every point in one of the middle  $\mathbb{Z}$ -blocks realizes both types simultaneously.  $\square$

**Corollary 109.22** (Decidability of the common pure-order theory). *The common first-order theory of the two orders in [note 109.13](#), in the language containing only  $<$ , is decidable.*

*Proof.* Given a sentence  $\varphi$ , compute its quantifier rank  $r$  and put  $t_r = 2^r - 1$ . Let  $s_r$  be the least factorial in  $\mathcal{F}$  that is at least  $\max\{1, t_r\}$ , and form the finite, effectively computable set

$$\mathcal{F}_r = \{s \in \mathcal{F} : s < t_r\} \cup \{s_r\}.$$

The quotient-matching strategy used in [note 109.20](#), together with [note 109.19](#), shows that both original orders are  $r$ -equivalent to  $L_r = \sigma(\mathcal{F}_r)$ . Indeed, pair a newly visited block of size less than  $t_r$  with the identical finite size, and pair any larger block, including  $I_\infty$ , with size  $s_r$ . Conversely, every block size appearing in  $L_r$  is available densely in the original order. All paired blocks are either isomorphic or above the local  $r$ -round threshold. It therefore suffices to decide whether  $L_r \models \varphi$ .

For completeness, this last decision is effective as follows. Consider a rational dense linear order  $D_r$  with unary predicates  $P_s$ , for  $s \in \mathcal{F}_r$ , partitioning it into dense colours. Let  $K = \max \mathcal{F}_r$ . Represent  $L_r$  as the pairs  $(q, i)$  with  $0 \leq i < K$  and

$$D_i(q) := \bigvee_{\substack{s \in \mathcal{F}_r \\ i < s}} P_s(q),$$

ordered lexicographically, first by  $q$  and then by  $i$ . This is an effective finite-tag interpretation: for fixed tags, equality translates to equality of the rational coordinates and equality of the tags, and

$$(q, i) < (q', j) \iff q < q' \vee (q = q' \wedge i < j).$$

Translate an existential quantifier over a point into the finite disjunction  $\bigvee_{i < K} \exists q (D_i(q) \wedge \dots)$ , translating the subformula with that tag fixed. Boolean operations and universal quantifiers are handled recursively. This produces a sentence in the finite language of  $D_r$ .

The theory of a dense linear order without endpoints partitioned into finitely many dense colours has effective quantifier elimination. To eliminate one existential quantifier, put the quantifier-free formula into disjunctive normal form. In each conjunction, the quantified point either equals a parameter, lies in an interval between parameters, or lies in an outer ray. Test the equality cases directly. For a nonempty interval or ray, existence is equivalent to compatibility of the finitely many colour conditions, since every permitted colour is dense and unbounded. Inconsistent order or colour

conditions give false. These tests are finite Boolean combinations of comparisons and colours of the parameters. Repeated elimination reduces the translated sentence to true or false and decides  $\varphi$ . The procedure concerns the pure-order reduct only; it does not decide the class theory or an expansion by evaluation or set-likeness predicates.  $\square$

Thus the two pure countable order types record whether the model's natural numbers are standard, but their first-order theories do not. Within either side of the dichotomy, the bare order loses all further information about the particular model and its admitted classes. In particular, it cannot recover the model's arithmetic, its class realization, or which labelled well-orders were originally supplied. These conclusions concern the reduct to  $<$ ; an expansion retaining set-likeness, label evaluation, internal permutation ranks, or the internal natural-number sort can retain substantially more information. The expanded structures remain separate research questions. No claim of elementary equivalence for those expansions is made here.

### 109.3 Source 21: finite tails, intrinsic blocks, and countable realizations

The largest-common-prefix comparison and the exact adjacency criterion are baseline results of the audited repository ([theorems 14.2](#) and [16.2](#)). We now derive a more complete description of the resulting finite blocks, their automorphisms, and their behavior in countable models. The proofs are included; no claim of historical priority is needed. A crucial qualification is that an internally finite block need not be externally finite in a nonstandard model.

Throughout this section, the carrier is  $X = \mathbf{No}$ , although the local arguments apply to any infinite linearly ordered carrier admitting the required well-orders. Write  $L = \mathfrak{W}_{\text{all}}(\mathbf{No})$  when speaking virtually. For a two-sorted model  $\mathcal{M} = (M, \mathcal{X}) \models \text{GBC}$ , write  $L^{\mathcal{M}}$  for the *external* collection of its admitted class well-orders, equipped with the externally interpreted lexicographic formula. Assertions involving quotient sets, automorphism groups, or topological derivatives are made in such an external realization. Their finite-variable ingredients remain formulas of class theory.

#### 109.3.1 The canonical terminal tail

The blocks in this section are blocks *of the lexicographic order of well-orders*. They must not be confused with the set-interval blocks inside an individual non-set-like class well-order.

**Definition 109.23** (Maximal finite terminal tail). For an admitted class well-order  $R$  on  $X$ , let

$$T_R = \{x \in X : \{y \in X : x \leq_R y\} \text{ is a finite set}\}.$$

When working in a model, “finite” in this formula means finite in that model. Put  $C_R = X \setminus T_R$ , let  $P_R = R \upharpoonright C_R$ , and write  $n(R) = |T_R|$ .

*Note 109.24* (Source 21, Lemma 10.2, “Existence of the maximal finite tail”). *The class  $T_R$  is a finite final segment, possibly empty. Its complement  $C_R$  is nonempty and has no  $R$ -greatest element. Moreover,  $n(R) = 0$  exactly when  $R$  has no greatest element. This is source 18's [lemma 58.1](#) (Part IX); source 21 obtains  $T_R$  by one comprehension instead of the predecessor recursion.*

*Source 21's proof.* Elementary comprehension defines  $T_R$ . If it is nonempty, let  $x_0$  be its  $R$ -least element. The final segment beginning at  $x_0$  is finite by definition, and every point of that segment also has a finite final segment. Minimality of  $x_0$  shows that this segment is exactly  $T_R$ . Since  $X$  is infinite,  $C_R$  is nonempty. If it had greatest element  $c$ , the final segment beginning at  $c$  would consist of  $c$  together with  $T_R$ , contradicting  $c \notin T_R$ . Finally, a nonempty finite final segment has a greatest element, while the greatest element of  $R$ , if present, belongs to  $T_R$ .  $\square$

Let  $B(R)$  consist of the orders obtained by retaining  $P_R$  as an initial labeled prefix and appending an arbitrary permutation of  $T_R$ . This family requires no choice of a class for each permutation. If  $n = n(R)$  and  $\pi : n \rightarrow T_R$  is a set bijection, its member is given by the single elementary formula

$$\begin{aligned} xR_\pi y \quad &\Longleftrightarrow \quad (x, y \in C_R \text{ and } xRy) \\ &\vee (x \in C_R \text{ and } y \in T_R) \\ &\vee (x, y \in T_R \text{ and } \pi^{-1}(x) < \pi^{-1}(y)). \end{aligned}$$

The set of bijections  $n \rightarrow T_R$  together with this formula defines one uniform class relation encoding the whole family. Thus ordinary GBC comprehension suffices; no class-choice principle is being used.

*Note 109.25* (Source 21, Theorem 10.3, “Exact terminal permutation blocks”). *Let  $E(R, S)$  mean that  $R = S$ , or that the complement of the maximal common labeled prefix of  $R, S$  is finite. Then*

$$E(R, S) \quad \Longleftrightarrow \quad S \in B(R).$$

*In particular,  $E$  is an equivalence relation. Its classes are convex chains of size  $n(R)!$ , ordered as the ordinary finite lexicographic permutation order; here  $0! = 1$ . Each class has a least and a greatest member. This is source 18’s [proposition 58.3](#) together with source 17’s [theorem 54.4](#) (Part IX), in the internal form of source 20’s [note 109.15](#); source 21 adds the single uniform formula  $R_\pi$  coding the whole block.*

*Source 21’s proof.* If  $S$  permutes  $T_R$  after  $P_R$ , the common-prefix residual is contained in  $T_R$  and is finite. Conversely, suppose  $R, S$  share an initial labeled prefix  $P$  with finite residual carrier  $F$ . Every point of  $F$  has finitely many successors in both orders. A point of  $P$  has finitely many successors in  $R$  exactly when it does in  $S$ : the restrictions to  $P$  agree, and both remaining carriers equal the same finite set  $F$ . Consequently  $T_R = T_S$ , and the orders agree off this set. This proves the equivalence and transitivity.

A fixed-prefix cylinder is convex: an order that first departs from the prefix compares with every completion of the prefix in the same direction. Hence  $B(R)$  is convex. Its uniform set codes are the permutations of the  $n(R)$ -element set  $T_R$ , and lexicographic comparison of the codes is exactly comparison of their appended finite words. The least and greatest append the labels in increasing and decreasing native order, respectively.  $\square$

*Note 109.26* (Source 21, Corollary 10.4, “Intrinsic finite condensation”). *In an  $\omega$ -standard model, or in an external realization where these tails are genuinely finite,  $E(R, S)$  holds exactly when the closed lexicographic interval between  $R$  and  $S$  is finite. Thus the possible finite-condensation block sizes are*

$$1, 2, 6, 24, 120, \dots$$

*For a nonsingleton block its intrinsic size  $n!$  recovers  $n \geq 2$ . Singleton blocks combine the possibilities  $n = 0$  and  $n = 1$ . This is the external reading of source 17’s [theorem 54.4](#) and source 18’s [proposition 58.3](#) (Part IX), with the same proof.*

*Source 21’s proof.* An  $E$ -class is finite and convex. Conversely, list a finite interval as  $R = T_0 < T_1 < \dots < T_k = S$ . Each consecutive pair is adjacent in the full order. The baseline adjacency theorem says that its common-prefix residual is finite. Transitivity of  $E$  gives  $E(R, S)$ . In a model this argument uses  $\omega$ -standardness precisely to turn the internally finite residuals supplied by that theorem into externally finite sets.  $\square$

### 109.3.2 A dense quotient with every factorial color

The following result uses the explicit internal equivalence  $E$ . It is valid internally even when  $\omega$  is nonstandard. Statements about a virtual quotient are abbreviations for their formulations using a finite number of class variables.

*Note 109.27* (Source 21, Theorem 10.5, “Density of each tail length”). *The quotient by  $E$  is dense and has no endpoints. Between any two distinct  $E$ -classes, for every  $n \in \omega$ , there is a class represented by an order with maximal finite tail of length exactly  $n$ . In particular, the tail lengths 0 and 1 are separately dense, although both give singleton blocks.* This is source 18’s lemma 58.5 (Part IX) and source 19’s note 109.5. Source 21’s proof differs: it passes to the greatest and least members  $R^+$ ,  $S^-$  of the two boundary blocks and uses their non-adjacency, instead of the two-change argument.

*Source 21’s proof.* Suppose  $B(R) < B(S)$ . Let  $R^+$  be the greatest member of  $B(R)$  and  $S^-$  the least member of  $B(S)$ . They cannot be adjacent, because the adjacency theorem would put them in the same  $E$ -class. Choose

$$R^+ < T < S^-.$$

The class of  $T$  differs from both boundary classes. This already proves density of the quotient.

For the prescribed tail length, compare  $T$  with each boundary. The two common prefixes are nested initial segments of  $T$ . Let  $C$  be the larger one and let  $t$  be the first  $T$ -label after  $C$ . The residual  $X \setminus C$  is infinite: otherwise  $T$  would be  $E$ -equivalent to the corresponding boundary. Thus

$$Y = X \setminus (C \cup \{t\})$$

is infinite. Every completion of  $T \upharpoonright (C \cup \{t\})$  remains strictly between  $R^+$  and  $S^-$ , because this prefix includes the two first disagreements determining those inequalities.

Choose an  $n$ -element set  $F \subseteq Y$  and a countably infinite set  $Z \subseteq Y \setminus F$ . One can obtain these sets from successive least elements of the restricted order  $T$ : ordinary set recursion with the class parameter and class replacement suffice. Let  $K = Y \setminus (F \cup Z)$ . Complete the fixed prefix by

$$(T \upharpoonright K) + \text{an } \omega\text{-ordering of } Z + \text{an ordering of } F.$$

Concatenation of these finitely many class well-orders is again a class well-order. The displayed  $\omega$ -part has no greatest element, so the maximal finite terminal tail of the result is exactly  $F$ . This construction is uniform in its set parameters and does not choose from a family of nonempty collections of classes.

Finally, the full lexicographic order has no endpoints: replace an order’s first label by a smaller or larger surreal and put the remaining labels afterward. Since every  $E$ -class has endpoints, the quotient also has no endpoints.  $\square$

The proof deliberately does not presume that native surreal density survives an arbitrary proper-class prefix. Such a prefix may already have exhausted all labels in a native open interval. What is used is a later completion cylinder with infinite residual carrier.

**Definition 109.28** (Rational shuffle). For a countable list of nonempty countable order types  $A_i$ , let  $\sigma(\{A_i\})$  denote the lexicographic sum over a copy of  $\mathbb{Q}$  partitioned into dense color classes  $Q_i$ , with each point of  $Q_i$  replaced by a copy of  $A_i$ . Back-and-forth for countably colored dense orders shows that its isomorphism type does not depend on the chosen dense partition.

*Note 109.29* (Source 21, Corollary 10.7, “Countable standard realization”). *If  $\mathcal{M} \models \text{GBC}$  is externally countable and  $\omega$ -standard, then*

$$L^{\mathcal{M}} \cong \sigma(\{1, 2, 6, 24, 120, \dots\}).$$

This is the first clause of source 18’s [theorem 58.6](#) (Part IX), with the same proof.

*Source 21’s proof.* By [notes 109.26](#) and [109.27](#), the external condensation quotient is countable dense without endpoints, with every listed block size dense. The colored back-and-forth theorem identifies its quotient with the corresponding colored rational order, and the finite blocks then determine the lexicographic sum.  $\square$

### 109.3.3 Automorphism lifting and a failure of reconstruction

*Note 109.30* (Source 21, Theorem 10.8, “Automorphisms of finite blocks”). *In the setting of [note 109.26](#), let  $D$  be the external finite-condensation quotient and color  $d \in D$  by its block size  $c(d)$ . Then*

$$\text{Aut}(L, <_{\text{lex}}) \cong \text{Aut}(D, <, c).$$

*The induced map on the quotient determines the automorphism uniquely.* This is the automorphism clause of source 18’s [corollary 58.9](#) (Part IX), with the same proof; the orbit description in the next paragraph is its orbit clause.

*Source 21’s proof.* An increasing automorphism preserves finiteness of closed intervals, hence preserves the condensation equivalence and the size of each class. Conversely, a color-preserving quotient automorphism lifts by the unique increasing bijection between each finite block and its target. The union of these bijections is an increasing bijection of  $L$ . Uniqueness follows from rigidity of finite chains.  $\square$

In the countable standard realization, two points are in the same automorphism orbit exactly when their blocks have the same size and they have the same rank inside those blocks. Sufficiency follows by extending a one-point color-preserving map on the rational quotient; necessity follows from [note 109.30](#).

**Corollary 109.31** (A greatest element is not intrinsic). *In a countable  $\omega$ -standard realization, there is an automorphism of the pure lexicographic order taking a represented well-order with no greatest element to one with a greatest element. Such an automorphism cannot be induced by any fixed relabeling bijection of the surreal carrier.*

*Proof.* By [note 109.27](#), choose orders of tail lengths 0 and 1. Both are singleton blocks, and colored rational-order homogeneity maps one block to the other. Lift that map using [note 109.30](#). [Note 109.24](#) distinguishes existence of a greatest element in the represented orders. Relabeling preserves the abstract order type of every represented well-order and therefore cannot have this effect.  $\square$

[merge] The automorphism is the one used in the proof of source 18’s [corollary 58.10](#), which exchanges a set-like order with one of type  $\text{Ord} + 1$ ; the clause on relabelings is source 21’s.

This is a concrete limit on recovering enumeration structure from the pure lexicographic order. It also answers an automorphism question more strongly than merely exhibiting numerical relabelings. The countable homogeneity argument must not be silently transferred to arbitrary uncountable class realizations.

### 109.3.4 The nonstandard correction

External countability does not imply  $\omega$ -standardness. Consequently, an unconditional claim that every countable realization has the finite-factorial shuffle type would be false. The correction has an exact form.

*Note 109.32* (Source 21, Lemma 10.10, “An externally infinite finite interval”). *Let  $\mathcal{M}$  be externally countable, and let  $N \in \omega^M$  be nonstandard. The external order on the internal arithmetic interval*

$$I_N = \{i \in \omega^M : i <^M N\}$$

*has type*

$$I_\infty = \omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*.$$

This is source 19’s [lemma 109.6](#) and source 20’s [note 109.17](#), with the same midpoint argument.

*Source 21’s proof.* Externally declare  $i \sim j$  if their internal arithmetic difference is at most some *standard* natural number. The class of 0 is the standard natural numbers and has type  $\omega$ . The class of  $N - 1$  consists of  $N - 1 - k$  for standard  $k$  and has type  $\omega^*$ . Every other class has type  $\mathbb{Z}$ : it consists of the elements  $i + k$  for standard integers  $k$ , and both distances to the endpoints are nonstandard.

The quotient of the interior  $\mathbb{Z}$ -classes is nonempty, countable, dense, and has no endpoints. If  $i < j$  represent distinct classes,  $j - i$  is nonstandard, so the internally computed midpoint  $\lfloor (i + j)/2 \rfloor$  represents a strictly intermediate class. For an interior  $i$ , the element  $\lfloor i/2 \rfloor$  gives a class strictly between the initial class and that of  $i$ ; the symmetric construction works near the upper endpoint. The interior quotient therefore has type  $\mathbb{Q}$ . Taking the ordered sum of its classes proves the formula.  $\square$

*Note 109.33* (Source 21, Theorem 10.11, “Exact countable nonstandard realization”). *If  $\mathcal{M} \models \text{GBC}$  is externally countable and  $\omega$ -nonstandard, then*

$$L^{\mathcal{M}} \cong \sigma(\{1, 2, 6, 24, 120, \dots, I_\infty\}), \quad I_\infty = \omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*.$$

*In particular it is not isomorphic to the order in [note 109.29](#).* This is the  $\omega$ -nonstandard clause of source 19’s [theorem 109.1](#) and of source 20’s [note 109.13](#); the nonisomorphism is proved by the same finite-condensation invariant.

*Source 21’s proof.* Use the external interpretation of the internal equivalence  $E$ . [Note 109.25](#) states internally that each class is the finite permutation order on  $n$  labels for some  $n \in \omega^M$ . Its ordinary lexicographic rank gives an internal order isomorphism with  $I_{n!}$ . The uniformly coded family preceding [note 109.25](#) includes every such permutation. Conversely, a class order on an internally finite set is a set relation, hence corresponds to one of these permutation codes. Thus this internal isomorphism is also an external bijection between the entire  $E$ -class and  $I_{n!}$ .

For standard  $n$  the block is the actual finite chain of size  $n!$ . For nonstandard  $n$ , its internal factorial is nonstandard, and [note 109.32](#) gives the external type  $I_\infty$ . The external quotient by  $E$  is countable dense without endpoints by [note 109.27](#). Every standard factorial color is dense. Fix one nonstandard  $n$ ; the same internal theorem says that its prescribed tail length occurs between every two distinct classes, so the external color  $I_\infty$  is also dense. Colored back-and-forth proves the asserted shuffle representation.

The  $I_\infty$  blocks have externally infinite finite-condensation classes of types  $\omega$ ,  $\mathbb{Z}$ , and  $\omega^*$ . None joins a neighboring  $E$ -block: the endpoints of a maximal terminal permutation block have no immediate neighbors outside it, by the internal adjacency theorem. The finite-factorial shuffle has only finite condensation classes. This intrinsic distinction proves nonisomorphism.  $\square$

*Remark 109.34* (Exactly what is being transferred). The preceding theorem does not assume that every admitted class well-order is externally well-founded. Internal well-orderhood and the proved internal formulas supply the external linear order, its explicit  $E$ -blocks, and the dense-color witnesses. It is precisely the external notion of finite condensation that changes in a nonstandard model. Calling its  $I_\infty$  blocks “finite-condensation blocks” externally would therefore be incorrect.

*Note 109.35* (Source 21, Proposition 10.13, “Different orders, the same elementary theory”). *The two countable orders*

$$A = \sigma(\{1, 2, 6, 24, \dots\}), \quad B = \sigma(\{1, 2, 6, 24, \dots, I_\infty\})$$

are elementarily equivalent in the pure language  $\{<\}$ , although they are not isomorphic. This is the countable case of source 19’s [theorem 109.9](#) and the elementary-equivalence clause of source 20’s [note 109.13](#). Source 21’s strategy differs: it plays an  $I_\infty$ -block against a single finite factorial block of size at least  $2t_r + 1$  instead of merging large colours.

*Source 21’s proof.* We give a winning strategy for every finite Ehrenfeucht–Fraïssé game. The displayed shuffle blocks are an auxiliary device for the strategy; no block predicate or color is added to the language. With  $r$  rounds remaining, put  $t_r = 2^r - 1$ . Match the finitely many blocks containing selected points in quotient order. Inside every matched pair, require each corresponding gap between selected points, including the initial and final gaps, to have either the same size less than  $t_r$ , or at least  $t_r$  points on both sides.

The standard finite-chain splitting argument preserves this invariant. Indeed,  $t_r = 2t_{r-1} + 1$ . In equal short gaps copy the position exactly. In a pair of long gaps, if the new point leaves fewer than  $t_{r-1}$  points on one side, copy that distance from the corresponding endpoint; the other side still has at least  $t_{r-1}$  points. If both resulting sides are long, choose a point leaving at least  $t_{r-1}$  points on each side. This works in  $I_\infty$  as well: every nonempty gap determined by finitely many selected points has a least and a greatest element, and successor or predecessor steps realize every required finite endpoint distance.

When a move enters a previously unmatched finite block, choose a fresh block of exactly the same size in the other quotient interval. Such blocks occur densely, and one can copy the selected position. When a move enters a previously unmatched  $I_\infty$  block, with  $r$  rounds left after this move, choose a fresh finite factorial block of size at least  $2t_r + 1$ . Match the selected point by copying a side of size less than  $t_r$ , if present; otherwise leave at least  $t_r$  points on both sides. The dense factorial colors always supply the required block in the correct quotient interval. Existing matched gaps satisfy the weaker invariant for the new number of remaining rounds.

After the last round the matching preserves order and equality. Thus the strategy wins every finite game, proving elementary equivalence. Nonisomorphism was proved by the external finite-condensation invariant in [note 109.33](#).  $\square$

[merge] The following group description of the nonstandard order is source 21’s alone.

There is also a useful group description. In the nonstandard countable order, let  $F$  be the set of points having an externally finite condensation class. Its convex components are the standard factorial blocks, and the convex components of its complement are the  $I_\infty$  blocks. Indeed, between any two distinct  $E$ -classes there are blocks of both kinds. Thus this partition is intrinsic, even

though individual nonstandard tail lengths are forgotten. After choosing identifications of its  $I_\infty$  blocks, one obtains

$$\text{Aut}(L^{\mathcal{M}}) \cong \left( \prod_{q \text{ colored } I_\infty} \text{Aut}(I_\infty) \right) \rtimes \text{Aut}(\mathbb{Q}, <, \text{colors}).$$

The kernel and quotient are intrinsic; the displayed splitting uses the chosen identifications. Similarly,

$$\text{Aut}(I_\infty) \cong \left( \prod_{q \in \mathbb{Q}} \mathbb{Z} \right) \rtimes \text{Aut}(\mathbb{Q}, <).$$

To verify the last formula, the initial  $\omega$  and final  $\omega^*$  condensation classes are rigid. The interior quotient is  $\mathbb{Q}$  and each of its classes is  $\mathbb{Z}$ , whose increasing automorphisms are exactly integer translations. A quotient automorphism and one translation per class give all automorphisms.

### 109.3.5 One derivative removes all permutation interiors

Let  $L'$  denote the set of nonisolated points in the external order topology. The topology here belongs to the external order of admitted class relations; it does not require a class of classes inside GBC.

**Theorem 109.36** (The first derivative). *For an external model realization as above,  $L'$  consists exactly of the singleton  $E$ -blocks and the two endpoints of every nonsingleton  $E$ -block. It has no isolated points, so*

$$L'' = L'.$$

*The isolated points of  $L$  are dense, and  $L'$  is closed and nowhere dense. In either countable case,*

$$L' \cong \sigma(\{1, 2\}).$$

*Proof.* In a linear order without endpoints, a point is isolated exactly when it has both an immediate predecessor and an immediate successor. The internal finite permutation chain has these two neighbors at every rank other than its endpoints, including nonstandard internal ranks. These remain actual neighbors externally. At an endpoint there is no neighbor on the exterior side: such an adjacency would extend the maximal terminal block. Thus precisely the stated points survive.

The quotient by  $E$  is dense without endpoints. Consequently every neighborhood, within  $L'$ , of a retained endpoint or singleton contains retained points from other blocks. This proves  $L'' = L'$ . By the density of the color 6, every neighborhood of a retained point also contains an interior point of a six-element block, which is isolated in  $L$ . The isolated points are therefore dense. Their union is open, so  $L'$  is closed; the same density makes its interior empty.

Finally, in a countable realization the dense quotient contains densely many singleton blocks and densely many nonsingleton blocks. After the latter are replaced by their endpoint pairs, colored back-and-forth yields  $\sigma(\{1, 2\})$ .  $\square$

Thus the first derivative forgets the distinction between the two countable raw orders, although external finite condensation detects it. For uncountable realizations the principal remaining invariant is the colored quotient: its isomorphism type, saturation, and automorphism group need not be fixed by the preceding local arguments.

### 109.4 Source 30: A compactness observation about finite condensation

This observation concerns ordinary set-sized linear orders, for example the external countable orders in a countable class-model realization. It does not treat a virtual collection of classes as the domain of an ordinary first-order structure.

**Proposition 109.37** (Finite factorial blocks are not first-order protected). *Let  $L$  be a linear order containing finite adjacent chains of arbitrarily large length. Then the complete first-order theory  $\text{Th}(L, <)$  has a countable model with an infinite finite-condensation class. In particular, if every finite-condensation class of  $L$  is finite, that property is not preserved by elementary equivalence.*

*Proof.* Expand the language by constants  $c_i$  for  $i \in \mathbb{Z}$ , and add

$$c_i < c_{i+1} \quad \text{and} \quad \neg \exists z (c_i < z < c_{i+1}) \quad (i \in \mathbb{Z})$$

to  $\text{Th}(L, <)$ . Every finite subset of these axioms is realized by placing the finitely many relevant constants consecutively inside a sufficiently long adjacent chain of  $L$ . Compactness gives a model of the complete theory with all these constants. Downward Löwenheim–Skolem gives a countable such model. Every interval  $[c_i, c_j]$  for finite integers  $i < j$  consists of the finitely many named successive points. Hence all the  $c_i$  belong to one finite-condensation class, which is infinite.  $\square$

Factorial terminal blocks supply the hypothesis because  $n!$  is unbounded in  $\omega$ . Thus an external classification as a dense shuffle of finite factorial chains cannot by itself serve as a first-order characterization of lexicographic well-order spaces. It requires the external structural condition or a suitable infinitary language. This conclusion does not contradict an exact classification within a previously specified family of countable class-model realizations: compactness may produce orders outside that family.

[merge] Source 30’s proposition is classical compactness, and its source does not cite the other countable-model manuscripts. Source 19’s [theorem 109.12](#) constructs such models of the common theory explicitly, one for every countable order  $A$ , and the  $\omega$ -nonstandard GBC realizations of [theorem 109.1](#) are models of the same theory with infinite finite-condensation classes. Together they show why the external finiteness condition in source 18’s [theorem 58.6](#) cannot be replaced by a first-order axiom, as source 19’s paragraph after [proposition 109.7](#) also says.

## 110 Foundations: full rank semantics and well-foundedness (source 27)

[merge] Source 27’s foundations section, printed whole. Its four levels of discourse and its account of ETR agree with the foundational sections of Parts V and IX ([part V](#), [section 57](#)); new is [theorem 110.1](#), which states as an equivalence what this report used only in one direction: the full structure  $(V_\kappa, \mathcal{P}(V_\kappa))$  satisfies GB exactly when  $\kappa$  is strongly inaccessible, and then satisfies KM + GC (sufficiency is used by source 08’s model (S08.12) and source 09’s [theorem 22.1](#)). Both directions are standard; source 27 does not claim novelty for them. Its ledger refers to results of its other sections, which this addition prints in other Parts.

### 110.1 Source 27: foundations that avoid size paradoxes

#### 110.1.1 Four safe levels of discourse

**A fixed set.** For  $X = \mathbf{No}_{<\theta}$  or any other set of labels,  $\mathcal{W}(X)$  is a subset of  $\mathcal{P}(X^2)$ . All relation-table spaces, all their subsets, their order topologies, and their Dedekind cuts are ordinary sets. This

is the cleanest environment for cardinal spectra, topology, computation, and first formalization milestones. An infinite birthday cutoff does not require an inaccessible cardinal.

**Definable classes in set theory.** In ZFC, the sign-sequence description defines a proper class **No**. One can state a schema about each formula defining a class relation, prove uniform constructions from specified formula parameters, and quantify over set-coded words. One cannot quantify over all arbitrary classes as objects of ZFC. Syntax codes do not erase this distinction: a universal satisfaction predicate for the universe is not supplied by the set of formula codes.

**Two-sorted class theory.** In GBC, individual class relations are variables of the second sort. Formulas such as  $R <_{\text{raw}} S$  and statements quantifying over class well-orders are legitimate. A uniformly given family has one graph  $\mathcal{R}(i, x, y)$  with set indices  $i$  in an ordinary class. This setting supports the comparison, residual maps, prefix automorphisms, and diagonal theorem proved above.

**An external model or a higher type.** If  $(M, \mathcal{X})$  is a set-sized model in a surrounding theory, its admitted classes are elements of the external set  $\mathcal{X}$ . The external collection of admitted well-orders is then a set, with an ordinary topology and automorphism group. Alternatively, a higher-order theory can explicitly add a sort for collections of classes. Either route must specify its semantics and comprehension principles; neither follows merely from writing braces around a class-variable predicate.

Kelley–Morse theory strengthens the permitted comprehension formulas, but its classes still have sets as members. It does not automatically turn an arbitrary collection of classes into a class. Work on hyperclass forcing makes such higher-level distinctions explicit [28]; that literature is context for the additional type level, not an axiom needed by the theorems here.

### 110.1.2 Why Global Choice is visible

Global Choice provides an ordinal enumeration of every proper class, including **No**. Its standard equivalent formulations distinguish it from ordinary set Choice [19]. In this particular setting, the repository proves the stronger converse: over GB, the existence of any class well-order of **No** implies Global Choice (theorem 13.1). Thus the baseline is not innocent notation.

For perspective, the set-code surjection  $d : \mathbf{No} \rightarrow V$  used above explains the mechanism once set Choice is available. A well-order of **No** lets one choose the least code of each set and hence obtain a global choice procedure. The choiceless version in the repository also establishes the required set Choice by set-valued rank recursion. We do not reclassify that established equivalence as an open question.

Set-sized results in sections 84.1 and 101 need much less. The explicit increasing-word split needs no choice at all; its homogeneous class-order identifications use Global Choice. The support optimum is a pointwise theorem about well-orderable sets of ordinals; only its use as a uniform completion procedure requires a fixed selection mechanism.

### 110.1.3 Set-state recursion and genuinely class-valued recursion

An ordinal-length process whose state and earlier history are sets at every set stage is available by ordinary recursion with class parameters. One constructs each set-length run, proves uniqueness, and takes its elementarily definable union. The residual isomorphism lemma follows this pattern. The fact that the final graph is a proper class does not make each intermediate state a class.

Elementary transfinite recursion, ETR, addresses stronger situations in which individual stages can themselves be classes and later stages refer to entire earlier class slices. Truth-predicate and class-game examples illustrate this distinction in the primary literature [22, 27]. We use no inference from “a recursion has length Ord” to “it requires ETR.” Conversely, we do not justify a simultaneous

choice of class isomorphisms merely by calling it ordinary recursion. The uniform graph construction in [lemma 96.1](#) is the required justification.

#### 110.1.4 Full rank models: an exact inaccessible-cardinal criterion

An inaccessible cardinal is a convenient way to replace the whole two-sorted universe by a full rank model. Its precise role can be stated as an equivalence.

**Theorem 110.1** (Full rank semantics). *In ambient ZFC, the full two-sorted structure*

$$(V_\kappa, \mathcal{P}(V_\kappa))$$

*satisfies GB, with the usual set part including Infinity, if and only if  $\kappa$  is strongly inaccessible. In that case it also satisfies KM with Global Choice.*

*Proof.* Suppose the full structure satisfies GB. Its set part makes  $\kappa$  a limit ordinal above  $\omega$ . If  $\text{cf}(\kappa) < \kappa$ , an external cofinal map  $f : \text{cf}(\kappa) \rightarrow \kappa$  is an available full class, with domain a set of  $V_\kappa$ . Its range has unbounded rank below  $\kappa$  and is not a set of  $V_\kappa$ , contrary to Class Replacement. Hence  $\text{cf}(\kappa) = \kappa$ , so  $\kappa$  is a regular cardinal.

If  $2^\lambda \geq \kappa$  for some cardinal  $\lambda < \kappa$ , ambient Choice gives a surjection  $\mathcal{P}(\lambda) \rightarrow \kappa$ . Its graph is also a full class, and its domain belongs to  $V_\kappa$ . Class Replacement would put its range  $\kappa$  in  $V_\kappa$ , again impossible. Thus  $\kappa$  is an uncountable regular strong limit cardinal.

Conversely, at a strongly inaccessible  $\kappa$ , every set in  $V_\kappa$  has external cardinality below  $\kappa$ . Any full class function on such a set has fewer than  $\kappa$  values, whose ranks are bounded below  $\kappa$  by regularity. Its range is therefore in  $V_\kappa$ . Standard rank closure supplies the set axioms, and this argument supplies Class Replacement. Every subset is admitted as a class, so even impredicative class comprehension holds. An external well-order of  $V_\kappa$  supplies a Global Choice class.  $\square$

The theorem characterizes *full rank initial-segment models*. It does not say that all Henkin models of GBC require inaccessible cardinals, nor that a set of surreals cut off at an arbitrary birthday is invalid. A singular birthday fragment is a legitimate set order; it is generally not the set part of a full class-theoretic universe.

#### 110.1.5 Internal versus external well-foundedness

There are three separate assertions: a relation is well-founded on sets of a model, it is well-founded on that model's admitted classes, and it is well-founded externally. Under GBC the first two agree, by the descending-sequence argument, but they need not agree with the third. Even transitivity of the set part is not by itself the full correctness condition for class well-foundedness [[27](#), Section 3].

For shared relations in two same-set GBC expansions, their internal well-foundedness agrees because their set-coded descending sequences agree. Their admitted relations may still differ, which is precisely what [note 102.5](#) detects. The distinction prevents two common errors: assuming that adding classes must destroy old internal well-foundedness, and assuming that an internal ordinal enumeration can always be traversed as an externally well-founded sequence.

#### 110.1.6 An axiom and object ledger

| Construction or theorem                            | Sufficient setting and object type                                                             |
|----------------------------------------------------|------------------------------------------------------------------------------------------------|
| All well-orders on a fixed set $X$                 | ZFC; a set of set relations.                                                                   |
| Terminal-cut factorization                         | ZF or elementary class definitions; a map on set-coded words.                                  |
| Pointwise minimum ordinal support                  | ZF with definable-class notation; all matching sets are well-orderable.                        |
| Direct raw labelled comparison                     | GBC; an elementary formula on two class parameters. No hyperclass is formed.                   |
| Uniform residual isomorphisms and branch transport | GBC with a baseline; one graph on set tuples, assembled from set runs.                         |
| Omitted convex copy for every uniform family       | GBC; diagonalization on an ordinary class index, with a formula on residual class orders.      |
| Dense core in raw relation-table order             | GBC and a set-like scan; an ordinary class of set codes.                                       |
| Marked-model embedding criterion                   | An external theorem about two set-sized GBC models with common sets and baseline.              |
| All subsets and topology of an admitted order      | A surrounding universe where the admitted class part is a set, or an explicitly stronger type. |
| Full $(V_\kappa, \mathcal{P}(V_\kappa))$ semantics | Exactly an ambient strongly inaccessible $\kappa$ for the usual GB axioms.                     |

## 111 Foundations, formalization plans and ledgers of sources 19–30

[merge] (3 October 2026.) Each batch-83 source states its foundations, a formalization plan tied to the repository’s Lean files, a ledger of results and assumptions, and a record of its checks and audit. They are printed here, whole and in source order, together with the baseline sections that no Part prints: source 19’s core and raw comparison (its Sections 3.1 and 4), source 20’s size-safe toolkit, source 23’s embedding spectra and core, and the class-comparison sections of sources 27 and 30. Their re-proofs of Parts I–IV are printed as numbered notes with the source’s proof kept; nothing in them is new against this report. Five sources’ foundations sections are printed where their mathematics is: source 24’s, source 26’s and source 28’s in Part X, source 25’s size and recursion audit in Part XIII, source 27’s foundations (with its full-rank criterion) in Part XIV. The sources’ research questions are in [section 113.12](#); the shipped finite checks and how to rerun them are in [section 111.49](#).

Every Lean declaration that these sections name as existing was checked on 3 October 2026 against `Algebra/SurrealNumbers/Surreal/Foundations/`: `SignSequence`, `SignSequence.lt_iff` (proved by `Iff.rfl`), `birthdays_bounded`, `small_bounded`, `not_small`, `IsPrefix`, `ordinalOrderEmbedding`, `ofSigns`, `simpler_wellFounded` (`SignSequence.lean`); `small_cut_fillers`, `exists_cut_separator_of_birthday_lt` (`SignSequenceCut.lean`); `cut`, `cut_realizes`, `birthday_cut_le_iSup`, `exists_separator_of_small_sets` (`SignSequenceCutOperation.lean`; a variant `HasSmallCutFillers.exists_separator_of_small_sets` and `ofSmallSets` are in `SmallCutData.lean`); `SmallCutData`, `HasSmallCutFillers`, `noUnrestrictedCuts` (`SizeObstructions.lean`); `isPrefix_of_minimum_birthday`, `existsUnique_prefix_of_ordConnected`, `existsUnique_minimum_birthday_of_ordConnected`, `ordConnected_separators` (`SignSequenceSimplicity.lean`) and `existsUnique_simplest_separator`, whose existence hypothesis the sources describe correctly. All exist, at the blobs the sources quote. Every other module or declaration

name in these plans (for example `WellOrders/ExhaustionTree`, `GroupEnvelope`, `ProfileExtension`) is a proposal of its source, as each source says; none exists, and none of this report's statements is formalized (section 1.5).

*Note 111.1* ([merge]; the class-theoretic conventions the twelve repeat). All twelve sources fix the same conventions, which are this report's (sections 1.3 and 1.3.1): GB has a ZF set part and no choice,  $GBC = GB + GC$ , and set-sized results are proved in ZFC (sources 19–30, in the subsections printed here and in section 61); a collection of class relations is a predicate on class variables, not a class (all twelve); a uniform family is one class relation with set indices (sources 20, 21, 22, 24, 27, 28, 29 with definition 80.2, 30); recursion with set values and set-sized histories is available in GBC, while class-valued recursion is ETR and is not used (sources 19, 20, 21, 22, 23, 25, 27, 29, 30, citing [22, 24]); in GBC a class well-order is well-founded exactly when it has no set-coded descending  $\omega$ -sequence, so well-foundedness of a fixed relation is absolute between class realizations with the same sets (sources 20, 22, 27, 30; the Hilbert's-tenth correction recorded in section 5.6), while internal and external well-foundedness differ (all twelve); KM does not make classes members of classes (sources 19, 20, 21, 22, 28, 29, 30); and an inaccessible full model  $(V_\kappa, \mathcal{P}(V_\kappa))$  is an optional external illustration (sources 19, 20, 21, 22, 23, 24, 28, 29), as in theorem 22.1. Each source's own wording is kept below.

### 111.1 Source 19: set-like global enumerations and their core

[merge] Source 19's Section 3.1, printed whole (the rest of its Section 3 is a note in Part X). Its core  $C$  is this report's core in the support coding,  $\mathcal{P}_s(e)$ ; (S19.2) is corollary 19.15 with the separation property of theorem 19.10.

Under Global Choice fix a set-like enumeration  $e : \text{Ord} \rightarrow \mathbf{No}$ . A bounded-support modification permutes some initial set of positions and agrees with  $e$  thereafter. Choose one canonical set code for each such modification. These codes form an ordinary class  $C$  of sets, with an evaluation relation that produces the associated global order. The earlier reports prove

$$C \cong \mathbf{No}, \quad C \text{ separates any two distinct exhaustive set-like enumerations.} \quad (\text{S19.2})$$

They also prove the stronger parameterwise interpolation statement for every uniformly set-indexed cut of set-like enumerations [39, §19] ([merge] theorem 19.10). Uniformity means that the family is supplied by one class relation with a set index; it does not mean an arbitrary external set of class objects.

One elementary fact will be used repeatedly. Every injective set prefix  $p : \alpha \rightarrow \mathbf{No}$  extends to a member of  $C$ : choose a large initial segment of  $e$  containing all labels in  $p$ , put the prefix first, and reorder the remaining set of labels before returning to the unchanged tail. If a proper class word  $F : \text{Ord} \rightarrow \mathbf{No}$  is injective, then at every set stage there are members of  $C$  on both sides of  $F$  sharing that prefix. Choose their next labels slightly below and above  $F(\alpha)$  and avoid the used set.

### 111.2 Source 19: raw class comparison and canonical blocks

[merge] Source 19's Section 4, printed whole; its two propositions are results of Parts III and IX and are recorded as notes.

An admitted class well-order is a strict linear class order whose restriction to every nonempty admitted subclass has a least element. In GBC one may equivalently use the usual well-foundedness test on sets; this is a statement inside the class model, not an assertion about all external subsets [27, §3].

**Definition 111.2** (Common labelled initial segment). For class well-orders  $R, S$  of the same labelled carrier  $X$ , let  $C(R, S)$  consist of the labels  $x$  for which

$$\text{Pred}_R(x) = \text{Pred}_S(x), \quad R \upharpoonright \text{Pred}_R(x) = S \upharpoonright \text{Pred}_S(x).$$

Here  $\text{Pred}_R(x) = \{y : yRx\}$ . Each equality expands to a first-order formula with  $R, S$  as class parameters.

*Note 111.3* (Source 19, Proposition 4.2, “Elementary comparison; prior result”). If  $R \neq S$ , the class  $C = C(R, S)$  is a proper initial segment of both orders, the orders agree on it, and their first labels outside  $C$  are different. Define  $R <_{\text{lex}} S$  when the first remaining  $R$ -label is numerically smaller than the first remaining  $S$ -label. This is a linear order, expressed as a formula on class parameters in GB. This is [theorems 14.2](#) and [14.7](#); source 19 calls it a prior result.

*Source 19’s proof.* If a label satisfies the defining property, every predecessor does too. Thus  $C$  is initial and the restrictions agree. Every common labelled initial segment is contained in  $C$ . If  $C = X$ , the relations agree everywhere. Otherwise take the least remaining label of each order. The predecessor class of each is exactly  $C$ ; equality of the two labels would put that label in  $C$ , a contradiction.

For transitivity, the common prefixes of  $R, S$  and of  $S, T$  are initial segments of  $S$ , so one contains the other. If containment is proper, the earlier comparison decides  $R$  against  $T$  with the same sign. If the prefixes coincide, compare the three next numerical labels; the transitivity of the label order applies. Trichotomy and asymmetry follow directly. No recursive matching of different labels and no class of equivalence classes is used.

*Note 111.4* (Source 19, Proposition 4.3, “First block and full block decomposition; prior results”). Let  $R$  well-order a proper class  $X$ . Its labels with set-sized predecessor class form a proper-class initial segment, possibly all of  $X$ , of type Ord. More generally, declaring  $x \sim_R y$  when the closed  $R$ -interval between them is a set gives convex blocks of type Ord, with at most one final set-sized block. In GB,

$$R \cong (J_R \times \text{Ord})_{\text{lex}} + \theta_R,$$

where  $J_R$  is represented by the actual least labels of the proper blocks and  $\theta_R$  is a set ordinal. This is the first block of [theorem 15.1](#) and the canonical block decomposition of Part IX (source 15’s [theorem 52.3](#); also [theorems 52.6](#) and [52.11](#)); source 19 calls both prior results.

*Source 19’s proof.* The first claim follows by enumerating each set predecessor segment by its unique ordinal rank. This segment cannot stop after only a set of labels: the least remaining label would also have set predecessors. Every ordinal rank occurs, since a missing rank would yield a first missing stage after a set initial segment. This yields its class isomorphism with Ord by elementary comprehension.

For the full decomposition, set intervals are closed under finite unions, proving transitivity of  $\sim_R$ . Each block has a least label by class well-ordering. Within a block every predecessor segment from that least label is a set. Thus its type is a set ordinal or Ord. A set block followed by another label would unite with the next label to remain a set interval, contradicting maximality. Hence a set block can only be final. The ranks within each proper block and the least block labels give the displayed isomorphism. This simultaneous construction does not iterate a class-valued quotient operation.

The quotient  $J_R$  need not be simpler than  $R$  up to isomorphism. Earlier work gives fixed-point examples [\[44, 46\]](#) ([merge] sources 16 and 18, Part IX). Consequently this decomposition alone does not justify a terminating recursive classification.

*Remark 111.5* (Existence and choice). Over GB without set choice, the existence of any class well-order of **No** is equivalent to Global Choice [39, Theorem 13.1] ([merge] [theorem 13.1](#)). The forward implication uses its restrictions to the binary sign levels to well-order every  $\mathcal{P}(\alpha)$  uniformly, and then constructs rank-wise well-orders of the universe by set recursion. In this article the global constructions simply state GBC as their hypothesis.

### 111.3 Source 19: formalizations that preserve the intended subject

The foundational issue is not repaired merely by replacing the word “set” with “class.” A class theory has its own sorts and its own comprehension principles. The earlier sections illustrate three distinct tasks: comparing supplied class relations, constructing one class from supplied parameters, and studying a domain whose elements are arbitrary classes. They require different formal interfaces.

#### 111.3.1 A size ledger

| Object                   | Safe internal treatment                                | Safe external treatment                                           |
|--------------------------|--------------------------------------------------------|-------------------------------------------------------------------|
| A surreal sign sequence  | A set with an ordinal domain                           | An element of the model’s interpreted surreal carrier             |
| <b>No</b> itself         | A proper class                                         | A set in a containing universe when the entire model is a set     |
| A global well-order $R$  | A class relation; allowed as a class parameter         | One element of the external set of admitted relations             |
| All global well-orders   | A predicate on class variables                         | The actual external set $\mathfrak{M}_{\text{all}}^{\mathcal{M}}$ |
| The bounded-support core | A class of canonical set codes                         | A set of codes with an interpreted evaluation relation            |
| A supplied core cut      | A class subset of those set codes                      | A subset of the external core                                     |
| All external core cuts   | No claim of a same-level class of such objects         | A subset of the power set of the external core                    |
| The decorated completion | A parameterwise or explicitly higher-sort construction | An ordinary set-theoretic lexicographic sum                       |

A two-sorted model need not be transitive,  $\omega$ -standard, or a  $\beta$ -model. Its assertions of well-foundedness concern the objects and subclasses that it admits. An external descending sequence might be absent from its set sort. None of the external model theorems silently replaces admitted well-orders by relations that are actually well-founded in the containing universe.

*Note 111.6* (Source 19, Proposition 13.1, “The uniform coding obstruction”). *In GBC there is no class relation  $A \subseteq I \times \text{Ord}$ , with  $I$  a class of set indices, whose rows enumerate every admitted binary class on  $\text{Ord}$ .* This is source 11’s diagonal non-coding theorem ([theorem 19.37](#)), here for rows that are binary classes on  $\text{Ord}$ , by the same diagonal class  $D$  along a class surjection onto the index class.

*Source 19’s proof.* If  $I$  is empty the assertion is immediate. Otherwise Global Choice gives a class surjection  $b : \text{Ord} \rightarrow I$ : enumerate a proper  $I$  in type  $\text{Ord}$ , or enumerate a set  $I$  and repeat a fixed value after its enumeration ends. Elementary comprehension forms

$$D = \{\alpha \in \text{Ord} : (b(\alpha), \alpha) \notin A\}.$$

For every  $i \in I$ , choose  $\alpha$  with  $b(\alpha) = i$ . Then  $D$  differs from the  $i$ th row at  $\alpha$ , a contradiction.

Pair-swapping a fixed global enumeration transfers this obstruction to uniform exhaustive coding of all set-like global orders. It explains why the core is useful but cannot contain every global

enumeration. It also explains the model-relative missing branches of Theorem 100.1. A single externally specified family can exist as a set in a larger universe without being a uniformly admitted family inside the original model.

### 111.3.2 Why the elementary constructions do not require ETR

In ordinary set recursion, the object constructed at every ordinal stage is a set, and the history below a fixed set ordinal is a set. With a fixed class parameter, GB proves the appropriate set recursion and Class Replacement. Unique compatible initial solutions can then be assembled by an elementary formula: a pair belongs to the final class precisely when it appears in some set-sized initial solution. This applies to birthday-controlled insertion, deterministic back-and-forth on partial set maps, and the set-valued recursive choices used throughout the global core construction.

By contrast, an elementary transfinite recursion with class-valued stages asks for a class  $S \subseteq \Gamma \times V$  satisfying

$$S_\gamma = \{x : \varphi(x, S \upharpoonright \gamma, Z)\},$$

where each  $S_\gamma$  may already be a proper class. This is the principle  $\text{ETR}_\Gamma$ , not a consequence obtained merely by calling the operation a recursion. Already  $\omega$ -length class-valued recursions can construct truth predicates. The distinction and its connections with determinacy and class forcing are developed in [22, 24, 27, 35].

The common labelled prefix is elementary because equality of the two predecessor relations expands into quantification over labels. The simultaneous set-interval block decomposition is elementary because one uses actual least block labels and set intervals. Neither construction attempts to recursively find an arbitrary isomorphism between differently labelled class well-orders. Such abstract comparison is the subject of stronger principles; for example, Williams's Lemma 3.17 uses an ETR hypothesis [35].

The model-theoretic shuffle proofs likewise use only ordinary set-valued constructions internally. The use of an external finite Ehrenfeucht–Fraïssé game does not assert that the entire external family of plays or strategies belongs to the class model.

### 111.3.3 Four workable foundational routes

**Bounded ZFC mathematics.** Fix  $X$ ,  $\alpha$ , or a birthday bound. Then every enumeration, cut, automorphism, and completion is a set. The infinite-tail spectrum, restriction classification, and bounded completion normal forms can all be formalized here. No inaccessible cardinal or class theory is needed for these results. This is the most direct route for the first machine-checked development.

**GBC with supplied class parameters.** State results as formulas about  $R, S, F, C$  and supplied uniform families. Define the comparison, first block, set-interval quotient, and trace cuts with elementary comprehension. When a theorem mentions all class well-orders, it universally quantifies a class variable; it does not create a new class containing those relations as elements. This route closely matches the elementary global proofs.

**External models.** Fix a set-sized structure  $\mathcal{M} = (M, \mathcal{X})$  in a containing ZFC universe. Its class sort is now an external set, so  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$ , its automorphism group, its power set, and its Dedekind completion are ordinary mathematical objects. This is the route used by the decorated-completion and model-spectrum theorems. The resulting object is model-relative; it is not a replacement for the class of all actual surreals in the containing universe.

A useful full-class example is  $(V_\Omega, \mathcal{P}(V_\Omega))$  for a strongly inaccessible  $\Omega$  in an outer universe. It gives strong comprehension internally. Such an example is a sufficient semantic setting, not a hidden assumption behind the set-sized theorems. In this model the set-like global orders correspond externally to  $\Omega$ -length exhaustive enumerations of the bounded surreal carrier, while arbitrary admitted well-orders can have any external order type of cardinality  $\Omega$ .

**An explicit higher sort or universe hierarchy.** One may introduce a sort of collections of classes, or work in nested universes and state exactly which objects are small at which level. This permits a domain of global orders and families of their cuts directly. It changes the ambient language or universe, and the additional comprehension or size assumptions must be listed. KM permits stronger quantification over classes in comprehension; it does not make proper classes into elements of other classes.

These routes are complementary. A proof can first be established as an ordinary theorem about a set linear order, then interpreted in a larger universe, or instantiated with the external orders of a class model. What must be proved separately is that the interpretation has the intended admitted relations and the intended smallness predicates.

#### 111.3.4 A Lean development tied to inspected repository sources

The inspected revision contains `Algebra/SurrealNumbers/Surreal/Foundations/SignSequence.lean` and `SignSequenceCutOperation.lean` [53]. The first defines

$$\text{SignSequence.}\{u\} : \text{Type } (u + 1)$$

and proves `birthdays_bounded`, `not_small`, and `small_bounded`. The last declaration makes a fixed birthday-bounded fragment small relative to  $u$ ; the first requires an explicit `Small.}\{u\}` hypothesis on the indexing type. The cut-operation file proves `exists_separator_of_small_sets`, with explicit `Small.}\{u\}` instances for both option subsets. These are exactly the size-sensitive facts needed by the elementary order theory. They do not yet certify the new results of this article.

Lean's universe hierarchy and impredicative propositions do not erase these distinctions [29]. A predicate on a large type may be perfectly well-formed without its extension being small in the smaller universe. In particular, writing a relation on `SignSequence.}\{u\}` does not prove that its predecessor types are `Small.}\{u\}`. Set-likeness should be recorded as that explicit condition. Likewise, an external Lean well-foundedness predicate on a type is not automatically the internal well-foundedness predicate of a chosen GBC model.

The following module boundaries are proposals; no modules with these names are claimed to exist in the inspected repository.

| Proposed layer             | Main statements                                                             | Why it comes here                               |
|----------------------------|-----------------------------------------------------------------------------|-------------------------------------------------|
| Labelled enumeration order | First disagreement, prefix cylinders, literal residual lexicographic sum    | Common set-level interface                      |
| Binary codes and fusion    | Prefix-free sign code; constant-subcylinder lemma; fusion into one fiber    | The main embedding mechanism                    |
| Fixed-type spectra         | Cardinal-layer division; deletion scheduler; lower and upper weighted ranks | New ZFC classification                          |
| Completion codes           | Full branches, numerical splits, limit boundaries; canonical comparison     | Exact bounded arrangement, beyond characters    |
| Restriction maps           | Three- and four-label witnesses; exact classification                       | Small, independently reusable theorem           |
| Class-model interface      | Two sorts, admitted comprehension and replacement, evaluation of formulas   | Internal/external interpretation boundary       |
| Raw comparison and core    | Common labelled prefix; bounded-support codes; first-block trace            | Parameterwise class results                     |
| External reconstruction    | Decorated completion and automorphism extension                             | Ordinary theorem on the external set order      |
| Model invariants           | Tail cylinders, nonstandard intervals, EF games                             | Exact external classification and common theory |

The finite restriction theorem is an attractive first target: it needs no surreal arithmetic and has short explicit witnesses. The next high-value target is the fusion lemma, because it isolates the main reason for strict nonembedding results. The cardinal-layer theorem then becomes a composition of independently checked encoders and fusion costs. Formalizing the entire GBC metatheory should be a separate project rather than an implicit side effect of introducing a large type.

An alternative formalization may use a set-theoretic universe such as a Tarski–Grothendieck model. Existing surreal formalization work gives relevant experience with foundations and Conway normal forms [37]. That work is methodological context here; the present proofs are order-theoretic and do not require a formalized normal-form theorem or surreal multiplication.

#### 111.4 Source 19: results, assumptions, and verification status

The results have different logical scopes. Keeping them separate is part of their content, not a qualification added after the fact.

| Result                                             | Foundation                                          | Remaining limitation                                                    |
|----------------------------------------------------|-----------------------------------------------------|-------------------------------------------------------------------------|
| Weighted fixed-type bounds and exact cube spectrum | ZFC                                                 | Least coding length may lie between different computed bounds           |
| Bounded completion normal forms                    | ZFC, dense full-size intervals                      | An explicit completion description is not a short isomorphism invariant |
| Exact monotone restrictions                        | ZFC; class version in GBC                           | Does not forbid carefully designed enlargement embeddings               |
| Common labelled class comparison                   | GB, supplied class parameters                       | Does not compare unlabelled class order types by isomorphism            |
| Decorated completion and automorphism extension    | External ZFC around a specified set-sized GBC model | Model-relative admitted fibers                                          |
| Missing persistent external branches               | Externally countable GBC model                      | The constructed branches need not be admitted classes                   |
| Two countable realization types                    | Externally countable GBC model                      | The common theory has many other countable models                       |

The repository and same-day continuation results are identified where used. The new arguments were developed with separate checks of the ordinal coding, residual reconstruction, and model-theoretic proofs. That is proof review within the preparation of this manuscript; it is not external peer review.

The included Python program exhaustively verifies the restriction classification on all carriers of size at most seven. It tests every subset and every adjacent pair in the lexicographically sorted permutation list; the recorded run contains 695,228 comparisons. This is meaningful evidence for the finite witness analysis. It does not certify any transfinite, class-theoretic, or cardinal-arithmetic statement. No new Lean proof was compiled, and no uncompiled Lean sketch is presented as a certificate.

The accompanying source is a standalone L<sup>A</sup>T<sub>E</sub>X document with an internal bibliography and no external figures.<sup>17</sup> The PDF was compiled from that source and checked by rendering its pages. The archive also contains a build command, the finite-check program and its output, and a concise source and proof-status record.

## 111.5 Source 20: a size-safe toolkit

### 111.5.1 Signs, birthdays, and set cuts

We use the sign-sequence presentation

$$\mathbf{No} = \bigcup_{\alpha \in \mathbf{Ord}} \{-, +\}^\alpha.$$

The birthday  $\text{bd}(x)$  is the domain length of  $x$ . At the first unequal position, compare  $- < \text{undefined} < +$ . The birthday fragment  $\mathbf{No}_{<\theta}$  is a set for every set ordinal  $\theta$ . Every set of surreal

<sup>17</sup>[merge] Source 19's source and PDF are in arrival commit `b63f0c852`. Its build command, finite-check program, output and status record are shipped as `code/19-residual-build.sh`, `code/19-residual-check_restrictions.py`, `data/19-residual-restriction_checks.json` and `19-residual-source_status.txt`; the checker writes its JSON beside itself (section 111.49).

numbers has bounded birthdays. For an infinite initial cardinal  $\kappa$ , put

$$\mu = |\mathbf{No}_{<\kappa}| = 2^{<\kappa}.$$

This is an equality of cardinals, and it is not a claim that every ordinal calculation involving  $\mu$  can be replaced by cardinal arithmetic.

The basic surreal separation property is: if  $A, B$  are sets and  $A < B$ , a surreal lies strictly between them. Empty sides are allowed. It implies the following strengthening used repeatedly.

*Note 111.7* (Source 20, Lemma 3.1, “A fresh separator”). *If  $A, B, U$  are sets of surreals with  $A < B$ , there is a surreal  $z \notin U$  such that  $A < z < B$ .* This is source 11’s lemma 5.2 (a set can be avoided), with the same one-line proof.

*Source 20’s proof.* Let  $U_0$  be the members of  $U$  lying strictly between  $A$  and  $B$ . Then  $A \cup U_0 < B$ . Choose  $z$  between these two sets. If  $z \in U$ , the inequalities would imply  $z \in U_0$ , contrary to  $U_0 < z$ .

Every nonempty open numerical interval of  $\mathbf{No}$  is a proper class. Otherwise apply note 111.7 with that interval as the forbidden set. The same argument shows that deleting a set preserves the set-cut property.

### 111.5.2 What the class theories permit

Here GB means Gödel–Bernays theory whose set part is ZF, without Global Choice built into the abbreviation; GBC adds Global Choice. All global baseline constructions in this article take place in GBC. A class well-order is a strict linear class relation for which every nonempty available subclass has a least member. It is *set-like* when every strict predecessor class is a set.

An individual member of  $\mathfrak{W}_{\text{sl}}$  or  $\mathfrak{W}_{\text{all}}$  is a class relation. Consequently “ $R \in \mathfrak{W}_{\text{all}}$ ” abbreviates a predicate on a class variable. It does not assert membership in a GB class containing other proper classes. A uniform family  $(R_i)_{i \in I}$  is one class relation

$$T(i, x, y) \quad \text{with row } R_i(x, y),$$

where the indices  $i$  are sets and  $I$  can itself be a set or a class. This is what “set-indexed” and “class-indexed” mean below.

In GBC, ordinary recursion with *set values* along  $\text{Ord}$  is available: each set-ordinal initial history is a set, and the compatible local histories define one class. It does not require full elementary transfinite recursion. In contrast, a recursion whose value at each stage is an entire class may require ETR, even when the stage order is small. The distinctions among  $\text{ETR}_\omega$ ,  $\text{ETR}_{\text{Ord}}$ , and full ETR must not be suppressed [22, 24].

*Note 111.8* (Source 20, Proposition 3.2, “Set-like global orders”). *In GBC, a proper-class set-like well-order is uniquely isomorphic to  $\text{Ord}$ . In particular, a set-like well-order of  $\mathbf{No}$  is equivalent to a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ .* This is the identification of set-like class well-orders with class bijections  $\text{Ord} \rightarrow \mathbf{No}$  used throughout this report (the reading of  $\mathfrak{W}_{\text{sl}}$  in section 1.3).

*Source 20’s proof.* Send each label  $x$  to the ordinal order type of its predecessor set. The range is an initial subclass of  $\text{Ord}$ . If it were bounded, the inverse map on a bounding ordinal would make the original carrier a set by Class Replacement. Hence the range is all of  $\text{Ord}$ .

The existence of a class well-order of all surreal labels already has choice strength. Over  $\text{GB} + \text{AC}$  it is equivalent to Global Choice: sets can be coded by well-founded extensional relations on ordinals, those relations by sets of ordinals, and those by surreal sign sequences. Choosing the least code in the supplied surreal well-order produces a global choice operation. The repository proves the stronger equivalence over GB without assuming set choice separately [39, Theorem 13.1] ([merge] theorem 13.1). The further results below do not need that strengthening.

### 111.5.3 The set-sized baseline

*Note 111.9* (Source 20, Theorem 3.3, “Fixed carrier spectrum; earlier result”). *Let  $X$  be an infinite linearly ordered set of cardinality  $\mu$ . Then  $|\mathcal{W}(X)| = 2^\mu$ , every linear order of cardinality at most  $\mu$  embeds in  $\mathcal{W}(X)$ , and*

$$\alpha \hookrightarrow \mathcal{W}(X) \iff \alpha < \mu^+ \quad (\alpha \text{ an ordinal}).$$

*The same upper bound holds for reverse well-ordered suborders.* This is [theorem 6.1](#) (the reals report’s spectrum theorem for every infinite alphabet); source 20 calls it an earlier result.

*Source 20’s proof.* There are at most  $2^\mu$  relations on  $X$ . Partition  $X$  into  $\mu$  two-element pieces and enumerate those pieces in a fixed ordinal order. Choosing independently which member of each pair appears first embeds the binary lexicographic cube  $2^\mu$  into  $\mathcal{W}(X)$  and proves the lower cardinality bound. If  $L$  has cardinality at most  $\mu$ , enumerate its elements by coordinates below  $\mu$ . The characteristic functions of its initial segments are nested, distinct, and lexicographically ordered as  $L$ ; the pair construction then embeds  $L$  into  $\mathcal{W}(X)$ .

Suppose a strictly increasing sequence of enumerations has length  $\mu^+$ . On a tail, its first entries stabilize: a monotone sequence in an alphabet of size  $\mu$  cannot keep changing through a regular  $\mu^+$ -sequence. Repeating this observation stabilizes each successive entry on a tail. At any limit stage below  $\mu^+$ , regularity supplies a common tail for all earlier requirements. The stabilized prefix cannot exhaust  $X$ , since then the strictly increasing tail would be constant. Continuing would therefore give an injection from  $\mu^+$  into  $X$ , a contradiction. The decreasing case is identical with inequalities reversed. An ordinal below  $\mu^+$  has size at most  $\mu$ , so the embedding direction has already been proved.

For  $\mathbf{No}_{<\kappa}$ , the cutoff is therefore  $(2^{<\kappa})^+$ , not automatically  $\kappa^+$ . The recent continuation also computes density, cellularity, point characters, and proper-gap spectra for the minimal stratum [46] ([merge] printed in Part VI); those more detailed formulas are not needed by the new class-level theorems here.

### 111.5.4 Variable set words are still a class of sets

*Note 111.10* (Source 20, Proposition 3.4, “Explicit compression of dictionary words”). *All set-length words over  $\mathbf{No}$ , with prefix-first dictionary order, admit an explicit order embedding into  $\mathbf{No}$ , without Global Choice. If  $w = (x_i)_{i<\alpha}$ , its code has birthday*

$$\sum_{i<\alpha} (1 + 2 \cdot \text{bd}(x_i) + 2).$$

*Here all sums and products inside the birthday expression are ordinal.* This is source 11’s explicit word code ([theorem 9.1](#)), with the same pair-doubling of signs.

*Source 20’s proof.* Replace each minus sign of  $x$  by the pair  $--$ , each plus sign by  $++$ , and append the pair  $-+$ . Call the resulting prefix-free sign word  $c(x)$ . Because  $-- < -+ < ++$ , this transformation preserves numerical comparison, including the case where one original sign sequence ends first. Code  $w$  by concatenating, for each entry, one plus sign followed by  $c(x_i)$ . Unequal entries are decided within their prefix-free entry codes. If one whole word ends first, the next sign of the longer code is a plus, so the shorter code is smaller. The displayed length follows by counting the signs in each block.

This compression includes injective words, hence all well-orders of variable set-sized surreal subsets. It does not encode arbitrary class relations by sets; every individual input word in the proposition is a set. Nor is it an isomorphism with  $\mathbf{No}$ , as the limit-prefix example in [section 61.4](#) shows.

### 111.5.5 Comparison of arbitrary class well-orders

For class well-orders  $R, S$  of the same labelled carrier  $X$ , let  $C(R, S)$  consist of those  $x$  such that their strict predecessor classes agree and the two relations agree on that predecessor class. Membership in  $C(R, S)$  is elementary with class parameters: all its quantifiers range over labels.

*Note 111.11* (Source 20, Lemma 3.5, “Largest common labelled prefix”). *The class  $C(R, S)$  is an initial segment of both orders, their restrictions to it agree, and it contains every common labelled initial segment. If  $R \neq S$ , it is proper in  $X$  and the labels*

$$a = \min_R(X \setminus C(R, S)), \quad b = \min_S(X \setminus C(R, S))$$

*are distinct.* This is the largest common labelled prefix of [theorem 14.2](#) (source 12’s [theorem 14.7](#)).

*Source 20’s proof.* If  $x \in C(R, S)$ , each predecessor  $y$  of  $x$  has the same predecessor class and inherited predecessor order in both relations. Thus  $y$  also belongs to  $C(R, S)$ . For two members, comparison can be read inside the predecessors of the later one, where the relations agree. Conversely, a common labelled initial segment has the same predecessors and relations at every one of its points, so it is contained in  $C(R, S)$ . If the two next labels were equal, their common predecessor class would be exactly  $C(R, S)$ , and that label would itself belong to the class, a contradiction.

*Note 111.12* (Source 20, Theorem 3.6, “Native class lexicography; earlier result”). *For  $R \neq S$  in  $\mathfrak{W}_{\text{all}}(X)$ , define  $R <_{\text{lex}} S$  when  $a < b$  numerically, with  $a, b$  from [note 111.11](#). This is a strict linear comparison and agrees with enumeration lexicography when both orders are set-like. It requires no comparison theorem for abstract class well-order types. This is [theorems 14.2](#) and [14.7](#); source 20 calls it an earlier result.*

*Source 20’s proof.* Trichotomy follows from  $a \neq b$ . For transitivity, the prefixes  $C(R, S)$  and  $C(S, T)$  are initial segments of the *same* well-order  $S$ , hence one contains the other. If one is shorter, the corresponding earlier divergence determines the comparison of  $R$  and  $T$  as well. If they are equal, compare the three next labels and use numerical transitivity. For set-like orders the common prefix is a set, and its ordinal length is exactly the first differing coordinate of the canonical enumerations.

Equality of predecessor *sets alone* would be insufficient: the enumerations  $(0, 1, 2)$  and  $(1, 0, 2)$  give the same predecessor set at 2 but disagree before it. Agreement of the inherited relations is essential.

### 111.5.6 The bounded-support core

Fix a baseline class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . A normalized core code is a set permutation  $\pi : \lambda \rightarrow \lambda$  such that

$$\lambda = \sup\{\xi + 1 : \pi(\xi) \neq \xi\}.$$

The empty permutation represents the baseline. Extend  $\pi$  by the identity above  $\lambda$  and evaluate the resulting enumeration as  $E_\pi = b \circ \hat{\pi}$ . The ordinary class of codes, ordered by their evaluations, is denoted  $\mathcal{P}_{\text{bd}}(b)$ . Equivalent terminology is the class of enumerations eventually equal to  $b$ , represented by their unique set codes.

*Note 111.13* (Source 20, Lemma 3.7, “Uniform completion”). *Every injective set prefix  $p : \delta \rightarrow \mathbf{No}$  extends to an enumeration represented in  $\mathcal{P}_{\text{bd}}(b)$ . One completion can be selected uniformly in  $p$ . This is source 11’s supported completion ([lemma 19.4](#)).*

*Source 20’s proof.* The set injection  $b^{-1} \circ p$  takes values below some ordinal. Choose an infinite initial cardinal  $\gamma$  larger than both that bound and  $\delta$ . The domain and range complements in  $\gamma$  both have size  $\gamma$ , so a bijection between them extends the injection to a permutation of  $\gamma$ . Use a fixed global well-order to choose one such set bijection, extend by the identity, and normalize.

*Note 111.14* (Source 20, Theorem 3.8, “Core interpolation and identification; earlier result”). *In GBC, the class order  $\mathcal{P}_{\text{bd}}(b)$  is isomorphic to  $\mathbf{No}$ . More strongly, between any two uniformly set-indexed separated families of injective class words  $\text{Ord} \rightarrow \mathbf{No}$  there is a core enumeration. Empty families are allowed on either side.* This is [theorem 19.10](#) and [corollary 19.15](#); source 20 calls it an earlier result.

*Source 20’s proof.* Call the two families  $(A_i)_{i \in I}$  and  $(B_j)_{j \in J}$ . When both are nonempty, Class Replacement bounds all cross first-disagreement ordinals by a set ordinal  $\beta$ . Build an injective prefix and keep only rows still agreeing with it active. At the current coordinate, the active left values form a set  $L$  and the active right values a set  $U$ , with  $L \leq U$  pointwise. If their intersection is empty, choose a fresh strict separator using [note 111.7](#), append it, and stop. If their intersection is the singleton  $\{z\}$ , append  $z$  and discard all rows with another value. The comparison invariant is preserved. Two common values would contradict the cross inequalities. At limits take unions. Both sides cannot stay active through  $\beta$ , so the procedure stops with a set prefix. If one side was empty, separation is possible at once. Complete the prefix using [note 111.13](#).

Thus every separated pair of sets of core codes has a strict interpolant. The core is a proper class, since transpositions involving arbitrarily large ordinals have distinct codes. Enumerate it and  $\mathbf{No}$  by  $\text{Ord}$  using Global Choice. Alternating extensions of a set-sized partial isomorphism give an isomorphism: at each step the required lower and upper images are sets, so interpolation supplies a fresh image. The histories remain sets at every set stage. This is the usual class back-and-forth argument, not an invocation of class-valued ETR.

We call a class order with this set-cut property an  $\eta_{\text{Ord}}$  order. The same back-and-forth proof shows that any two such proper class orders are isomorphic, that set-sized partial order isomorphisms extend to automorphisms, and that every class linear order embeds into one under Global Choice. The classical surreal universality and homogeneity background is discussed by Ehrlich and Hamkins [15, 33]. The new automorphism theorem later in this article concerns the much stronger demand of extending an automorphism to the ambient space of global well-orders.

For an injective set prefix  $p$ , write

$$\mathcal{P}_{\text{bd}}(b)(p) = \{c \in \mathcal{P}_{\text{bd}}(b) : E_c \restriction \text{dom}(p) = p\}.$$

These nonempty prefix cylinders are convex. The core is dense in  $\mathfrak{W}_{\text{sl}}$ , but it need not meet an interval between arbitrary non-set-like raw orders. A common proper prefix with a small residual carrier is one basic reason. This distinction drives the local-size results below.

### 111.5.7 Which core cuts encode class orders

The new automorphism results require a precise account of represented cuts. We record the relevant earlier criterion, with its proof, so that the dependence on enumeration structure is visible.

*Note 111.15* (Source 20, Lemma 3.9, “The first ordinal block”). *For  $R \in \mathfrak{W}_{\text{all}}(\mathbf{No})$ , the class*

$$B_R = \{x \in \mathbf{No} : \{y : yRx\} \text{ is a set}\}$$

*is a proper initial class and, with its induced order, has type  $\text{Ord}$ . Let  $f_R : \text{Ord} \rightarrow B_R$  be its canonical enumeration. For every core code  $c$ , comparison of  $E_c$  with  $R$  is the same as comparison of  $E_c$  with  $f_R$ . Thus the strict core cut of  $R$  depends only on  $f_R$ .* This is source 11’s canonical first block ([theorem 15.1](#)) with source 16’s observation that the core cut of a raw order is that of its first block ([corollary 46.4](#)).

*Source 20’s proof.* The class is initial and set-like by definition. If it were a set, its complement would be nonempty, and the least point of that complement would have exactly  $B_R$  as its predecessor

set. It would then belong to  $B_R$ , a contradiction. Apply [note 111.8](#). If  $E_c$  and  $f_R$  differ, their first differing ordinal coordinate already determines the raw comparison with  $R$ . If they agree everywhere,  $f_R$  is onto  $\mathbf{No}$  because  $E_c$  is, so  $R$  is exactly that core order.

*Note 111.16* (Source 20, Theorem 3.10, “Recognition by straddling prefixes; earlier result”). *Let  $L$  be a nonempty proper initial class of  $\mathcal{P}_{\text{bd}}(b)$  with no greatest element. The following are equivalent in GBC:*

1.  $L = \{c : E_c <_{\text{lex}} f\}$  for an injective class word  $f : \text{Ord} \rightarrow \mathbf{No}$ ;
2. for every set ordinal  $\delta$ , some injective prefix of length  $\delta$  has a cylinder meeting both  $L$  and its complement;
3.  $L$  is the strict core cut of a raw class well-order of  $\mathbf{No}$ .

*The injective word in (1) is unique. The cut has a set-like representative exactly when this word is onto. Recovery of the word uses only elementary comprehension with  $L$  as a class parameter. This is the represented-cut theorem of Part VIII, source 14’s [theorem 45.1](#) ([note 46.1](#) lists its six earlier proofs); clause (3) is source 16’s raw-trace corollary. Source 20 calls it “the relevant earlier criterion” and gives its proof, a seventh route by straddling prefixes; Part XIII uses it.*

*Second route (source 20).* At most one cylinder of any fixed length straddles  $L$ : distinct cylinders are disjoint and ordered, so two straddlers would place a point outside an initial class below a point inside it. If straddlers exist at all lengths, uniqueness forces their prefixes to cohere. Define  $f(\alpha)$  as the last value of the unique straddling prefix of length  $\alpha + 1$ . This is an elementary definition from uniquely specified sets. Coherence proves injectivity. At the first difference between a core row and  $f$ , the straddling cylinder one coordinate longer determines which side of  $L$  that row occupies. If  $E_c = f$ , the code  $c$  cannot lie in  $L$ : a larger member of  $L$  would give the opposite comparison. Hence (1) follows.

Conversely, for every set prefix of an injective class word, continue to its next value, choose fresh labels on either side of that value, and complete the two prefixes in the core. They lie on opposite sides of the word’s cut. Thus every length has a straddler and (1) implies (2). The same first-difference argument proves uniqueness of the word.

By [note 111.15](#), a raw representative gives an injective word, so (3) implies (1). Given an injective word, append a fixed well-order of its unused labels. Its initial word is still the first ordinal block: all later points, if present, have the proper range of  $f$  among their predecessors. The resulting raw order has the required cut. It is set-like exactly when there are no unused labels. If some other set-like representative existed, uniqueness of the word would force it to be the same nonexhaustive word, which is impossible.

The test quantifies over all ordinal *lengths*, each of which is a set. It does not choose one class at each stage. This is why recovery is elementary even though the recovered word is a class. The later symmetry theorem will show that the cylinder structure in this test contains information absent from the bare linear order of the core.

## 111.6 Source 20: formalization without paradoxes

### 111.6.1 Four workable foundations

There is no single formalization that silently turns all rows of the interpretation table into the same object. Four complementary approaches are useful, and their relationships explain several apparent paradoxes.

**Ordinary set theory at a fixed stage.** Choose a set alphabet  $X$  or a birthday cutoff  $\mathbf{No}_{<\theta}$ . Its relations, well-orders, enumeration strata, order topologies, and Dedekind cuts are ordinary sets. The fixed-carrier theorem, sharp filtration criterion, ordinal condensation formula, and countable topological example fit this framework directly. One can also work with a set-indexed family of such stages. A proper-class inverse limit is an additional statement; it is not automatically supplied by existence of all its individual stages.

**Two-sorted class theory.** In GB or GBC, the labels are sets, individual global well-orders are classes, and their comparisons are formulas with class parameters. A uniform family has one relation on set indices and set labels. This supports birthday gluing, the core construction, class automorphisms, local coding obstructions, and analysis of a supplied condensation history. One may quantify over class variables in an assertion without using those variables as members of a new class.

**Stronger comprehension and recursion.** KM permits stronger class comprehension, but its second sort still does not consist of objects allowed to be members of ordinary classes. It therefore does not turn “all class well-orders” into a GB-style class of elements. ETR supplies class-valued recursion histories along specified well-founded class orders. Our termination theorem identifies what happens to such a history once it exists; it does not prove that its existence has the exact strength of full ETR. The known distinction between set-valued recursion and class-valued ETR is essential here [22, 24].

**A containing universe or an explicit model.** In an outer universe, fix a set model  $(M, \mathcal{X})$  of a two-sorted class theory. The admitted classes are now external objects, so their well-order space and any desired quotient are external sets. The full model  $(V_\kappa, \mathcal{P}(V_\kappa))$  at an inaccessible cardinal provides particularly transparent cardinal calculations. Countable models provide the shuffle classifications proved above. These are two different external realizations, not inconsistent answers to one unqualified cardinality question.

### 111.6.2 What an inaccessible full model actually contains

Let  $\kappa$  be inaccessible in the ambient universe and consider  $(V_\kappa, \mathcal{P}(V_\kappa))$ . Its internal surreal carrier is, externally,  $\mathbf{No}_{<\kappa}$  of cardinality  $\kappa$ . All its ambient subsets are available as classes. A subclass of this carrier is an internal set exactly when its ambient cardinality is less than  $\kappa$ . Consequently the external full well-order space is

$$\mathcal{W}(\mathbf{No}_{<\kappa}),$$

while its internally set-like part is

$$\mathcal{W}_\kappa(\mathbf{No}_{<\kappa}).$$

Indeed an actual well-order of a carrier of size  $\kappa$  is internally set-like precisely when all its predecessor segments have size below  $\kappa$ , which forces its type to be exactly  $\kappa$ .

Both spaces have cardinality  $2^\kappa$ , but their geometry differs. The minimal stratum has a dense set of size  $\kappa$ : choose a completion for each injective prefix of length below  $\kappa$ . There are only  $\kappa^{<\kappa} = \kappa$  such prefixes, and every nonempty order interval contains one of their cylinders. Fresh separators exist because  $\mathbf{No}_{<\kappa}$  fills cuts of size below  $\kappa$ .

The full order has  $2^\kappa$  disjoint nonempty intervals. Reserve three labels and vary the enumeration of all other labels in  $2^\kappa$  ways. For each common exhaustive prefix, its six possible final permutations form a convex six-point block. An open interval between the first and last point of each block is nonempty, and the different blocks are disjoint. An embedding into the minimal stratum would give

$2^\kappa$  disjoint nonempty intervals in an order with a dense subset of size  $\kappa$ , which is impossible. This re-proves the earlier full-model nonembedding result [39] ([merge] theorem 20.1) and locates the new interval and condensation calculations in the same concrete model.

There is no conflict with class universality of **No**. Internally, universality concerns class orders *whose elements are sets*. Externally the full well-order space has  $2^\kappa$  points, whereas the internal surreal carrier has only  $\kappa$ . Similarly, the new one-point nonextension theorem does not deny that a new class order can embed into **No**: it denies an embedding satisfying all comparisons already fixed by a specified automorphism on an entire proper-class core.

### 111.6.3 Changing the class collection while keeping the sets

Suppose  $(M, \mathcal{X})$  and  $(M, \mathcal{Y})$  are GBC realizations of the same first-order set model. For a relation available in both class collections, well-foundedness has the same truth value in both models. In GBC a failure of class well-foundedness is witnessed by a set-coded descending  $\omega$ -sequence; the sets, and hence all such witnesses, are unchanged. This is the precise absoluteness used here [35, Observation 4.12]; related stronger results appear in [27, §3].

The common native comparisons are stable as well, because their definitions use only set quantifiers and the supplied class relations. With a common baseline  $b$ , the set-coded core and its evaluations are also unchanged. What can change is which additional relations, class cuts, automorphisms, or uniform histories are available. Thus class extensions may add new points to the surrounding well-order space; they do not make an old shared well-order ill-founded merely by adding more classes.

An external branch through the stages of a countable model need not be an admissible internal class. The gluing theorem uses Class Replacement to bound the birthdays of a descending sequence. Omitting admissibility would remove that step. The countable shuffle theorem respects this boundary: its back-and-forth is external and its external enumeration need not belong to the model.

### 111.6.4 A practical route in Lean

The pinned ProveIt sources contain useful universe-aware interfaces. They were inspected at the revision on the title page; this article did not run a Lean build or add a Lean theorem.

| <code>SizeObstructions.lean</code> | <code>SmallCutData</code> ,<br><code>HasSmallCutFillers</code> ,<br><code>noUnrestrictedCuts</code>                               | Distinguishing small cut filling from the inconsistent unrestricted form |

The files lie under `Algebra/SurrealNumbers/Surreal/Foundations/` [7, 8, 31]. In particular, `SignSequence.{u}` lives in `Type (u+1)`, and `not_small` rules out its being small relative to universe  $u$ . The fact that it has a Lean type is not a proof that the entire carrier may be used as one of the small index types in a cut theorem.

The most direct formalization begins with a generic linearly ordered carrier and well-order relation codes. Prove common-prefix comparison, its transitivity, restriction reversal examples,

two-label persistence, and the finite-change theorem before specializing to surreals. These arguments use no surreal arithmetic. The next layer formalizes coherent filtrations and the countable-witness condition, followed by the set-sized ordinal condensation formula. This yields useful verified results without first constructing a full class-theory library.

For genuine class statements there are two honest routes. One can work relative to explicit universes and retain every smallness condition, or formalize a two-sorted model with a class-code type and an evaluation relation. In the second route, “internally well-ordered” must be expressed using the model’s interpretation. Substituting Lean’s external `WellFounded` for that notion would exclude the very nonstandard models studied in [section 109.2](#). In a full transitive model the two notions coincide, which is why the inaccessible calculations are simpler.

Core automorphisms then require a general set-cut interpolation interface, uniform set-valued recursion, and a precise coding of evaluations. The one-point extension obstruction should be formalized with one new marker adjoined to the class of core codes, as in [theorem 97.7](#). That formulation avoids constructing a type intended to mean “every proper class of the whole ambient universe.” Complete condensation histories should take the history as an input first; a separate theorem can derive its existence from the selected ETR axiom or semantic model.

### 111.6.5 The exact boundaries that prevent paradoxes

The usual contradictions disappear when the quantifiers are kept in their declared domains. A cut theorem realizes cuts with small sets of constraints, not the cut having the entire carrier as its lower side. A global enumeration enumerates surreal *labels*, not all class relations on those labels. A representative of a canonical block is an actual least label; the whole proper block is not thereby made a set. An external power set is formed in the containing universe, not in a smaller universe that would regard its domain as proper.

Finally, first-divergence comparison never identifies arbitrary abstract class well-orders with ordinals. It uses shared labels and compares two initial segments of one supplied order. This is weaker than the general problem of constructing isomorphisms between arbitrary class well-order types. The literature proves ETR implications for that comparability problem; those implications must not be promoted to equivalences without a separate proof [\[27, 35\]](#).

### 111.7 Source 20: results and verification status

| Result                                                 | Foundation used                                                 | Status in this article                                               |

| Decidability of the common pure-order theory | Effective finite-game reduction and coloured dense-order elimination | New procedure in <a href="#">corollary 109.22</a>                                    |
| Countable topology and omitted cuts          | ZFC, countable dense alphabet                                        | New proofs in <a href="#">theorem 67.11</a>                                          |

The principal arguments were read independently with particular attention to class quantifiers, residual alphabets that need not be dense, internal finiteness, and recursion strength. That review found and corrected several wording issues, including open-interval qualifications and an overbroad attribution about earlier condensation histories. It did not provide a formal certificate or establish literature priority.

### 111.7.1 Finite diagnostics supplied with the article

The archive includes a standard-library Python program and its saved output. The program checks all unordered pairs of permutations on carriers of sizes two through five. It verifies the decisive-pair persistence statement on every relevant restricted carrier and the coordinatewise monotonicity of witnesses on every relevant nested pair of carriers. It also evaluates finite surreal signs as exact dyadic rationals to check the dictionary-word encoder independently of the encoder's own sign comparison.

The saved run passes 58,255 decisive-pair restriction checks and 609,862 nested-witness checks, across 7,432 permutation pairs. It also passes 28,920 exact dyadic comparisons for 241 words with at most two entries, each entry having at most three signs. The explicit nonmonotone restriction example is reproduced in the output.

These are finite operational diagnostics. They establish no class automorphism theorem, transfinite induction, cardinal calculation, nonstandard-model classification, or ETR implication. Those conclusions rest on the written proofs. No Lean build, additional axiom audit, or machine verification of this article is claimed.

### 111.7.2 Rebuilding and reusing the deliverable

The main LaTeX file is self-contained and uses a conventional TeX Live installation. It has no external figures, bibliography database, or generated source dependencies. Compile with

```
latexmk -pdf -interaction=nonstopmode -halt-on-error \
  surreal_orders_limits_symmetries_models.tex
```

Run the independent finite diagnostics with

```
python3 finite_diagnostics.py --output finite_diagnostics_results.json
```

[merge] Shipped here as `code/20-limits-finite_diagnostics.py` and `data/20-limits-finite_diagnostics_results.json`; the L<sup>A</sup>T<sub>E</sub>X source and PDF are not shipped (they are in arrival commit `b63f0c852`). Rerun on a copy with an explicit `-output` (section 111.49). The article’s definitions, proofs, and distinctions between internal and external statements are part of the deliverable. The software output is an auxiliary record of finite checks, not a replacement for them.

## 111.8 Source 21: a practical route to rigorous formalization

The mathematics can be formalized in several compatible ways. The best starting point is a small-carrier development that isolates labelled order comparison from surreal arithmetic. The genuinely class results should then be expressed in a chosen model of class theory or through an explicit universe-relative smallness interface.

### 111.8.1 An axiom and size ledger

The following ledger records sufficient foundations used by the proofs. It is not an assertion that every entry is optimal.

| Construction                                                              | Sufficient setting                                       | Essential restriction                                                                                     |
|---------------------------------------------------------------------------|----------------------------------------------------------|-----------------------------------------------------------------------------------------------------------|
| Set alphabet, fibers, noncardinal invariants, fixed-cardinality coherence | ZFC                                                      | The carrier and all indexing families in these sections are sets.                                         |
| Largest common labelled prefix                                            | GB, given the class well-orders                          | Elementary comprehension; equality of predecessor classes uses set quantifiers.                           |
| Canonical first block and set-interval blocks                             | GB, given the class well-order                           | Ranks of set intervals define all blocks simultaneously.                                                  |
| Normalized core and uniform prefix completion                             | GBC                                                      | One fixed baseline and explicitly coded set support.                                                      |
| Set-cut interpolation and large-cut conjugacy                             | GBC                                                      | Uniform set-indexed inputs; set-valued recursion, even when its length is Ord.                            |
| Represented-cut reconstruction and extension obstruction                  | GBC                                                      | Cuts are individual classes of core codes; the family of all cuts is virtual.                             |
| External countable classifications                                        | A metatheory containing a countable two-sorted GBC model | Its admitted class objects form a countable set externally; standardness is stated separately.            |
| Full inaccessible-universe interpretation                                 | An inaccessible $\Omega$ in the metatheory               | The specific realization is $(V_\Omega, \mathcal{P}(V_\Omega))$ ; this is an additional model assumption. |
| Uniform class-valued recursion                                            | An appropriate ETR principle                             | Not supplied by calling an ordinal-length construction “recursion”; state the value size.                 |
| Actual hypercollection of class well-orders                               | A larger universe or a third-order theory                | Comprehension and choice at the new level must be specified.                                              |

For example, the canonical block theorem does not need class-valued recursion because its equivalence relation is defined directly. Conversely, an argument that selects an arbitrary isomorphism

for each of a proper collection of residual fibers does not become uniform just because each individual isomorphism exists. A proof must either give an elementary unique construction, assume a suitable higher-level choice principle, or restrict its conclusion to individually specified inputs. The cut-reconstruction proof of the extension criterion takes the first route.

### 111.8.2 The small-carrier formal core

A first formalization can parameterize everything by a type  $X$  with a linear label order. A well-order presentation consists of a relation  $R : X \rightarrow X \rightarrow \text{Prop}$ , proofs that it is a strict linear order, and well-foundedness. The following dependency order avoids involving surreal addition, multiplication, or analytic constructions.

1. Define predecessor sets and the common labelled prefix. Prove initiality, maximality, and existence of the two first outside labels for distinct well-orders on the same carrier.
2. Define lexicographic comparison through these labels and prove trichotomy and transitivity. Relate it to first disagreement for ordinal-indexed exhaustive enumerations.
3. Prove convexity of prefix cylinders, partial-injection completion inside a sufficiently large cardinal, and the first-cardinality fiber decomposition. These results can be tested on finite carriers, but their formal proofs should not be replaced by finite tests.
4. Add the elementary interval-size or short-chain hypothesis and derive the agreement topology, point characters, density, and cellularity. The noncardinal birthday theorem then becomes an application of the three-symbol padding code and an ordinal product calculation.
5. Formalize the fixed-slot embeddings and prove their literal composition equation. This supplies a useful coherence result before introducing any proper-class model.

The countable homogeneity theorem is a separate manageable milestone. Its main ingredients are the uniqueness of a countable dense order without endpoints, order sums, finite-prefix cylinders, and a back-and-forth on countable structures. The Baire coding can be verified as two continuous inverse maps on countable permutations; it need not be derived from a broad descriptive-set-theoretic library.

### 111.8.3 Using the repository's universe-relative surreal interface

The audited repository already contains sign-sequence foundations for bounded birthdays, small cuts, and size obstructions [7, 8, 9, 31]. The relevant files distinguish smallness relative to a universe from unrestricted families. Their existence does not confer formal status on the new results of this paper.

The concrete universe parameters matter. In the pinned source, `Surreal.Foundations.SignSequence` lives in `Type (u + 1)`, while its birthday is an `Ordinal.{u}`. The declarations `SignSequence.birthdays_bounded`, `SignSequence.small_bounded`, and `SignSequence.not_small` distinguish small families and bounded birthday subtypes from the encompassing type. Numerical first disagreement is exposed by `SignSequence.lt_iff`. Small-cut interpolation is available through `SignSequence.small_cut_fillers` and `SignSequence.exists_separator_of_small_sets`; the latter requires explicit `Small.{u}` instances for both option sets. The constructor `SignSequence.cut` comes with `SignSequence.cut_realizes` and `SignSequence.birthday_cut_le_iSup`. Finally, `Surreal.Foundations.noUnrestrictedCuts` rules out unrestricted cut filling for any irreflexive relation by taking the whole carrier as the left option set. These are source-audited interfaces, not a new kernel check of the repository or of this manuscript.

One sound design exposes the following mathematical interface:

- a universe-relative ordinal type and sign sequences on small ordinal domains;
- a linear numerical order using centered termination;
- bounded birthdays for small families;
- a separator for every small separated pair of families;
- the impossibility of replacing “small” by arbitrary families of the encompassing surreal type.

There are then two different formal targets. The first is a theorem about all well-orders of a particular type in a sufficiently large universe. That is an ordinary type-theoretic theorem, with explicit universe parameters. The second is a theorem inside a formalized two-sorted set theory, whose class variables range over the classes admitted by that model. One should not identify these targets merely because both are written with an expression resembling “all well-orders.”

The main nonextension theorem is particularly suitable for a modular formalization. Its abstract input is a genuine class order  $S$  with small-cut interpolation, a prefix completion operation, and an elementary cut decoder. The output is an obstruction to extending an automorphism. Surreal field structure is irrelevant. A final module can instantiate the interface with the normalized surreal core.

#### 111.8.4 Definable codes are a restriction, not a substitute for all classes

A formula code with set parameters can describe a definable class well-order. Such codes are sets, but the evaluation of every formula uniformly requires an appropriate satisfaction relation. Over a fixed set model, satisfaction is an external set relation and this approach is straightforward. For the entire set universe, an unrestricted internal truth predicate cannot be inserted silently into GB. Restricting formula complexity, adding a suitable truth class, or working externally with a fixed model are distinct options.

Even when evaluation is available, different codes can define the same relation. Numerical lexicography then orders their evaluations, giving a preorder on codes until extensional duplicates are identified. Finally, a definable-code family need not exhaust the admitted class relations, and [note 86.16](#) prevents any internally uniform set-code family from exhausting all global enumerations. The code language and its interpretation are part of the formal object.

### 111.9 Source 21: source audit and verification record

The principal repository input was read through the selected GitHub connection at the immutable revision `109aaca1505c12d70ae169bdc2011f40bd476f7d`. The relevant directory is `Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders`. Its README describes a 116-page synthesis of four manuscripts and explicitly states that the synthesis is not formally verified.<sup>18</sup> We read its complete `article.tex`, its README, and the supplied research status records. Its source labels remain useful identifiers even when page numbers change in later revisions.

| Audited topic                 | Repository label or location                              | Use here                                       |
|-------------------------------|-----------------------------------------------------------|------------------------------------------------|

<sup>18</sup>[merge] True at `109aaca15`; the report has since grown to thirty sources and is still not formalized.

| Audited topic                     | Repository label or location                    | Use here                                                          |
|-----------------------------------|-------------------------------------------------|-------------------------------------------------------------------|
| Uniform set-cut interpolation     | <code>swo:gl:interpolation</code>               | Proof retained with the uniformity and recursion bounds explicit. |
| Core isomorphic to <b>No</b>      | <code>swo:gl:pbd-no</code>                      | Background for large-cut conjugacy.                               |
| Exact adjacency                   | Section 16                                      | Input to intrinsic terminal-block condensation.                   |
| Prefix and automorphism questions | <code>swo:n16.4</code> , <code>swo:n16.5</code> | Negative recovery results and the extension obstruction.          |
| Noncardinal cutoffs               | <code>swo:st:n14.2</code>                       | Exact invariants and the self-similarity obstruction.             |
| Coherent stage embeddings         | <code>swo:st:n14.9</code>                       | Solved within a common cardinality band.                          |
| Changes of class realization      | <code>swo:n16.8</code>                          | Preservation, new represented cuts, and external classifications. |

The new mathematical arguments were checked for their cardinality assumptions, ordinal arithmetic, use of uniform class parameters, behavior at principal cuts, and distinction between internal and external finiteness. Separate checks covered the noncardinal formulas, fixed-slot composition law, countable homogeneity and topology, core automorphism obstruction, and nonstandard terminal-block analysis. These were written-proof checks, not exhaustive searches over infinite objects and not kernel verification.

The deliverable is a standalone LaTeX source with an internal bibliography ([merge] not shipped here; source 21 ships no code or data, and its two audits are `21-obstructions-SOURCE_AUDIT.txt` and `21-obstructions-LEAN_INTERFACE_AUDIT.txt`). It compiles with pdfLaTeX; the accompanying build command uses `latexmk` to settle references. The final PDF was checked for unresolved references, overfull material, and rendered-page layout. Repository files were read but no repository build was performed and no repository content was changed.

## 111.10 Source 22: foundations, raw class orders, and universe dependence

### 111.10.1 Global choice and the interpretation of a class well-order

A class relation  $R$  on a class  $A$  is *set-like* when every predecessor segment  $\{y \in A : yRx\}$  is a set. A set-like class well-order of a proper class has order type  $\text{Ord}$ , and its unique ordinal enumeration is available by elementary class definitions using its set predecessor segments. An unrestricted class well-order need not be set-like. Orders of types  $\text{Ord} + 1$  and  $\text{Ord} + \text{Ord}$  have points with proper-class predecessor segments and cannot be enumerated exhaustively by a single  $\text{Ord}$ -word.

Global Choice supplies a set-like global well-order and hence the baselines used above. The maintained report proves the stronger choice equivalence, over **GB** without assuming set choice: the existence of a class well-order of the whole surreal class is equivalent to Global Choice [39, 40] ([merge] theorem 13.1). We use this as a previously established result, not as a new theorem. The explicit choice parameters in sections 86.3 and 102.1 therefore have genuine foundational content.

When “well-order” is stated internally in a two-sorted model, it refers to the model’s available subsets or classes. Under **GBC**, a fixed class linear order is well-founded exactly when it has no set-coded descending  $\omega$ -sequence. For the nontrivial direction, if an available nonempty subclass has no least member, use Global Choice to select a predecessor at each finite step; recursion on

$\omega$  with class parameters and replacement yield a set-coded descending sequence. Conversely, the range of a descending sequence is an available subclass with no least member.

It follows that enlarging the class realization over the same set universe does not change well-foundedness of a *fixed already available relation*. It can change which relations exist. External well-foundedness of a nonstandard model is a separate matter: an external descending sequence need not be a set of that model.

### 111.10.2 Direct comparison without an ordinal enumeration

The direct common-head construction from the earlier report [39] avoids forcing a non-set-like class order into an Ord-enumeration. We spell it out because it explains why raw comparison itself does not require ETR.

For class well-orders  $R, S$  on the same labelled carrier  $A \subseteq \mathbf{No}$ , put

$$I(R, S) = \{x \in A : \text{Pred}_R(x) = \text{Pred}_S(x) \text{ and the two orders agree there}\}.$$

Equality and agreement here are expressed by quantifying over elements, not by collecting proper predecessor classes into a set.

*Note 111.17* (Source 22, Proposition 10.1, “Elementary raw lexicographic comparison”). *The class  $I(R, S)$  is the largest common labelled initial part of  $R$  and  $S$ . If  $R \neq S$ , the complement has an  $R$ -least element  $a$  and an  $S$ -least element  $b$ , with  $a \neq b$ . Declaring*

$$R <_{\text{lex}} S \iff a < b \text{ numerically}$$

*defines a strict linear comparison of the available class well-orders. The definition is elementary in  $R, S$  and agrees with enumeration lexicography in the set-like case. This is [theorems 14.2 and 14.7](#); source 22 credits it to the earlier report.*

*Source 22’s proof.* If  $x \in I(R, S)$  and  $yRx$ , then  $y$  belongs to the common predecessor class of  $x$ . The agreement of the restricted orders there shows that the predecessor classes of  $y$  agree and carry the same restricted order. Thus  $y \in I(R, S)$ ; the argument is symmetric for  $S$ . Any common labelled initial part is contained in  $I(R, S)$ , proving maximality.

If  $R \neq S$ , this common part is proper. Its complement is an available nonempty class, so it has least elements  $a$  and  $b$  in the respective well-orders. If  $a = b$ , both predecessor classes would be  $I(R, S)$  with agreeing orders, forcing  $a \in I(R, S)$ , a contradiction. Trichotomy and asymmetry follow from the numerical label order.

For transitivity, suppose  $R <_{\text{lex}} S <_{\text{lex}} T$ . The heads  $I(R, S)$  and  $I(S, T)$  are initial parts of  $S$ , so they are comparable by inclusion. If one is strictly shorter, the other comparison still agrees at the first disagreement of that shorter head, and that comparison decides  $R <_{\text{lex}} T$ . If the heads are equal, the three next labels have the form  $a < b < c$  numerically, so again  $R <_{\text{lex}} T$ . When ordinal enumerations exist, the common head is exactly their common prefix.

One application of this construction, or extraction of one canonical set-like initial head, must not be confused with an arbitrary iteration whose successive states are proper classes. The latter can call for stronger recursion principles.

### 111.10.3 Which orders embed?

For set alphabets, [note 62.15](#) gives the exact ordinal spectrum and universality for linear orders of size at most the alphabet cardinal. In the global setting, the ordinary-class universality statement is stronger but must be carefully typed.

*Note 111.18* (Source 22, Proposition 10.2, “Ordinary-class universality”). *In GBC, every linear order whose carrier is an ordinary class of sets embeds, by a class map, into  $\mathbf{No}$ , and hence into the set-coded core  $\mathcal{P}_s(b)$  and the virtual global enumeration order.* This is the class universality of [propositions 5.13](#) and [19.20](#); source 22 says it is the usual surreal universality mechanism.

*Source 22’s proof.* Use Global Choice to enumerate the carrier in a set-like order, with domain a set ordinal or  $\text{Ord}$ . At stage  $\alpha$ , the previously placed points form a set. Their images below and above the next element determine a separated set cut of  $\mathbf{No}$ . Choose a separator, for example by the canonical simplest-cut operation or by the fixed global choice, and place the next point there. Every initial recursion segment is set-valued, so ordinary transfinite recursion with class parameters gives the desired class embedding.

To embed  $\mathbf{No}$  into  $\mathcal{P}_s(b)$ , choose uniformly a supported completion of each singleton prefix  $(x)$ . First labels show that  $x < y$  implies the completion of  $(x)$  is below the completion of  $(y)$ . Compose the two embeddings.

This is the usual surreal universality mechanism, not a historical novelty [15, 39]. It does not quantify over a same-level class whose elements are arbitrary classes. In particular, it does not imply an embedding of the entire higher-order collection of raw well-orders into an ordinary class order.

#### 111.10.4 Why GBC is enough for the new reconstruction

Four superficially similar operations have different strengths:

- (i) Set transfinite recursion with already supplied class parameters produces set-valued stages along each set ordinal; the compatible initial solutions can be collected by elementary comprehension.
- (ii) The height of one cylinder is the order type of a *set* of ancestors. No global class rank needs to be recursively constructed.
- (iii) The branch reconstructed from a cut has a unique value at each coordinate, explicitly defined by the existence of a crossed *set* prefix. It is obtained by comprehension, not by repeated choices of new classes.
- (iv) A recursion with proper classes as successive states is a different assertion. Its solution is a class of pairs coding all stage memberships, and its existence is not automatically a theorem of GBC.

The distinction is substantive. Gitman and Hamkins connect elementary transfinite recursion for class relations with clopen determinacy for class games [22]. Gitman, Hamkins, Holy, Schlicht, and Williams identify the class forcing theorem with  $\text{ETR}_{\text{Ord}}$  over GBC [24]. None of these stronger principles is silently used in [theorems 87.1, 87.4, 102.2](#) and [102.3](#).

#### 111.10.5 Three safe frameworks

**Set fragments in ZFC.** Fix a birthday cutoff and an enumeration ordinal. Every carrier, function space, and relation space is a set. All results of [note 62.15](#) and [sections 63.1, 63.2](#) and [63.4](#) live at this level. Singular cutoffs are allowed; inaccessible cardinals are not assumed.

**Classes in a two-sorted theory.** In GBC, set prefixes and support codes form ordinary classes. Enumerations and raw relations are class variables. Incidence and evaluation are ordinary class relations with set-coded arguments. Assertions about all enumerations are formulas with class quantifiers, not definitions of an ordinary class of enumerations. Stronger comprehension in KM does not by itself turn classes into members of classes; it changes the allowed formulas and resulting class existence, not the basic sort distinction.

**An explicitly larger universe or additional sort.** In an external universe, the classes of a fixed set model may form a set, and their functions and relation spaces can then be ordinary set objects externally. Alternatively, a higher-order theory may introduce a sort of collections of classes. Both approaches are legitimate when the ambient theory, available collections, and permitted maps are stated. Their conclusions must not be read back as same-level class constructions in GBC.

A ZFC treatment by definable-class schemata is also possible. A supplied definition can be substituted into the elementary constructions. However, syntactic codes of formulas are not a uniform truth predicate, and ranging over all formula codes does not automatically produce a definable evaluator for all classes.

### 111.10.6 A full inaccessible-universe interpretation

Suppose, in an external metatheory, that  $\kappa$  is strongly inaccessible and consider

$$(V_\kappa, \mathcal{P}(V_\kappa)).$$

This is a full class model of the relevant class axioms. Its surreal carrier is externally the set  $\mathbf{No}_{<\kappa}$ , of size  $\kappa$ . Its set-like global well-orders correspond exactly to exhaustive length- $\kappa$  enumerations of that set. Indeed, set-likeness says that each predecessor class has size less than  $\kappa$ ; an external well-order of a  $\kappa$ -sized set with this property has order type  $\kappa$ . Unrestricted class well-orders correspond to all external well-orders on that labelled set, including types  $\kappa + 3$  and longer.

Since  $\kappa^{<\kappa} = \kappa$ , [theorem 63.4](#) gives density and cellularity  $\kappa$  for the set-like enumeration order, while its  $\kappa + 3$  raw stratum has  $2^\kappa$  pairwise disjoint open intervals. This yields another proof of the earlier nonembedding phenomenon [39] ([merge] [theorem 20.1](#)).

*Note 111.19* (Source 22, Corollary 10.3, “A stratum obstruction to raw-to-set-like embedding”). *In the full inaccessible-universe interpretation, the unrestricted raw enumeration order does not order-embed into the set-like enumeration order.* This is source 11’s full-model nonembedding theorem ([theorem 20.1](#)); source 22 obtains it again from its invariant table (Part X), a different route.

*Second route (source 22).* Choose in each of  $2^\kappa$  distinct length- $\kappa$  cylinders of the  $\kappa + 3$  stratum three increasing points. Under an order embedding, their outer-point intervals remain pairwise disjoint nonempty intervals, because each contains the image of the middle point. This would force cellularity at least  $2^\kappa$  in the target, whose cellularity is  $\kappa$ . No assertion about equality of a suborder’s order topology with its inherited topology is needed.

At the opposite external size extreme, if both sorts of a model  $(M, \mathcal{X})$  are externally countable, its available global enumeration order is externally a countable dense order without endpoints. An external back-and-forth gives an isomorphism with  $\mathbb{Q}$ . That map need not be available in the model. This explains why an external order-type statement alone cannot replace the labelled reconstruction of [theorem 102.3](#).

### 111.10.7 The forbidden constructions

A hypothetical surreal realizing the cut  $(\mathbf{No}, \emptyset)$  would be greater than every surreal, including itself. Therefore only set-sized, or suitably universe-small, cuts may be filled without contradiction. Similarly, the collection of all ordinal lengths is not a set, and a set of all support codes cannot have unbounded heights. The diagonal argument in [section 102.1](#) rules out an exhaustive uniform class parametrization of all global enumerations by set-valued indices. These are distinct size obstructions, and none is repaired by merely changing notation from “set” to “class”.

## 111.11 Source 22: a concrete, universe-explicit formalization program

### 111.11.1 Actual inspected interfaces

The ProveIt sign carrier uses a lower universe for ordinal lengths and a larger universe for the entire carrier. The following source interface was inspected at the pinned revision [7]:

```
structure SignSequence : Type (u + 1) where
  birthday : Ordinal.{u}
  signAt : Ordinal.{u} -> SignType
  signAt_ne_zero_iff : forall i, signAt i != 0 <-> i < birthday
```

This display transliterates logical symbols for readability; the repository uses Lean’s usual Unicode syntax. Its actual namespace is `Surreal.Foundations`. Inside `SignSequence`, the inspected declarations include

| Existing declaration                             | Role in the present mathematics                                                |
|--------------------------------------------------|--------------------------------------------------------------------------------|
| <code>lt_iff</code>                              | First-disagreement characterization of numerical order.                        |
| <code>birthdays_bounded</code>                   | Bounds the birthdays of a lower-universe-small family.                         |
| <code>not_small</code>                           | The complete sign carrier is not small in the universe of its ordinal lengths. |
| <code>small_bounded</code>                       | A fixed birthday bound gives a small fragment.                                 |
| <code>IsPrefix, truncate</code>                  | Prefix and restriction operations, separate from numerical order.              |
| <code>exists_cut_separator_of_birthday_lt</code> | A separator at a prescribed birthday above all option birthdays.               |
| <code>small_cut_fillers</code>                   | Realization of separated small cuts.                                           |

The last two declarations occur in `SignSequenceCut.lean`, in the namespace

`Surreal.Foundations.SignSequence.`

See [8]. Their parameter types explicitly use `SmallCutData` and `HasSmallCutFillers`. The file constructs the separator through a complete lexicographic order of bounded Boolean words. It does not assume a field structure or an unrestricted cut operation.

These source declarations are existing inputs, not formalizations of the new theorems. No Lean compiler or repository build was run for this manuscript, and no new Lean proof file is supplied. The formalization ledger of the earlier report likewise does not claim that its own global enumeration results have been kernel-checked [40].

### 111.11.2 Set-sized modules first

A first implementation should be independent of surreal arithmetic. It should expose an abstract linear alphabet, ordinal coordinate intervals, and a bijective enumeration subtype. The first-disagreement comparison can reuse a lexicographic function-order interface. The mathematical dependencies suggest the following sequence.

**Prefix and residual module.** Define extendible prefixes, residual carriers, and the order type of the remaining coordinate interval. Prove concatenation and restriction inverse, then cylinder convexity. The theorem must retain the complement-cardinality hypothesis rather than assuming that an arbitrary long partial injection extends.

**Characters and finite blocks.** Express the lower and upper sides as ordered sums over first-disagreement coordinates. Formalize the cofinality of a sum with no last index and with a last index. Derive character transfer, then the finite  $n!$  block description and the adjacency lemma. This isolates the infinite reasoning from finite permutation enumeration.

**Topology and cardinal arithmetic.** State richness as an alphabet hypothesis. Count short injective prefixes; distinguish an open cylinder, a convex cylinder, a  $\pi$ -base, and a base. The two separate lower-bound constructions—many short cylinders and many late residual intervals—then prove [theorem 63.4](#). Instantiate richness for the bounded sign carrier only after the abstract result is complete.

**Unranked tree incidence.** Formalize an abstract node/core incidence relation with extension, incompatible-cylinder separation, and fresh strict refinement. Prove that inclusion recovers prefix, that each ancestor collection is small, and that its ordinal order type recovers height. A bounded-height set version should be checked before passing to a class-model interface.

### 111.11.3 Do not identify all function types with available classes

Both `Ordinal.{u}` and `SignSequence.{u}` live at a level capable of containing their lower-universe-small fragments. The type of all functions between those types is a perfectly legitimate object in a sufficiently large type universe. It is nevertheless not automatically the class sort of a specified GBC model. A model may admit only some such external functions as classes.

Accordingly, the global layer should use an explicit two-sorted model or an explicit predicate of admissible class graphs, together with comprehension and replacement interfaces. A uniform family is represented by one admissible relation with set-valued indices. The trace decoder takes an admissible class parameter and constructs another admissible class by a verified elementary formula. In a higher-universe full-model implementation, label the conclusions as external statements about that full collection.

Universe polymorphism prevents type-in-type errors; it does not automatically express all the subtleties of an arbitrary class realization. Conversely, no new large-cardinal hypothesis is needed merely to prove the abstract set-alphabet theorems in Lean. The inaccessible cardinal in the preceding section belongs to one particular model comparison, not to their proof dependencies.

### 111.11.4 Useful interfaces rather than unsupported code claims

The following is a proposed mathematical specification, not compiled Lean:

**ResidualCylinder:**

input: an extendible injective prefix  $p$  of an alpha-enumeration  
output: an order isomorphism from enumerations of the residual alphabet onto the cylinder of  $p$

**RecoverHeight:**

input: cylinder incidence with distinct nodes and fresh refinement  
output: the unique ordinal type of the set of strict ancestors

**DecodeTrace:**

input: a normalized class cut crossing a proper class of nodes  
output: its unique injective ordinal-class word, defined by crossed set prefixes, together with a coverage criterion

These specifications expose the actual proof obligations: extendibility, small ancestor sets, uniqueness, and admissibility of the defining formulas. Writing a declaration named after a theorem without proving these obligations would not constitute a formalization.

### 111.12 Source 22: conclusion

There are two independent sources of complexity. In set-sized enumeration spaces, a prefix of length below the alphabet cardinal remains flexible, whereas a full cardinal-length prefix may leave an arbitrary residual order. That elementary distinction produces a complete cardinal-topological classification of fixed-length strata, finite factorial blocks, and a sharp contrast between finite and countable tails.

In the global problem, the decisive distinction is between an ordinary class of set codes and the higher-order collection of available class words. Retaining cylinder incidence recovers the missing ordinal ranks; retaining labels allows exhaustive branches to be recognized; and retaining the admitted traces over fixed parameters recovers the available class predicates themselves. Each step has an elementary definition with an explicit size boundary. None requires a same-level class of all well-orders, an unrestricted surreal cut, or an implicit class-valued recursion.

### 111.13 Source 22: theorem and dependency ledger

| Result                                                                       | Framework                           | Status and principal input                                                     |
|------------------------------------------------------------------------------|-------------------------------------|--------------------------------------------------------------------------------|
| Birthday richness, <a href="#">note 62.15</a>                                | ZFC                                 | Derived here from the established sign separator theorem.                      |

| Faithful realization recovery, <a href="#">theorem 102.3</a>                 | Metatheory of GBC models            | Same set universe and shared parameters; no internal collection of all traces. |
| Raw comparison, <a href="#">note 111.17</a>                                  | Class theory with given well-orders | Earlier direct construction; proof included.                                   |
| Full-model nonembedding                                                      | External inaccessible model         | Earlier phenomenon, obtained again from the invariant table.                   |

No row asserts a new Lean-checked theorem. The finite executable checks have a different scope, described next.

### 111.14 Source 22: finite regression checks and reproducibility

The accompanying `code/finite_checks.py` uses only the Python standard library. It checks finite first-disagreement comparisons, residual-cylinder convexity and factorial size, recovery of prefix inclusion and height in an injection tree with spare labels, pair-swap order preservation and trace decoding, and the forced-last-label counterexample when spare labels are absent. Its machine-readable output is `data/finite_checks.json`. The delivered run passed 1,388,197 assertions, including 533,417 ordered word-pair cases, 16,071 residual cylinders, and all 267,289 node pairs in a 517-node finite injection tree. The pair-swap decoder was checked on all 16 four-bit words inside an ambient order of 40,320 permutations.

These checks do not verify uncountable cardinal arithmetic, transfinite cofinalities, small-cut filling, class comprehension, or model reconstruction. They guard the finite combinatorial mechanisms used in the written proofs. Their code is deterministic, and the recorded assertion counts can be reproduced by running

```
python3 code/finite_checks.py --output data/finite_checks.json
latexmk -pdf -interaction=nonstopmode -halt-on-error article.tex
```

The LaTeX source has an internal bibliography and no external image or font-file dependencies. A working build script, source audit, status note, and checksum manifest are included in the archive.<sup>19</sup> Fonts installed in the build environment are not distributed.

### 111.15 Source 22: source audit and boundaries of the review

The inspected repository commit is

d5bd4a67b41b89688a079997574a94bcd855bb83.

The maintained report and guide are at

```
Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/article.tex
Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/README.md.
```

The guide was used for the scope, merger history, theorem inventory, review status, and formalization boundary. The specific existing Lean declarations listed in [section 111.11](#) were read directly in the following pinned source blobs:

```
Algebra/SurrealNumbers/Surreal/Foundations/SignSequence.lean
Blob: e2c093860f29b0b9ea312d50099fc4aa89a76a99.
Algebra/SurrealNumbers/Surreal/Foundations/SignSequenceCut.lean
Blob: c5c35afd98a5ad293687367ee9fb0244f94cc91c.
```

The Library copies of the two earlier continuation manuscripts were consulted for their results and proposed next questions. Both cite the earlier repository revision

0ecd158fd163bc4aca0ee40ccf6479ca6cf5f2a8.

<sup>19</sup>[merge] Shipped as `code/22-unranked-finite_checks.py`, `data/22-unranked-finite_checks.json`, `data/22-unranked-pdf_validation.json`, `22-unranked-SOURCE_AUDIT.md`, `22-unranked-RESEARCH_STATUS.md` and `code/22-unranked-build.sh`. The build script changes into its own directory and calls `code/finite_checks.py` and `article.tex`, so it builds nothing in this layout; the checksum manifest (9/9 entries verified at placement), the source and the PDF are not shipped. Rerun on a copy with an explicit `-output` ([section 111.49](#)).

They are separately credited in the bibliography and are not assumed to have been merged into the pinned repository.<sup>20</sup>

The source audit is targeted, not a certification of every theorem in the 116-page maintained report ([merge] 116 pages at d5bd4a67b). The new theorems are proved in this article rather than justified solely by an earlier manuscript's assertion. The bibliography distinguishes repository material, unpublished user-supplied continuations, and primary published or arXiv sources. Bibliographic verification does not establish historical novelty, and finite checks do not substitute for proof review.

## 111.16 Source 23: embedding spectra and what the new results do not change

### 111.16.1 Fixed set carriers

For an infinite linear alphabet  $X$  of cardinality  $\mu$ , let  $\mathcal{W}(X)$  consist of complete ordinal enumerations of  $X$ , and  $\mathcal{W}_\mu(X)$  of those of length exactly the initial ordinal  $\mu$ . The following baseline is already in the repository and its companion reals report [39, 1]. We include a proof to isolate it from the new termination theorems.

*Note 111.20* (Source 23, Theorem 8.1, “Fixed-set baseline”). *Both orders have cardinality  $2^\mu$ . They contain an embedded copy of every linear order of cardinality at most  $\mu$ . Their increasing ordinal embedding spectrum, and their decreasing ordinal embedding spectrum, consist exactly of the ordinals  $\beta < \mu^+$ . This is theorem 6.1; source 23 calls it a baseline “already in the repository” and includes a proof.*

*Source 23's proof.* The upper cardinal bound follows by representing each well-order as a relation on  $X$ . Partition  $X$  into  $\mu$  two-element sets and write each as  $\{a_i, b_i\}$  with  $a_i < b_i$ . For a binary word of length  $\mu$ , enumerate the  $i$ th pair as  $(a_i, b_i)$  for bit zero and  $(b_i, a_i)$  for bit one. Concatenating the pairs has ordinal length  $2 \cdot \mu = \mu$ . The first different bit decides the first different label. This embeds the binary lexicographic cube  $2^\mu$  and proves the lower cardinal bound.

For a nonempty linear order  $J$  with  $|J| \leq \mu$ , list its elements, with repetitions if needed, as  $(x_i)_{i < \mu}$ . Associate to  $x \in J$  the binary word  $c_x(i) = 1$  exactly when  $x_i < x$ . If  $x < y$ , then  $c_x \leq c_y$  coordinatewise and the inequality is strict at an index listing  $x$ . Hence  $x \mapsto c_x$  is a lexicographic embedding. Compose with the pair coding. The empty order embeds trivially.

For the upper ordinal bound, suppose  $(f_\eta)_{\eta < \mu^+}$  were strictly increasing in  $\mathcal{W}(X)$ . Construct by recursion a common eventual prefix of length  $\alpha$  for every  $\alpha < \mu^+$ . At a successor stage the next values on a tail of the family are nondecreasing in  $X$ . A nondecreasing  $\mu^+$ -sequence with at most  $\mu$  distinct values is eventually constant: otherwise the change stages would be cofinal in  $\mu^+$ , contradicting its regularity. At a limit stage less than  $\mu^+$ , take the supremum of the earlier stabilization stages.

No eventual common prefix can already exhaust  $X$ , because by Lemma 80.1 all later enumerations would then coincide. Thus the recursion yields an injection  $\mu^+ \rightarrow X$ , a contradiction. The decreasing case uses nonincreasing next values. The lower spectrum bound follows from the universality already proved.

The global word orders discussed above are ordinary proper classes, not one of these fixed-set orders. Under global choice they all embed into **No**, whether or not they are saturated, by the usual forth construction along an Ord-enumeration. Conversely singleton words embed **No** into each of them. Thus they are equimorphic. Theorem 81.9 and Theorem 82.1 show why equimorphism alone loses essential local information.

<sup>20</sup>[merge] They are sources 17 and 13 of this report, placed in f0cd7032d after source 22's pin and printed in Parts VI–IX.

### 111.16.2 Birthday cutoffs

For an infinite cardinal  $\kappa$ , the sign sequences of length below  $\kappa$  form the set  $\mathbf{No}_{<\kappa}$  of cardinality  $2^{<\kappa}$ . Theorem 111.20 therefore applies with  $\mu = 2^{<\kappa}$ . If  $\kappa$  is regular, a family of fewer than  $\kappa$  options has birthdays bounded below  $\kappa$ , so the usual sign-cut construction gives the corresponding small-cut saturation of this stage. At singular stages the birthday bound needs separate care.

The repository develops a finer singular strong-limit dichotomy for binary coding length ([merge] theorem 8.3). We do not use that dichotomy or re-prove its optimality here. Neither its correctness nor any purported strengthening is needed for the termination or condensation theorems.

### 111.16.3 The set-coded core of the global enumeration order

The class of set words must not be confused with the virtual order  $\mathfrak{W}_{\text{sl}}$  of all class bijections  $\text{Ord} \rightarrow \mathbf{No}$ . Nevertheless, an ordinary class of set codes is already dense in the latter and interpolates every uniformly set-indexed cut. This is a prior result of the repository [39]; the following proof connects it to the bounded-prefix method used above.

Fix a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . A set-supported permutation of  $\text{Ord}$  is coded canonically by its set of moved pairs, with identity understood elsewhere. Let  $\mathcal{P}_s(b)$  (source 23's  $P_b$ ) be the ordinary class of these codes, ordered by comparing their evaluations  $b \circ \pi$ . Distinct codes have distinct evaluations.

*Note 111.21* (Source 23, Lemma 8.2, “Completing a set prefix”). *Every injective set word  $p : \alpha \rightarrow \mathbf{No}$  extends to  $b \circ \pi$  for a set-supported permutation  $\pi$  of  $\text{Ord}$ . This is source 11's supported completion (lemma 19.4), for source 23's support-graph codes.*

*Source 23's proof.* Put  $u = b^{-1} \circ p$ , an injection from  $\alpha$  into  $\text{Ord}$  with set graph. Choose an infinite cardinal  $\kappa$  strictly above all ordinals in its domain and range and with  $|\alpha| < \kappa$ . The two complements  $\kappa \setminus \alpha$  and  $\kappa \setminus \text{ran } u$  both have cardinality  $\kappa$ . Any bijection between them completes  $u$  to a permutation of  $\kappa$ . Extend that permutation by the identity above  $\kappa$ , then retain only its moved pairs as the code.

*Note 111.22* (Source 23, Theorem 8.3, “Uniform small cuts have core separators”). *Suppose  $I, J$  are sets and  $(e_i)_{i \in I}, (f_j)_{j \in J}$  are uniformly presented class bijections  $\text{Ord} \rightarrow \mathbf{No}$ , with  $e_i < f_j$  for every  $i, j$ . Some evaluation of a code in  $\mathcal{P}_s(b)$  lies strictly between the two families. Consequently  $\mathcal{P}_s(b)$  is set-cut saturated and isomorphic to  $\mathbf{No}$  in GBC; its evaluations are dense in  $\mathfrak{W}_{\text{sl}}$ . This is theorem 19.10 and corollary 19.15; source 23 calls it “a prior result of the repository”.*

*Source 23's proof.* Uniform presentation means that each indexed family is given by a class relation on index, ordinal position, and surreal value. It permits Class Replacement on set index domains. If both sides are nonempty, let  $\delta_{ij}$  be the first disagreement of  $e_i$  and  $f_j$ . Choose a set ordinal  $\beta$  above all  $\delta_{ij}$ . Every prefix cylinder meeting both families has length less than  $\beta$ . All such prefixes therefore belong to a set: restrict the uniformly given words to set positions below  $\beta$ , collect their set restrictions, and use Replacement.

As in Lemma 81.7, these crossing prefixes form a chain. Their union  $p$  is an injective set word, and all constraints outside its cylinder are correctly oriented. If its cylinder meets both families, its lower and upper sets of next labels are strictly separated: a shared next label would yield a longer crossing prefix. Choose a fresh separator  $a$  of those sets. If only one family meets the cylinder, choose  $a$  strictly above, or strictly below, its set of next labels as required. If neither meets it, choose any unused  $a$ . No input word terminates at  $p$ , since every input has domain  $\text{Ord}$ .

In every case all comparisons are decided by the prefix  $p \frown (a)$ . Complete it by Lemma 111.21; any completion preserves those decisions. When an index set is empty, an appropriate fresh first

label bounds the other family’s first labels, and the same completion works. When both are empty, the baseline itself suffices.

Applying this to sets of codes proves saturation of  $\mathcal{P}_s(b)$ . It is a proper class, since every possible first surreal label is attained by the completion lemma. The back-and-forth argument of Corollary 81.10 gives  $\mathcal{P}_s(b) \cong \mathbf{No}$ . Taking two singleton index sets proves density in the virtual enumeration order.

This theorem realizes *uniformly set-indexed* cuts, not arbitrary class-indexed cuts and not an external collection of unrelated classes. The index sets being small is what bounds the first-disagreement positions. Also, the ordinary class  $\mathcal{P}_s(b)$  is not an exhaustive coding of  $\mathfrak{W}_{sl}$ ; Section 111.17 gives the diagonal obstruction. There is no conflict between a surreal-sized dense core and a strictly higher-level domain of all admitted global enumerations.

## 111.17 Source 23: why the constructions do not create a class paradox

### 111.17.1 Three levels that must not be conflated

The word orders  $\mathcal{T}_\varepsilon(\mathbf{No})$ ,  $\mathcal{I}_\varepsilon(\mathbf{No})$ , and  $\mathcal{T}_\varepsilon^{\text{inc}}(\mathbf{No})$  are ordinary classes: each element is a set function on a set ordinal. The polynomial carrier  $P(\Gamma)$  is also an ordinary class, even when  $\Gamma$  is proper, because its elements are finite graphs. Class parameters are used to define membership, but they do not become members.

By contrast, an exhaustive Ord-enumeration of  $\mathbf{No}$  is a proper-class function. The expressions  $\mathfrak{W}_{sl}$  and  $\mathfrak{W}_{all}$  abbreviate predicates on such functions or relations. A map between all their members requires an explicit interpretation: a uniform formula transforming class parameters, a higher sort, or an external map over a set-sized model. These meanings are not interchangeable.

The condensation quotient presents a third common hazard. A block may be a proper class, so the expression “the class of all blocks” is not an ordinary class in GB. The least-representative construction in Theorem 106.3 removes this hazard. The successor operation (S23.3) likewise quantifies over a set transversal, not a set of proper-class objects.

### 111.17.2 Global choice and the scope of class universality

Global choice supplies a set-like well-order of the universe and hence Ord-enumerations of proper classes. It supports the forth and back-and-forth constructions used here. The repository proves the stronger equivalence that a class well-order of  $\mathbf{No}$  exists exactly when global choice holds, over its stated GB conventions [39]. We rely on the forward global-choice construction; no new proof of that choiceless equivalence is claimed.

Under global choice, every admitted class linear order embeds into  $\mathbf{No}$ : enumerate its domain and at each set stage fill the cut determined by images already chosen. This standard class-universality argument is explicitly discussed by Hamkins [21]. It does not say that there is one class of *all* class linear orders or a uniform map on such a collection. We also do not infer any converse choice principle from universality alone.

### 111.17.3 No exhaustive class of set codes for global enumerations

The following diagonal makes the relevant obstruction concrete. It is consistent with, and independent of the new local word constructions; it is also part of the earlier report’s foundational picture [39].

*Note 111.23 (Source 23, Proposition 13.1, “Uniform-code diagonal”). There cannot be an ordinary class  $D$  of set codes with a uniform class evaluation  $F(d, \alpha)$  such that every exhaustive class bijection*

$\text{Ord} \rightarrow \mathbf{No}$  equals  $F(d, -)$  for some  $d \in D$ . This is [theorem 19.37](#), by the same pair switch along a class surjection onto the codes.

*Source 23's proof.* Assume otherwise and choose a class surjection  $i \mapsto d_i$  from  $\text{Ord}$  onto  $D$ ; global choice supplies it, allowing repetition if  $D$  is a set. Fix a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . Partition the ordinal positions into consecutive pairs  $(2 \cdot i, 2 \cdot i + 1)$ . On each pair put the two values  $b(2 \cdot i)$  and  $b(2 \cdot i + 1)$  in the order that makes the first one different from  $F(d_i, 2 \cdot i)$ .

This defines an exhaustive class bijection  $g$  by an elementary formula, with no recursive choices. It differs from  $F(d_i, -)$  at position  $2 \cdot i$  for every  $i$ . Since every code is listed,  $g$  has no code, a contradiction.

A bounded-support core can nevertheless be an ordinary class of set codes and be isomorphic to  $\mathbf{No}$ . Such a core is not an exhaustive coding of all class bijections. The termination theorem constructs other ordinary class orders isomorphic to  $\mathbf{No}$ ; it does not evade this diagonal.

#### 111.17.4 Set-valued construction versus class-valued recursion

The fresh-separator lemma uses two small cuts. The crossing-prefix proof uses a bounded set of supplied prefixes. Direct raw comparison uses an elementary common-part predicate. Polynomial condensation uses one explicit formula. None requires a general recursion whose values are arbitrary classes.

A generic iteration of ([S23.3](#)), a recursively chosen class at each stage, or a truth predicate for a class structure is different. The literature on elementary transfinite recursion makes this distinction precise [[22](#), [24](#)]. A proof that an explicit formula satisfies a recursive specification is not a proof of the unrestricted recursion scheme. Conversely, it is unnecessarily strong to assume ETR merely because a verified explicit example has a class-length indexing order.

### 111.18 Source 23: bounded universes and a concrete interpretation

#### 111.18.1 Ordinary ZFC approximations

A set cutoff avoids higher-order collections. Choose a set of surreal labels  $X$ , a set ordinal bound on word lengths, and any chosen relation codes. All resulting carriers and relation families are sets. The class theorems cannot simply be copied without their smallness margins: lengths may reach the bound, required fresh labels may leave  $X$ , and set-cut saturation becomes saturation only for families below an appropriate cardinal.

For example, the proof of the termination theorem needs the union of a small family of prefixes still to have allowed length. Regularity of a length bound is a natural sufficient hypothesis. The finite checks in the package deliberately do not replace this requirement by a finite analogue and then claim a transfinite conclusion.

#### 111.18.2 A full inaccessible-universe model

Let  $\kappa$  be strongly inaccessible and work externally with the full two-sorted structure whose sets are  $V_\kappa$  and whose classes are all subsets of  $V_\kappa$ . Internally, ordinals form a proper class; externally that class has order type  $\kappa$ . Internal set-sized families have external cardinality below  $\kappa$ , and every such family of elements of  $V_\kappa$  belongs to  $V_\kappa$ .

The internal surreal sign carrier has external size  $\kappa$ , and its set-cut property becomes saturation for families of size below  $\kappa$ . Its set words also have external size  $\kappa$ . The full global enumeration collection is now an external set of bijections  $\kappa \rightarrow \mathbf{No}^{V_\kappa}$ , with cardinality  $2^\kappa$ . It is not an internal

ordinary class enumerated by  $\kappa$  set codes. This is a concrete setting in which Proposition 111.23 has an ordinary cardinal shadow.

**Proposition 111.24** (Polynomial orders become ordinal powers). *In this full model, if an admitted class well-order  $\Gamma$  has external order type  $\beta$ , then  $P(\Gamma)$  has external order type  $\kappa^\beta$ , with ordinal exponentiation. Internal set-interval condensation is the operation of collapsing intervals of external cardinality below  $\kappa$ .*

*Proof.* After externally reindexing  $\Gamma$  by  $\beta$ , the polynomials are finite-support functions  $\beta \rightarrow \kappa$ . They form the usual ordinal base- $\kappa$  expansions below  $\kappa^\beta$ , compared at their highest different exponent. This can also be proved without an expansion algorithm: at a successor exponent the order is the sum of  $\kappa$  copies of the preceding order, and at a limit it is the union of the initial suborders with bounded finite support. These are exactly the successor and limit equations for ordinal exponentiation.

A subclass of  $V_\kappa$  is an internal set exactly when it has external size below  $\kappa$ . The forward direction follows from inaccessibility; for the converse, regularity bounds the ranks of fewer than  $\kappa$  objects and places their set in  $V_\kappa$ . Apply this to the intervals.  $\square$

For  $\Gamma = \omega$ , the concrete example is  $\kappa^\omega$ . Its finite successive condensations again have order type  $\kappa^\omega$ , yet their limit equivalence is universal. Thus the class construction has an entirely familiar ordinal realization once the size level is fixed. The inaccessible hypothesis is a sufficient external model for this explanation, not an axiom needed by the GBC proofs of the explicit constructions.

### 111.18.3 Model dependence

In a two-sorted model with fewer available classes, “all global enumerations” means only the available class functions. An arbitrary external enumeration or isomorphism need not be internally available. Likewise, external countability of a model does not make its internal proper classes into internal sets. Statements about external order types, internal uniform transformations, and a higher-order powerclass must be labelled separately. No conclusion about all such class realizations is being inferred from the full inaccessible case.

## 111.19 Source 23: a size-explicit formalization program

### 111.19.1 Interfaces that actually exist

The inspected repository includes the following relevant interfaces [8, 54, 39]. The statements here describe their source; no build was run in this investigation.

| Source interface                                                                                                                                                   | Role in the proposed development                                               |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------|
| <code>SignSequence.lean</code> : universe-indexed sign carrier and bounded birthdays                                                                               | Separates the large carrier from lower-universe families.                      |
| <code>SignSequenceCut.lean</code> :<br><code>exists_cut_separator_of_birthday_lt</code>                                                                            | Supplies a separator at a prescribed birthday strictly above option birthdays. |
| <code>SignSequenceCut.lean</code> :<br><code>small_cut_fillers</code>                                                                                              | The abstract small-cut property needed for the termination proof.              |
| <code>SmallCutData.lean</code> :<br><code>ofSmallSets</code> , reindexing, and<br><code>HasSmallCutFillers</code> .<br><code>exists_separator_of_small_sets</code> | Converts predicate-based sets of options to explicitly small indexed data.     |

| Source interface                                                       | Role in the proposed development                                    |
|------------------------------------------------------------------------|---------------------------------------------------------------------|
| <code>SizeObstructions.lean:</code><br><code>noUnrestrictedCuts</code> | Prevents an accidental same-size<br>unrestricted cut-filling axiom. |

In particular, a Lean type named `Set X` does not mean that every such set is small at the cut-index universe. The explicit `Small` hypotheses are the mathematical content of the size boundary. An attempt to fill all cuts indexed at the carrier's own size would admit the cut with every element on the left and nothing on the right, an immediate contradiction.

### 111.19.2 The first formalization milestone

A practical first development should stay abstract. Take a linearly ordered carrier  $A$  in a larger universe, with small-cut fillers indexed in a lower universe. Represent a word by a lower-universe ordinal length and a map from its initial segment to  $A$ . Record or prove smallness of the index type. In the injective version add injectivity as a predicate, not as a new carrier with silently different size.

The proof dependency order is:

1. Prove the two-cut fresh-separator lemma and preservation under a small forbidden family.
2. Define an external marker cut, its extended letter comparison, word lexicography, concatenation, and convex cylinders.
3. Construct the small set of prefixes of a small family of input words. Prove uniqueness of a crossing prefix at each length and the bounded union lemma.
4. Formalize the maximal-prefix separator proof, retaining separately the endpoint-child case and the no-small-approach case.
5. Instantiate with the sign carrier, then prove the increasing-word counterexample using an explicit countable increasing family.

No surreal field arithmetic is needed. This produces a useful checked theorem before attempting virtual orders or internal models of set theory. The article's exact character theorem can follow afterward, since it needs cofinality definitions and cardinal minimality beyond the separator proof.

### 111.19.3 Polynomial and raw-order formalization

There are two complementary routes. In a universe-relative type theory, finite-support polynomials can be represented by finite maps into a large ordinal type. The set-interval predicate should be replaced by *lower-universe smallness* of interval types. Proving that a higher coordinate disagreement contains a copy of the large ordinal carrier then proves non-smallness. This is the type-theoretic version of Lemma 108.7.

For literal GB or GBC claims, formalize a two-sorted model and interpret the constructions inside it. The theorem about arbitrary class well-orders needs an admitted-subclass well-order predicate, not only the absence of a small descending sequence under unstated choice. The quotient should be the subtype of least representatives. The family  $E_t$  should be defined directly by tail agreement; proving its recursive laws is then a theorem, not an axiom asserting an iteration exists.

A higher-universe representation of all relations on a given type is also legitimate. It creates a larger type of codes and must not be identified with a same-level proper-class collection. Universe raising solves the typing problem by changing the size level, not by eliminating Cantor-style obstructions.

### 111.19.4 Verification boundary

No new Lean or Rocq source is supplied as verified code. The package’s Python program tests finite lexicographic comparisons, cylinder convexity, crossing chains, finite-support ordering, and tail-equivalence identities. It cannot certify class well-foundedness, small-cut saturation, the absence of a set cofinal family, or a transfinite limit step. The ordinary proofs in this article are the evidence offered for those assertions.

### 111.20 Source 23: conclusions and result ledger

The main distinction is not between a small order and an unimaginably large one. It is between different carriers, different continuation rules, and different logical levels. For arbitrary and injective set-length words, the termination cut controls all local point characters and exactly when the order becomes surreal-like in the strong saturation sense. For increasing words, the continuation restriction defeats every fixed marker. For raw class well-orders, a safe quotient construction reveals arbitrarily long explicit condensation hierarchies, and those structures occur inside every interval between distinct set-like enumerations.

| Result                                             | Role here                    | Setting                                     |
|----------------------------------------------------|------------------------------|---------------------------------------------|
| Fixed-set cardinality and ordinal spectra          | Prior result, proof included | ZFC                                         |
| Dense set-coded core and uniform cut interpolation | Prior result, proof included | GBC                                         |
| Fresh separators and crossing reduction            | Proof tools developed here   | Saturated class alphabet                    |
| Exact termination criterion                        | Main extension; full proof   | GBC suffices                                |
| Uniform point characters                           | Main extension; full proof   | GBC suffices                                |
| Increasing-word obstruction for every marker       | Main extension; full proof   | GBC suffices                                |
| Direct raw comparison                              | Prior mechanism, re-proved   | Elementary class definitions                |

| Dense raw complexity between set-like endpoints    | Main extension; full proof   | GBC                                         |
| General arbitrary-order iteration and collapse     | Not settled                  | Questions in Section <a href="#">113.17</a> |
| Lean verification of the new theorems              | Not claimed                  | Implementation plan only                    |

### 111.21 Source 23: repository and literature audit

The pinned repository source is 109aaca1505c12d70ae169bdc2011f40bd476f7d. The targeted inspection included:

- the surreal collection guide and the guide to `foundations-and-computation/surreal-well-orders`;
- the existing report’s stated theorem coverage and verification boundary, including its distinction between set words, set-like global orders, raw orders, and relation codes;
- `SignSequenceCut.lean` and `SmallCutData.lean`, including the explicit universe-relative smallness requirements.

The recursive repository tree was too large to inspect exhaustively. This was a targeted source audit, not a full repository review or build. The later branch-tip query returned a merge commit having the pinned revision as a parent; the article intentionally keeps the earlier inspected revision fixed.

The earlier continuation manuscript [41] was consulted for its exact termination and residual-iteration questions ([merge] source 13 of this report; its termination question was answered by source 16, Part VII). Its research agenda, not an unverified imported theorem, is the dependency for the new results. We have not certified all assertions in that continuation or in the merged report. The principal new proofs were written to be independent of the earlier fine cut classifications and support formulas.

The Kanovei–Shelah paper was checked directly, including the displayed index definition on its second page [16]. Its actual construction orders maps from the continuum cardinal into  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters. It should not be quoted as literally proving every theorem about the order of all well-orderings of  $\mathbb{R}$ , much less all surreal well-orders. Its relevance is the useful technique of linearly ordering rich codes rather than demanding a canonical choice of one representative.

The current paper on finite condensation [68] supplies context for the word “condensation,” not a proof of our set-interval analogue. The class-recursion references [22, 24] justify keeping ordinary elementary class constructions separate from a general class-valued recursion scheme. No claim of exhaustive literature search or historical priority is made.

## 111.22 Source 23: reproducibility and finite diagnostics

The package contains the standalone source `article.tex`, its compiled PDF, a build script, an executable standard-library Python checker, its JSON output, a research-status note, and checksums.<sup>21</sup> Run

```
python3 code/finite_checks.py -output data/finite_checks.json
sh build.sh
```

from the package directory.

The checker uses finite alphabets and exact integer comparisons. It verifies lexicographic ordering for several termination positions, convexity of all tested prefix cylinders, uniqueness of crossing prefixes at each length for separated finite constraint families, and the ordering and nested tail-equivalence identities for finite coefficient vectors. The checks also distinguish increasing words from arbitrary injective words in the examples used by the article. Finite raw-order comparisons and the paired-permutation diagonal are also checked. The recorded run passes 547,480 exact checks, with seed 20261003.

There is no finite surrogate test asserting that an interval is a set rather than a proper class. In a finite model every interval is a set, so such a surrogate would destroy the point of Lemma 108.7.

<sup>21</sup>[merge] Shipped as `code/23-termination-finite_checks.py`, `data/23-termination-finite_checks.json`, `code/23-termination-build.sh` (it compiles an `article.tex` beside itself and builds nothing here), `23-termination-RESEARCH_STATUS.md` and `23-termination-SOURCE_AUDIT.md`; the source, the PDF and the checksum manifest (8/8 verified) are not shipped.

Likewise, the limit stages of the polynomial hierarchy and the absence of small cofinal families are proved in the text, not inferred from a long finite run.

The PDF was compiled with pdfL<sup>A</sup>T<sub>E</sub>X and inspected by rendering pages. No Lean environment was available for a kernel check. Generated compilation auxiliaries are not part of the distribution.

### 111.23 Source 24: a formalization plan tied to the inspected ProveIt sources

The source inspection was deliberately narrow; the concrete module described below is cited as source code [10], not as verification of the new results. The relevant report’s README identifies the existing well-order study as an unformalized research report. The current work was not inserted into the repository and the repository was not built. We inspected an actual foundation module rather than treating a prose claim that the surreal library exists as verification of the new theorems.

#### 111.23.1 A concrete existing interface

At the pinned revision, the file

Algebra/SurrealNumbers/Surreal/Foundations/SignSequenceSimplicity.lean

imports the sign-option theory and proves, in namespace `Surreal.Foundations.SignSequence`, declarations including

```
isPrefix_of_minimum_birthday,
existsUnique_prefix_of_ordConnected,
existsUnique_minimum_birthday_of_ordConnected,
ordConnected_separators,
existsUnique_simplest_separator.
```

The last declaration has the essential shape

```
(c : SmallCutData.{u, u + 1} SignSequence.{u} (\x y => x < y))
(hc : exists x, c.IsRealizedBy x)
: exists unique x,
  c.IsRealizedBy x and
  forall y, c.IsRealizedBy y -> IsPrefix x y
```

This display is an English-like rendering of the inspected signature, not a compilable Lean replacement. Most importantly, `hc` is an *existence hypothesis*. The theorem gives a unique simplest separator once existence is supplied; it does not itself prove that every cut has a separator. The explicit small-cut universe parameters are also part of the interface, not removable decoration.

#### 111.23.2 Recommended separation of modules

A new development should begin with an arbitrary infinite alphabet and only later instantiate it with surreal birthday cutoffs. One possible module organization is the following; all names here are proposed, not claims about files already present.

| Proposed module                  | Main obligations                                                                                             |
|----------------------------------|--------------------------------------------------------------------------------------------------------------|
| WellOrders/Enumeration           | Labelled well-order equivalence, fixed-length words, absence of proper-prefix ambiguity for a fixed carrier. |
| WellOrders/PrefixExtension       | Complement cardinalities, ordinal-tail type, completion of short injections.                                 |
| WellOrders/PrefixTopology        | Convex clopen cylinders; equality of prefix and order topologies under thickness.                            |
| WellOrders/ForwardCompletion     | Prefix uniformity, Cauchy-filter stabilization, injective completion, exhaustion requirements.               |
| WellOrders/ExhaustionTree        | Child partition, exact branching, regular-limit unions, the homeomorphism of Theorem 66.2.                   |
| WellOrders/PermutationContinuity | Bounded-image predicate; continuity criteria; complete two-sided uniformity.                                 |
| WellOrders/CountableCompletion   | Complete metric, real-line completion, explicit dense $G_\delta$ representation and gap cardinality.         |
| Surreal/ThickCutoffs             | Sign-cone interval lemma and cardinality at all infinite birthday cutoffs.                                   |
| ClassOrders/CommonPrefix         | The predecessor formula and raw lexicographic transitivity with explicit class-model semantics.              |
| ClassOrders/UniformFamilies      | Uniform family coding, Class Replacement bounds, small-net rigidity, class completion schemes.               |

Here *ordinal tail type* is a real obligation: a prefix of length  $\alpha < \mu$  leaves a tail of type  $\mu$  because  $\mu$  is initial. The corresponding statement for arbitrary fixed ordinal lengths is false in that simple form. Likewise, the formalization of the regular tree must expose the use of regularity at every limit stage.

### 111.23.3 Suggested proof boundaries and audit points

The general alphabet layer needs no surreal arithmetic. It requires an infinite cardinal, an ordinal or chosen well-ordered index type of that cardinality, a set of labels, and ordinary cardinal comparison. For the order topology, add thickness. The surreal-specific layer then discharges exactly that alphabet interface through signs.

The finite executable model should remain separate from the theorem layer. Enumerating finite permutations can test that a child-cylinder partition is disjoint and exhaustive at finite levels, but it cannot establish regular-limit closure. Testing finite partial injections can catch a reversed composition or a mistaken inverse, but it cannot distinguish regular from singular cardinalities. The distinction belongs in quantified cardinal and ordinal lemmas.

For a class-model formalization, represent a class as a predicate or relation on the universe of the model and specify which predicates are admitted in its class part. Do not identify the full ambient function type with the internal class collection unless a full-class model is the intended semantics. If a higher-universe formalization is chosen instead, write every smallness assumption explicitly; a Lean `Set` of large objects is not automatically small in the universe used by a small-cut theorem.

A useful audit sequence is: first verify all fixed-set theorems; then verify the cutoff instantiation; then verify statements about a single uniformly coded class family; only afterwards address a higher-sort domain of all class relations. This order keeps the most delicate logical issue out of otherwise elementary topology proofs.

### 111.24 Source 24: conclusions

The natural lexicographic enumeration spaces have more than one completion, and the difference is mathematically informative. Forward stabilization preserves injectivity but can lose labels. Inverse stabilization prevents that loss. Dedekind completion is larger again: it also fills cylinder edges and numerical gaps. The three constructions agree on many finite tests while diverging sharply in transfinite settings.

For regular minimal enumeration cardinalities there is an explicit generalized Baire model, with branching  $\mu^{<\mu}$ . At the countable surreal cutoff the topology is completely metrizable and familiar, while the order has continuum many missing real-line completion points. At singular cardinalities the bounded-set ideal becomes visible through discontinuous right translations and inversion. These are structural results about the requested lexicographic orders, not consequences of pretending that the surreals form a set.

At the global level, the same subject is rigorous once the size level is kept explicit. A class of set codes can supply every short prefix but cannot enumerate all global well-orders. Set-indexed approximation is rigid; class-indexed approximation is expressive. Arbitrary class well-orders admit an elementary labelled comparison even when their common prefix is a proper class, but their tails require a theory beyond ordinal-class words. These distinctions are the central safeguards against paradoxes and the most useful guide to further formalization.

### 111.25 Source 24: source audit, provenance, and limits

The repository snapshot used for the inspection is

109aaca1505c12d70ae169bdc2011f40bd476f7d

The main provenance paths are:

Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/README.md  
 Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/article.tex  
 Algebra/SurrealNumbers/Surreal/Foundations/SignSequenceSimplicity.lean

The report README was inspected, including its scope, provenance, and unformalized status. The full merged article was not independently re-audited theorem by theorem for this project. Relevant continuation claims and the explicit complete-metrizability question were checked in the available prior manuscript source. The foundation Lean file was read; its Git blob is

3bf0fb22cb5a5c50b05360fd8e5dbeafb104e959.

No new Lean kernel verification is asserted, and no repository-wide build or audit was performed.

The distinction between inherited and developed results is as follows. The interpretation taxonomy, the support-core framework, raw common-prefix comparison, and earlier spectra and cut classifications come from the predecessor reports. Their relevant elementary mechanisms are reproved where needed. The exact forward-completion theorem, the exhaustion-adapted regular homeomorphism, the countable completion-complement analysis, the singular continuity criteria, and the small-net/inverse-reconstruction comparison are the principal developments of this article. This is a scope statement, not a historical-priority claim.

The references to the three continuation manuscripts denote available research drafts dated 3 October 2026. They are not described as journal publications or assumed to have been merged into the pinned repository.<sup>22</sup> Public sources were used to verify the Kanovei–Shelah construction, the

<sup>22</sup>[merge] They are sources 17, 13 and 14 of this report.

generalized bounded-topology context, and the distinction between elementary comprehension and stronger class recursion. None of those external sources is being cited as having proved the new results of this manuscript.

### 111.26 Source 24: assumption and dependency ledger

| Result                          | Essential assumptions                                         | Important exclusion                                                            |
|---------------------------------|---------------------------------------------------------------|--------------------------------------------------------------------------------|
| Forward completion              | ZFC, infinite $ X  = \mu$ , domain the initial cardinal $\mu$ | No numerical order or regularity is needed.                                    |
| Prefix/order topology agreement | $\mu$ -thick numerical alphabet                               | Not asserted for arbitrary sparse alphabets or the full variable-length order. |
| Regular Baire model             | Regular $\mu$ , Choice                                        | No assumption $\mu^{<\mu} = \mu$ ; no singular conclusion.                     |
| Countable real completion       | Countable dense alphabet without endpoints                    | Homeomorphism does not imply order isomorphism with irrationals.               |
| Singular continuity criteria    | Bounded initial-segment topology on $\text{Sym}(\mu)$         | Boundedness is not the same as cardinality less than $\mu$ .                   |
| Global prefix extension         | GBC, fixed $b$ , set-sized prefix                             | Not an exhaustive parametrization of class words.                              |
| Small-net rigidity              | Uniformly set-indexed class relation, Class Replacement       | Does not apply to externally class-sized index sets.                           |
| Global inverse reconstruction   | Supplied uniform class net and two-sided stabilization        | No collection of all class nets and no unrestricted class recursion is formed. |
| Raw class comparison            | Given class well-orders, elementary comprehension             | No assumption that every class well-order has type Ord.                        |
| Full external model             | An inaccessible $\Theta$ in the external metatheory           | This is a conditional model, not a consequence of the weaker base theories.    |

### 111.27 Source 24: finite regression checks and reproducibility

The accompanying Python program uses only the standard library. It checks finite analogues of the mechanisms most vulnerable to indexing mistakes: first-disagreement comparison, convexity of prefix cylinders, disjointness and coverage of the least-unused-label child partition, independent pair-block binary coding, finite partial-injection extension, and central-termination sign-cone comparisons. It also checks the first several instances of the escaping-label example and the identities relating forward and inverse permutations.

The recorded run passed on 5,913 finite permutations and 16,071 prefix cylinders; it checked 10,158 child partitions, 20,775 lexicographic comparisons, 3,618 partial-injection extensions, and 3,255 interval-cone extensions. Full counts and the precise test scope are in `data/finite_checks.json`.

These checks are deliberately described as regression tests. Every finite injection from a finite set to itself is already surjective, so a finite experiment cannot reproduce the missing-label completion boundary. Nor can a finite permutation distinguish regular from singular cardinality. The limiting

examples and the class results are established by the written proofs, not by extrapolation from the test data.

The package contains the standalone LaTeX source, the compiled PDF, the verification script and its JSON output, a build script, a source-audit note, and a checksum manifest.<sup>23</sup> The PDF uses ordinary installed TeX packages. A clean rebuild needs a LaTeX distribution providing `newtx`, `tcolorbox`, and the other packages listed in the preamble, together with Python 3 for the optional checks. No external bibliography database, downloaded image, font file, or network request is needed by the build.

## 111.28 Source 25: a concrete formalization program

### 111.28.1 Existing interfaces actually inspected

The pinned repository revision contains a universe-indexed sign-sequence carrier [7]. Its relevant declaration is

```
structure SignSequence : Type (u + 1) where
  birthday : Ordinal.{u}
  signAt : Ordinal.{u} -> SignType
  signAt_ne_zero_iff : forall i, signAt i != 0 <-> i < birthday
```

This display transcribes the interface using ASCII arrows; it is not an independently compiled source file. Numerical order is lifted from the lexicographic order of zero-extended sign functions. The module includes `lt_iff`, `birthdays_bounded`, `small_bounded`, `not_small`, and a separate `IsPrefix` relation. In particular, numerical order and simplicity are not conflated.

The inspected cut module [8] supplies two relevant declarations:

```
exists_cut_separator_of_birthday_lt
small_cut_fillers
```

The former constructs a separator of a specified birthday strictly above all option birthdays. These are precisely the inputs needed for Lemma 86.3; the homogeneity theorem does not require surreal arithmetic.

The repository research article is not itself a Lean development of the results proved here. This task did not run the repository's Lean build, and no new theorem in the present article is claimed to have been kernel-checked.

### 111.28.2 The first target should be the regular set theorem

Theorem 94.1 is a good initial formalization target because its structures, branch spaces, and automorphism groups are ordinary types of set-sized objects. The class theorem should not be simulated by silently treating all large-universe objects as small.

A reusable development can abstract over an ordered alphabet  $X$  and a fresh-cut extension property. It should then separate six mathematical layers.

<sup>23</sup>[merge] Shipped as `code/24-completions-finite_checks.py`, `data/24-completions-finite_checks.json`, `data/24-completions-build_validation.json`, `code/24-completions-build.sh` and `24-completions-SOURCE_AUDIT.md`; the checker's default output is `data/finite_checks.json` beside `code/`, so always pass `-output`; the build script compiles an `article.tex` that is not shipped. The source, PDF and checksum manifest (8/8 verified) are in arrival commit `b63f0c852`.

| Proposed module                  | Principal obligation                                                                  |
|----------------------------------|---------------------------------------------------------------------------------------|
| <code>PrefixProfile</code>       | First disagreement, prefix equivalence, profile preservation, and induced node action |
| <code>SupportedCompletion</code> | Extension of partial injections using an explicit reserve and a support bound         |
| <code>ProfileExtension</code>    | The maximum and no-maximum cases of Lemma 89.1                                        |
| <code>CoreHomogeneity</code>     | Set-sized back-and-forth, partial-bijection invariants, and branch transport          |
| <code>LabelCoherence</code>      | Root-edge representatives, coordinatewise normal form, and small-support rigidity     |
| <code>ExhaustiveExtension</code> | Core trace injectivity, the represented-trace criterion, and the nonextension witness |

These are proposed module names, not declarations reported as already present. The most valuable early milestone is the no-maximum case of the one-point lemma. It is easy to test only successor divergences and accidentally omit the genuinely transfinite content.

### 111.28.3 Proof data worth exposing explicitly

A partial-configuration record should contain its domain and range, a bijection between them, the proof of pairwise first-disagreement equality, and the proof of order preservation. The fixed noncore markers should be treated as additional supplied constraints, not incorrectly inserted into the type of core codes.

The extension lemma should return a *prefix witness* first, with proofs of injectivity and all profile constraints. Supported completion should then be a separate operation. This factorization makes the two independent sources of existence clear: alphabet cut filling and permutation completion. At singular lengths either source can fail for different reasons.

The inverse branch action needs its own proof. A function preserving prefixes injectively need not be a tree automorphism; the construction must retain surjectivity on the core and derive an inverse node map. Similarly, the trace criterion requires preservation of represented cuts in both directions, not only that exhaustive cuts map into exhaustive cuts.

The edge-label relation can be formalized on the subtype of immediate-successor pairs. Its canonical representative is a root edge, so no quotient of proper classes or higher-universe equivalence classes is needed. The coordinatewise normal-form theorem is then a transfinite induction on the prefix length.

### 111.28.4 Universe discipline for the eventual class analogue

In the repository’s sign interface, ordinals of universe  $u$  and the full sign carrier inhabit the next universe, while a fixed birthday fragment is small relative to  $u$ . A theorem using `Small.{u}` I must not be generalized to an arbitrary higher-universe index type without a new proof. The small-cut property only accepts the intended lower-universe option families.

A universe-relative analogue of the main theorem would need an explicit notion of small support, a chosen enumeration or appropriate presentation of the alphabet, and the exact closure principle required by its back-and-forth. It is not enough to replace `Ord` with `Ordinal` in an informal proof. Lean’s universe hierarchy is a size-management mechanism, not automatically a model of every GBC class statement.

For a direct foundational formalization, one may instead work inside a formal model of set and class theory, with elementary comprehension and class replacement explicit. That approach is heavier but makes the “no ETR” claim an actual theorem about axioms. The regular set theorem and the class-theory theorem are complementary targets rather than interchangeable encodings.

### 111.29 Source 25: conclusions and theorem ledger

The ambiguity in the original question is productive when made explicit. Fixed set carriers yield ordinary set orders with bounded ordinal spectra. Full surreal enumerations form a higher-level domain, but a set-coded core and an ordinary class of prefix nodes make a large part of their geometry accessible in GBC. Raw class well-orders require direct relation comparison rather than a fictitious enumeration of every class type by Ord.

The new structural conclusion is that the supported core and its complete unranked prefix geometry are still not enough to identify exhaustive branches. Their symmetries have a precise configuration classification, and all noncore injective branches lie in a single orbit. Exhaustiveness becomes visible only after adding information that links labels across nodes. The natural equality-of-edge-labels relation does more than recover coverage: together with the supported core, it removes every automorphism.

| Result                                                      | Framework                       | Status in this article                                       |
|-------------------------------------------------------------|---------------------------------|--------------------------------------------------------------|
| Fixed-set spectrum, Theorem 86.1                            | ZFC                             | Earlier general-alphabet result, proof supplied              |
| Class-order universality, Proposition 86.2                  | GBC                             | Standard small-cut construction, recalled                    |
| Supported completion, Lemma 86.4                            | GBC                             | Earlier core mechanism, proof with reserve supplied          |
| Unranked height recovery, Proposition 88.1                  | GBC                             | Earlier continuation result, re-established                  |
| One-point profile extension, Lemma 89.1                     | GBC                             | Main extension lemma proved here, including limit case       |
| Configuration orbits, Theorem 90.1                          | GBC                             | New continuation result; set-valued recursion                |
| Invisible exhaustiveness, Theorems 91.1, 91.2               | GBC                             | New negative recognition result, robust under set parameters |
| Cylinder-preserving nonextension, Theorem 92.2              | GBC                             | Strengthening of earlier core extension obstruction          |
| Edge-coherent normal form and rigidity, Theorems 93.1, 93.3 | GBC                             | New positive reconstruction and rigidity results             |
| Regular set theorem and group size, Theorems 94.1, 94.2     | ZFC, stated cardinal hypotheses | Set analogues and exact cardinality proved here              |
| Cofinal profile obstruction, Theorem 95.1                   | ZFC                             | Explicit sharpness mechanism and singular warning            |
| Raw comparison and diagonal obstruction                     | GBC                             | Earlier mechanisms, re-established for scope and foundations |

No entry in this ledger is a claim of independent refereeing, bibliographic priority, or a new Lean proof. The mathematical evidence for the new entries is the sequence of ordinary proofs above; the finite checks below have a narrower role.

### 111.30 Source 25: repository and literature audit

#### 111.30.1 Snapshot and scope

The repository was inspected at revision

7ff7736ecf3a0adc8536b2d083cf819e1ba39ace.

The targeted sources were the maintained surreal-well-orders article and its README, and the foundational Lean files `SignSequence.lean` and `SignSequenceCut.lean`. The repository source includes continuation material in addition to the originally merged manuscripts; we do not infer a current compiled page count from the README’s historical description.

The audit was not a line-by-line review of the entire repository, and it did not build Lean, validate all prior manuscript claims, or modify any remote file. The principal dependencies needed here—fresh separation, supported completion, core density, prefix recovery, and the class-order comparison—are either explicitly identified with inspected interfaces or re-proved in the body of this article.

The Library continuations consulted for provenance were the cut-reconstruction manuscript, the second continuation on spectra and extension obstructions, the residual-geometry manuscript, and the termination-and-condensation manuscript listed below. Their titles and relevant research questions were retrieved to avoid presenting an already supplied result as a fresh contribution. We do not claim to have independently reviewed all proofs in those manuscripts.

### 111.30.2 Literature scope

The Kanovei–Shelah paper was checked for the actual index space used in its construction, which explains the correction in Section 2. The class-recursion references distinguish elementary set-valued recursion from ETR and related stronger principles. Ehrlich’s survey [15] provides historical context for the surreal continuum; the specific new prefix-homogeneity and rigidity arguments are not attributed to that survey.

Historical novelty has not been established by an exhaustive literature search. Theorems marked as continuation results are claimed relative to the inspected material, and their validity must be judged from their stated hypotheses and proofs.

### 111.31 Source 25: executable checks and reproducibility

The archive includes a deterministic Python program using only the standard library. It tests finite restrictions of ordered prefix recodings over rational labels, the maximum-attained one-point construction in both directions, the first-disagreement/prefix-equivalence identity, finite supported completions, and a cross-node label-coherence counterexample.

The recorded run used seed 20261003 and 2,500 trials. It passed 269,329 assertions, broken down as follows.

| Checked finite mechanism                         | Assertions |
|--------------------------------------------------|------------|
| Profile preservation in sampled prefix recodings | 36,847     |
| Fresh injective extension prefixes               | 2,500      |
| Forward one-point profile extension              | 13,587     |
| Backward prefix injectivity                      | 2,500      |
| Backward one-point profile extension             | 13,587     |
| Prefix equivalence from first disagreement       | 184,235    |
| Finite supported completions                     | 16,071     |
| Failure of cross-node label coherence            | 1          |
| Two-sided fresh-cut example                      | 1          |
| Total                                            | 269,329    |

A finite sampled recoding is not asserted to be an automorphism of the entire rational injection tree. It tests the local finite profile mechanism. In particular, these checks do *not* verify the no-maximum limit case, proper-class recursion, global homogeneity, the exhaustive-branch non-invariance theorem, cardinal arithmetic, or Lean kernel correctness. The JSON result file records these exclusions explicitly.

The supplied build script runs the checks and compiles the standalone LaTeX source. The principal commands are

```
python3 code/finite_checks.py --output data/finite_checks.json
latexmk -pdf -interaction=nonstopmode -halt-on-error article.tex
```

The bibliography is internal to the source. There are no external figure dependencies. The archive includes the compiled PDF, this source, code and recorded results, a status note, an audit note, and a checksum manifest.<sup>24</sup> Installed font files are not distributed.

## 111.32 Source 26: a concrete formalization program

### 111.32.1 Existing inspected Lean interfaces

The pinned repository contains a universe-indexed sign carrier [7] in

`Algebra/SurrealNumbers/Surreal/Foundations/SignSequence.lean`.

The inspected declaration has the shape

```
structure SignSequence : Type (u + 1) where
  birthday : Ordinal.{u}
  signAt : Ordinal.{u} -> SignType
  signAt_ne_zero_iff :
    forall i, signAt i != 0 <-> i < birthday
```

[merge] Transliterated to ASCII; the source prints Lean’s Unicode symbols. The carrier is the sign presentation, with termination represented by zero. Its inspected declarations include `lt_iff` for first-disagreement numerical comparison, `ofSigns`, `ordinalOrderEmbedding`, `birthdays_bounded`, `not_small`, and `small_bounded`. The same file distinguishes `IsPrefix` from numerical comparison and proves `simpler_wellFounded` for proper-prefix simplicity.

The repository README additionally records small-cut results in neighboring files. Those declarations were reported there, but their full proofs were not re-audited for this continuation. No theorem about the new non-Borel boundary is being represented as an existing Lean theorem. The article’s proposed module names below are plans, not claims that files with those names already exist.

### 111.32.2 Separate the general alphabet layer from surreal arithmetic

The principal construction can be formalized before any surreal theory. A minimal interface is an index type with a well-order and a cardinal/minimal-length condition, a label type of the same cardinality, and a prefix-agreement relation. At the level of schematic Lean definitions, the core data are as simple as

<sup>24</sup>[merge] Shipped as `code/25-symmetries-finite_checks.py`, `data/25-symmetries-finite_checks.json`, `code/25-symmetries-build.sh`, `25-symmetries-RESEARCH_STATUS.md` and `25-symmetries-SOURCE_AUDIT.md`; source, PDF and checksum manifest (8/8 verified) are in arrival commit `5ad44b1ed`.

```

universe u

def InjectiveWords (I X : Type u) :=
  {f : I -> X // Function.Injective f}

def PermutationWords (I X : Type u) := I ~- X

def PrefixAgree {I X : Type u} [LT I]
  (a : I) (f g : I -> X) : Prop :=
  forall i, i < a -> f i = g i

```

[merge] Transliterated to ASCII; the source prints Lean’s Unicode symbols. These type-level sketches do not implement the cardinal hypotheses or proofs and were not compiled for this article. The substantive obligations are not these wrappers. They are cardinal complement calculations, cofinal block decomposition, the topology generated by cylinders, and the proof that the omitted-label map is continuous.

A suitable development should avoid making “cardinal  $\mu$ ” both an arbitrary well-ordered type and an initial ordinal without an explicit bridge. The proof of Lemma 62.9 must retain the fact that every proper prefix has smaller cardinality and that its residual tail has order type  $\mu$ . At a nonminimal domain the corresponding statement is false, as Proposition 69.29 illustrates.

| Proposed module             | Main obligations                                                                                                          |
|-----------------------------|---------------------------------------------------------------------------------------------------------------------------|
| Words/MinimalPrefixes       | Initial-cardinal tail reindexing; extension of short injections; two unused-label extensions.                             |
| Words/PrefixTopology        | Clopen cylinder base, Hausdorffness, local character, thick-alphabet order-topology equivalence.                          |
| Words/PrefixCompletion      | Coherent stabilized prefixes, complete injection uniformity, density, open exhaustion requirements.                       |
| Words/OmittedLabelCode      | First-mismatch partition, disjoint reservoirs, marker bijections, exact omitted range, continuity and order preservation. |
| Words/SingularBoundary      | Small non-Borel Cantor set; continuous-preimage contradiction; complete-metric $G_\delta$ criterion.                      |

### 111.32.3 The smallest trustworthy boundary proof

The first-mismatch identity (28) and the ordered markers are finite-coordinate combinatorics. Their transfinite use requires a separate cardinal block lemma. Once that lemma is available, the range calculation and continuity proof do not require a developed theory of surreal addition, multiplication, or analytic functions. The only specifically surreal input is thickness of the birthday alphabet.

For the final non-Borel step, a formalization can either use a library perfect-set theorem for Borel Cantor subsets, if the relevant version is available in the pinned environment, or isolate it as a named imported theorem whose proof must be supplied. It should not introduce an unproved

new axiom while presenting the resulting theorem as kernel-verified mathematics. The two cases in Lemma 69.16 also require the ordinary choice-based cardinal alternatives for the continuum and the Bernstein recursion in the equality case.

The complete-metric criterion is proved in Appendix 69.9 precisely to avoid a hidden Polish/separability assumption. Its necessity direction is sufficient for the main negative result. Formalizing that direction first would minimize dependencies while retaining the full conclusion.

For the global part, a sound first target is a class model represented by a carrier of sets, an explicit predicate selecting admitted class relations, and the relevant comprehension/replacement axioms. Alternatively, work one universe higher and label the theorem as an external, universe-relative statement. Using the full ambient function type as if it were automatically the internal class part would erase the distinction that the proof is meant to preserve.

### 111.33 Source 26: conclusions

The singular boundary of the minimal enumeration space is now visible on a very small and explicit test family. Compactly many injections, each omitting at most one label, already force non-Borelness of exhaustiveness. As a result, the complete-metrizability question has a cardinal-independent negative answer at every uncountable countable-cofinality length. Together with local character and the countable case, this yields an exact classification rather than merely an example of a bad metric.

The closed-trace theorem strengthens the conclusion when the enumeration cardinal exceeds the continuum. The  $\sqcup_\omega$  surreal cutoff satisfies all needed assumptions in ZFC and turns the abstract alphabet theorem into a statement about the numerical lexicographic order of labelled surreal well-orders. It is a Baire, metrizable, densely ordered space with extensive closed-subspace universality and no nonempty completely metrizable open part.

These advances coexist with, rather than replace, the earlier order spectra and class-theoretic constructions. Fixed carriers, variable carriers, numerical increasing words, nonminimal lengths, raw class well-orders, and quotient order types remain distinct objects. At the global level, uniform coding is a powerful rigorous substitute for a nonexistent ordinary class of all class relations, but diagonalization marks its limit. Keeping the alphabet, length, topology, and logical level explicit is both the main defense against paradoxes and the clearest route to further formal verification.

**111.34 Source 26: assumptions and dependency ledger**

| Result                        | Assumptions                                       | Main dependencies                              |
|-------------------------------|---------------------------------------------------|------------------------------------------------|
| Prefix extension and topology | ZFC, $ X  = \mu$ initial infinite                 | Complement cardinalities; ordinal tail type    |
| Order-topology equality       | Previous assumptions; thick linear alphabet       | Two-sided unused labels; first disagreements   |
| Forward completion            | Initial infinite $\mu$                            | Cauchy-filter stabilized prefixes              |
| Metric classification         | Initial infinite $\mu$                            | Local character of $\mu$                       |
| Compact coding                | cf $\mu = \omega$ , $\mu > \omega$ , $ A  < \mu$  | Reservoir absorption; first mismatch; markers  |
| Non-Borelness                 | ZFC, uncountable cf $\mu = \omega$                | Coding; classical Borel perfect-set property   |
| Closed universality           | Previous cofinality; $\mu > \mathfrak{c}$         | Arbitrary Cantor-complement coding             |
| Bounded-image refinement      | Fixed baseline $X \cong \mu$                      | Localized reservoirs; bounded inverse coverage |
| Surreal application           | Infinite birthday cardinal $\kappa$               | Sign trunks; $\mu = 2^{<\kappa}$ ; thickness   |
| Raw class comparison          | Given class well-orders; elementary comprehension | Common predecessor formula                     |
| Support core and diagonal     | GBC, fixed baseline                               | Set reserves; pair swaps; uniform evaluation   |
| Small-net rigidity            | Uniform set-indexed family; Class Replacement     | Set of least disagreement ordinals             |

No main set-sized theorem uses large cardinals,  $CH$ ,  $GCH$ , or a regularity assumption on the birthday cutoff. An inaccessible cardinal appears only in a separately labelled external class-model illustration. No result about all unrestricted class well-orders is deduced by treating them as exhaustive Ord-words.

**111.35 Source 26: source audit and reproducibility****111.35.1 Pinned repository inspection**

The GitHub default-branch reference was read during this work and pinned to

7ff7736ecf3a0adc8536b2d083cf819e1ba39ace

The relevant paths were:

Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/README.md

Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/article.tex

Algebra/SurrealNumbers/Surreal/Foundations/SignSequence.lean

The report README was inspected in successive ranges, including its scope, source-status disclosures, formalization boundary, and review corrections. The beginning of the merged article was inspected for definitions, provenance, and the stated result inventory. Its full, very large synthesis was *not* independently re-audited theorem by theorem. The first 230 lines of the sign-sequence foundation file were read at the pinned revision, covering the declarations listed in Section 111.32.

The inspected Git blob identifiers are:

| File           | Blob identifier                          |
|----------------|------------------------------------------|
| Report README  | 4a60c55651c7fddba35441fe0283e6956f838551 |
| Merged article | f3f69663cd63682ad2e1db808bcb3c6e8fd940ce |
| Sign carrier   | e2c093860f29b0b9ea312d50099fc4aa89a76a99 |

The earlier *Prefix Completions* source was retrieved from the user’s available file library. Its explicit singular question, completion theorem, two-sided-topology limitations, and complete-metric appendix were read. It is cited as an available research draft, not a journal publication or an assumed part of the pinned merge ([merge] source 24 of this report).

The external references were checked against primary publisher or author/archive sources. The Kanovei–Shelah indexing definition was checked in the paper, including its rendered page. Publisher metadata for the Gonshor and Kechris books were verified, but neither book was newly read in full for this task. The Dimonte–Motto Ros reference supplies context from its abstract and declared scope, not a theorem imported without checking its hypotheses. There is no claim of an exhaustive bibliographic novelty search.

### 111.35.2 Executable checks and their exact scope

The companion Python program checks three finite mechanisms. It exhausts finite sets of binary branches through depth four and verifies disjoint first-mismatch release with exactly the matching branch unreleased. It verifies first-disagreement order preservation for the two-marker pair code. It also checks common-labelled-prefix comparison on finite permutation orders and convexity of finite prefix cylinders.

These tests can detect a reversed bit convention, a mistaken release stage, a duplicate release, or an incorrect finite comparison formula. They cannot prove infinite cardinal absorption, the perfect-set property, non-Borelness, complete metrizability, Class Replacement, or a proper-class theorem. The infinite results stand on the written arguments and their stated standard inputs. No Lean build, kernel verification, or repository modification was performed.

The recorded run passed 5,645,785 assertions, including 1,050,698 subset–branch configurations, 174,251 marker-code pairs, 15,018 finite order pairs, and 16,072 prefix cylinders. These counts measure regression coverage only.

The package contains the standalone source and compiled PDF, a build script, the finite-check program, its recorded results, a README, and a checksum manifest.<sup>25</sup> It needs no external images, bibliography database, or nonstandard font files. Rebuild and rerun with

```
python3 code/finite_checks.py --output data/finite_checks.json
latexmk -pdf -interaction=nonstopmode -halt-on-error \
  surreal_lexicographic_boundaries.tex
```

## 111.36 Source 27: comparing global well-orders without a class of classes

### 111.36.1 Well-foundedness and set-likeness

A class relation  $R$  on  $X$  is a class well-order if it is a strict linear order and every nonempty admitted subclass has an  $R$ -least element. In GBC, equivalently, every nonempty set subclass has a least element. Indeed, if a nonempty class  $A$  had none, Global Choice would recursively choose a

<sup>25</sup>[merge] Shipped as `code/26-nonborel-finite_checks.py`, `data/26-nonborel-finite_checks.json`, `code/26-nonborel-build.sh` and `26-nonborel-RESEARCH_STATUS.md`; source, PDF, README and checksum manifest (7/7 verified) are in arrival commit 0d7b2441d.

descending  $\omega$ -sequence in  $A$ ; its range is a set, a contradiction. This equivalence concerns classes admitted by the model. It does not identify an internally well-founded relation in a nonstandard model with an externally well-founded one.

The relation is *set-like* if  $\text{Pred}_R(x) = \{y : yRx\}$  is a set for every  $x$ . A set-like class well-order on a proper class has order type  $\text{Ord}$ : each predecessor set has a set ordinal type, these ranks form an initial subclass of  $\text{Ord}$ , and a bounded range would make the carrier a set. Conversely, any class bijection  $\text{Ord} \rightarrow X$  transports ordinal order to a set-like class well-order.

An arbitrary class well-order need not be set-like. A well-order of type  $\text{Ord} + 1$ , realized on **No** using Global Choice, already supplies a counterexample. This explains why a naive instruction to compare the “first unequal ordinal entries” is incomplete in the raw interpretation.

### 111.36.2 An elementary common-prefix formula

The next construction is an established foundation of the repository [39]; we reproduce it because the new large-family theorem depends on its exact strength.

**Definition 111.25.** For class well-orders  $R, S$  on the same labelled class  $X$ , put

$$C(R, S) = \{x \in X : \text{Pred}_R(x) = \text{Pred}_S(x) \text{ and } R, S \text{ agree on } \text{Pred}_R(x)^2\}.$$

Here agreement means agreement of the two class predicates on all pairs in the common predecessor class. No power class is formed.

*Note 111.26* (Source 27, Theorem 3.2, “Direct labelled comparison”). *In GBC,  $C(R, S)$  is the largest common labelled initial segment on which  $R$  and  $S$  agree. If  $R \neq S$ , let  $a$  and  $b$  be the respective least elements outside it. Then  $a \neq b$ , and*

$$R <_{\text{raw}} S \iff a <_X b$$

*defines a strict linear comparison of class well-orders. Its formula uses only set quantifiers with  $R, S$  as class parameters. No ETR is needed. This is theorems 14.2 and 14.7; source 27 calls it “an established foundation of the repository”.*

*Source 27’s proof.* If  $x \in C(R, S)$  and  $yRx$ , then  $y$  belongs to the common predecessor class. Any predecessor of  $y$  lies in that class, and agreement there shows that  $\text{Pred}_R(y) = \text{Pred}_S(y)$  with the induced orders equal. Thus  $y \in C(R, S)$ , and the same argument applies to  $S$ . The orders agree on  $C(R, S)$  because  $uRv$  with  $v \in C(R, S)$  is equivalent to  $u \in \text{Pred}_R(v) = \text{Pred}_S(v)$ , and hence to  $uSv$ . Conversely, every common labelled initial segment with agreement is contained in  $C(R, S)$ .

If  $C(R, S) = X$ , the two orders are equal. Otherwise its complement has least members  $a, b$  in the two well-orders. Both predecessor classes are exactly  $C(R, S)$ . If  $a = b$ , the definition would put this point in  $C(R, S)$ , a contradiction.

For transitivity suppose  $R < S < T$ . The common prefixes  $C(R, S)$  and  $C(S, T)$  are initial segments of  $S$ , hence one contains the other. If the first is properly shorter, the first divergence of  $R$  from both  $S$  and  $T$  occurs there, with the same smaller label. If the second is shorter, use the symmetric argument. If the prefixes coincide, the three next labels satisfy  $a < b < c$ . In every case  $R < T$ . Totality and asymmetry follow directly from totality of  $<_X$ .

This theorem constructs a *formula*  $R <_{\text{raw}} S$  on class variables. It does not assert the existence of a class containing all such  $R$ . General isomorphism comparison of unrelated class well-orders is a different problem and can require stronger principles [27]. The labelled identity comparison avoids that task.

### 111.36.3 The first set-like block and its convex fibers

Let  $I_R$  be the elements whose  $R$ -predecessor class is a set. It is an initial segment. Its inherited order has a canonical enumeration  $c_R : \text{Ord} \rightarrow I_R$ : for every set ordinal one can perform the set-length recursion choosing the next element, and uniqueness assembles the prefixes. Equivalently  $c_R(\alpha) = x$  exactly when the set  $\text{Pred}_R(x)$  has order type  $\alpha$ . This also proves uniformity for a uniformly given family  $R_i$ .

For a fixed class injection  $h : \text{Ord} \rightarrow X$ , consider all raw well-orders with  $c_R = h$ . If  $Y = X \setminus \text{ran } h$ , these are exactly the orders

$$h + Q, \quad Q \text{ a class well-order of } Y. \quad (\text{S27.2})$$

Every point of  $Y$  has all of  $\text{ran } h$  before it, so none belongs to the initial set-like block. Two different blocks  $h, k$  first disagree at a set ordinal, and that disagreement decides comparison of *every* order in their respective fibers. Therefore each fiber is convex. Within one fiber, comparison is precisely raw comparison of the tails  $Q$ . These are formula-level statements, and remain meaningful when the fibers are collections of class variables.

The fiber may have one point, finitely many points, a set-sized order, or an entire raw class-order comparison, depending on  $Y$ . This residual information is why replacing every raw well-order by its first ordinal block loses much more than redundant notation.

### 111.36.4 A set-coded core for the set-like interpretation

Fix a baseline class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . A permutation  $\pi$  of  $\text{Ord}$  with set support is completely represented by the set graph of its moved points. The associated enumeration is  $E_\pi = b \circ \pi$ . Let  $\mathcal{P}_s(b)$  denote the ordinary class of these canonical codes, compared by their enumerations. Distinct codes have distinct enumerations.

Every injective set prefix extends to such an enumeration: translate it by  $b^{-1}$  to a partial injection of ordinals and complete that injection to a permutation with set support. An explicit optimum is obtained in [section 101](#). Between two set-like enumerations, take their common set prefix and insert a fresh numerical label strictly between their first unequal labels, then complete. A set of used labels cannot exhaust a surreal interval, so a fresh label exists. Hence the core meets every nonempty interval of the set-like comparison.

More strongly, the repository proves that  $\mathcal{P}_s(b)$  fills every separated cut specified by a *uniform set-indexed* family of core elements, and in GBC it is isomorphic to  $\mathbf{No}$  [39]. This is a property of an ordinary class of set codes. Theorems below show why it cannot be promoted to a dense uniform family for the entire raw order.

## 111.37 Source 27: a concrete formalization route

The best first machine-checked development is a generic library of well-ordered words and relation scans. It should depend on an ordered alphabet and explicit size parameters, then specialize to the surreal carrier. This keeps the proofs reusable and makes the size distinctions visible in the interfaces.

### 111.37.1 What ProveIt already provides

At the pinned revision the independent sign carrier is defined as `SignSequence : Type (u + 1)`. It has an ordinal birthday in `Ordinal.{u}`, a sign at each such ordinal, and the condition that the

sign is nonzero exactly below the birthday. Its numerical order is lifted from lexicographic order on the zero-extended signs. The inspected declarations include the following [7, 8, 9, 31].

| Existing declaration                             | Role in a future development                                                |
|--------------------------------------------------|-----------------------------------------------------------------------------|
| <code>SignSequence.lt_iff</code>                 | First-disagreement characterization of the numerical order.                 |
| <code>ordinalOrderEmbedding</code>               | The all-plus embedding of ordinals into the sign carrier.                   |
| <code>birthdays_bounded</code>                   | Every small indexed family has a strict ordinal birthday bound.             |
| <code>small_bounded</code>                       | Each bounded-birthday subtype is small in the lower universe.               |
| <code>not_small</code>                           | The whole sign carrier cannot be resized to the lower universe $u$ .        |
| <code>small_cut_fillers</code>                   | Existence of a strict separator for small separated cuts.                   |
| <code>exists_separator_of_small_sets</code>      | A set-interface form of small-cut interpolation.                            |
| <code>exists_cut_separator_of_birthday_lt</code> | A separator at a prescribed birthday above all option birthdays.            |
| <code>noUnrestrictedCuts</code>                  | Formal obstruction to demanding strict separators for arbitrary large cuts. |

The first entries are in `SignSequence.lean`; the last four are in the cut and size modules named in [section 61.16](#). We inspected their source statements. This article does not claim to have rebuilt `ProveIt` or machine-checked its new lexicographic theorems.

### 111.37.2 Universe levels should remain part of the statement

Lean’s universe hierarchy provides a disciplined way to say that a carrier is too large for one universe while still being an object in a larger one [29]. It does not identify all universe levels or provide a type of every type. In the inspected development, both `Ordinal.{u}` and `SignSequence.{u}` live in `Type (u + 1)`. The lower universe  $u$  controls the small well-ordered representatives; `Small.{u}` asks whether a type can be resized to that lower universe. Predicate types and collections of predicates on a fixed carrier do not each automatically require a new universe. The crucial distinction is between a construction with explicit fixed universe parameters and an unbounded totality across all universe levels. Relation types, family indices, and the model in which a class interpretation is made should retain their actual universe parameters in every theorem interface. An order embedding of a bounded universe’s word type into a larger surreal type is compatible with all the negative results above. It does not establish an embedding of a literal collection of every proper-class relation into the same foundational level. Similarly, proving a small-cut property does not permit instantiating it with the whole carrier as a small set.

### 111.37.3 Recommended theorem interfaces and implementation order

**Stage 1: generic words.** Represent a word by a well-ordered domain and an entry function, or by an ordinal and entries on its initial segment. Use an explicit sum type for the terminator; do not use a distinguished alphabet element unless taking a stated quotient. Prove first-difference uniqueness, linearity, common-prefix rules, convexity of cylinders, and prefix-freeness for exhaustive

injections. The split map of [theorem 82.4](#) should be formalized here, as an exact order isomorphism independent of any surreal arithmetic.

**Stage 2: set relations and scans.** A scan is an order-indexed bijection onto ordered pairs; retain its ordinal type in the data. Define the characteristic table and its order embedding into a binary power. Formalize adjacent-pair coding, stabilization of a  $\mu^+$ -sequence of binary words, and the exact spectrum. Then prove the prefix-neighborhood lemma and the two scan-topology theorems. The six-coordinate construction is a small, concrete counterexample generator with a genuinely transfinite consequence.

**Stage 3: permutation completion.** Separate forced moved points from available reserve points. The main reusable equivalence is ([S27.14](#)). Formalize the finite and infinite cardinal cancellation cases, followed by increasing enumeration of fresh ordinals and ([S27.16](#)). Keep the existence of a matching separate from selecting one computationally. The exact finite optimizer in the accompanying diagnostics is a test of the specification, not a proof of the infinite reserve case.

**Stage 4: an explicit class model.** For the class theorems, formalize a two-sorted model or a fixed universe-bounded interpretation. Expose an interface for elementary comprehension, Class Replacement, and a set-like global enumeration. Prove the common labelled prefix formula and its linearity without introducing a class of class relations. Define a family as a single relation with a set index argument. The diagonal theorem can then be formalized directly.

**Stage 5: set-state recursion and prefix automorphisms.** Prove one lemma assembling compatible unique set-length runs. Apply it first to the residual back-and-forth, then to the local-map evaluator. This isolates the exact foundational step and prevents accidentally assuming a principle of class choice. The branch-transitivity theorem, the coverage bounds, and the cross-node label classification then follow with short structural arguments.

**Stage 6: external model comparison.** Express the trace reconstruction formula and prove its invariance for models sharing their first-order set structure and the displayed class predicates. The marked-model theorem should be an external theorem about these models, not an internal quantification over a universe's own entire semantic apparatus.

These stages form a dependency order, not a promise of an existing implementation. The source audit is deliberately explicit about which items are already Lean declarations and which are proposed new modules.

### 111.38 Source 27: finite diagnostics, proof status, and reproduction

The archive includes a Python program using only the standard library. It checks all effective oriented scans on three labels, the explicit enumeration-versus-table reversal, finite versions of the six-point fiber construction, the exact increasing-word factorization at every cut of a finite alphabet, and the finite support optimum by exhaustive permutation search. The program writes a JSON record of counts and results. Its checks remain active when Python optimization is enabled.

These checks have a limited and explicit role. They detect mistakes in orientation, prefix termination, partitioning, and support-height conventions. They do not prove regularity arguments at  $\mu^+$ , infinite reserve requirements, Global Choice, any class recursion claim, or absence of a uniform class family. Those conclusions rest on the mathematical proofs in the article. In particular, the finite support search always has balanced finite boundary cardinalities; the  $\omega$ -shift obstruction cannot be discovered by extrapolating that test alone.

The theorem statements and their foundational assumptions were reviewed independently during preparation. This is not external peer review and does not change their status to machine-checked mathematics. The stronger general-gap cut-classification proposal was not proved and is left in [section 113.21](#), rather than included among the theorems.

The LaTeX source is self-contained and uses an internal bibliography. Compile with

```
latexmk -pdf -interaction=nonstopmode -halt-on-error
surreal_lexicographic_orders.tex
```

Run the finite diagnostics with

```
python3 finite_checks.py -output finite_checks.json
```

[merge] Shipped as `code/27-scans-finite_checks.py` and `data/27-scans-finite_checks.json`, with `27-scans-SOURCE_AUDIT.txt`; the source and PDF are in arrival commit 79049d58c. The distributed PDF was compiled from the distributed source, checked for unresolved references and citations, and rendered for visual inspection. The separate source-audit note records exactly which repository files were inspected and preserves the pinned revision.

## 111.39 Source 28: a formalization plan tied to the inspected repository

### 111.39.1 Separate the generic theorem from its surreal instance

The new algebra and topology use only a set of coordinates, an ideal of allowed control sets, and permutations. A Lean development should first formalize that generic layer. Surreal-specific code is needed only to supply a thick linearly ordered alphabet and to connect its numerical order topology with the generic prefix topology. This avoids importing arithmetic or real-closed-field results into proofs that do not use them.

A sensible dependency order is as follows. First implement injective partial maps, exhaustive completions, and prefix agreement. Then implement an admissible control ideal, its agreement topology and uniformity, and the exact translation and inversion criteria. Next prove the maximal-subgroup theorem and the symmetric-ideal envelope theorem. The bounded ideal then supplies the singular normalizer and closure results; the small-set ideal supplies the character and complete-group statements. Finally instantiate the order-topological interface at a birthday cutoff.

| Proposed module                    | Main obligations                          | Dependencies to keep explicit                               |
|------------------------------------|-------------------------------------------|-------------------------------------------------------------|
| <code>PartialInjection</code>      | Small and bounded extension lemmas        | Cardinality of both complements; reserve construction.      |
| <code>AgreementIdeal</code>        | Neighborhoods, uniformity, control ideal  | Finite unions, singleton coverage, complement size.         |
| <code>PermutationContinuity</code> | Exact criteria and maximal subgroup       | Internal transposition witnesses.                           |
| <code>GroupEnvelope</code>         | Symmetric ideal and minimality            | Conjugation of pointwise stabilizers.                       |
| <code>BoundedPermutation</code>    | Self-normalizer and one-sided closure     | Singular cofinality; enlarged bounded support.              |
| <code>SmallSetCharacter</code>     | Exact character and diagonal lower bound  | Cofinal small-subset families, not just ordinal cofinality. |
| <code>AgreementCompletion</code>   | Injection completion and two-sided limits | Stabilization on whole control sets.                        |
| <code>SurrealEnumeration</code>    | Thickness and order-topology instance     | Sign cones, universe-indexed alphabet size.                 |

These are proposed module names, not claims that such files already exist in ProveIt. No uncompiled code with admitted proofs is presented as a verified implementation.

### 111.39.2 What the inspected Lean file actually proves

The inspected source [10] is

```
Algebra/SurrealNumbers/Surreal/Foundations/SignSequenceSimplicity.lean.
```

In the namespace `Surreal.Foundations.SignSequence`, it proves, among other declarations,

```
isPrefix_of_minimum_birthday,  
existsUnique_prefix_of_ordConnected,  
existsUnique_minimum_birthday_of_ordConnected,  
ordConnected_separators,  
existsUnique_simplest_separator.
```

The final theorem has an explicit existence premise for the separator of a `SmallCutData.{u, u + 1}` cut. It establishes a unique simplest separator *given existence*. It must not be used as an independent proof that every permitted small cut is filled. The minimum-birthday theorem similarly concerns a nonempty order-convex set.

There are also two unrelated prefix notions to keep separate: a surreal sign prefix, relevant to birthday and simplicity, and an enumeration prefix, relevant to the coordinate topology studied here. A theorem about one is not an instance of a theorem about the other without an explicit map and proof.

### 111.39.3 Universe discipline and class semantics

A Lean expression of the form `Set A` denotes predicates on the type `A`; it does not, merely by its name, impose the set-versus-proper-class distinction of GBC. A universe-indexed surreal carrier is a type at a specified level. To model global class statements, one should either formalize a two-sorted class model inside the type theory or state external comparison results for a smaller universe embedded in a larger one.

Set-level filter completeness can be formalized in the usual way once its carriers are genuine types. The global small-net and coherent-prefix results should be separate theorems about a model and a supplied class relation. Their hypotheses include Class Replacement or the corresponding semantic closure property. Treating a type of all class relations as an ordinary internal class would reproduce precisely the foundational error the manuscript avoids.

### 111.39.4 A feasible first verification target

The shortest useful verified chain is: conjugation of pointwise stabilizers; the ideal continuity criteria; maximality under the finitary-subgroup hypothesis; and the ideal-envelope theorem. These do not need ordinal arithmetic. A second chain formalizes the bounded extension lemma and the singular normalizer argument, with Lemma 70.5 as a separate cardinal-combinatorial result. The cofinality diagonal in Theorem 70.21 is an independent, compact target.

This modular sequence would provide checked mathematical advances before tackling the larger surreal and class-model interfaces. The current manuscript supplies the proofs and dependency map, not a completed new Lean development or a repository-wide verification certificate.

## 111.40 Source 28: conclusion

The lexicographic study becomes more informative, not less, when its competing interpretations are separated. For a fixed thick set of labels, the minimal enumeration order has a prefix topology. At singular enumeration size, that topology sees bounded positions rather than all small coordinate

sets. Its failure to support the full permutation-group structure is therefore a precise filtration phenomenon, not a defect in surreal arithmetic.

The boundedness-preserving subgroup has a strong algebraic position: it is maximal under the finitary hypothesis and self-normalizing. Its forward closure and completion are exactly describable, while the inverse-bounded locus provides a dense complete metric subspace at countable cofinality. The canonical group envelope replaces bounded control by arbitrary small-set control. Its large character is forced by a direct diagonal argument, and its two-sided completeness has an explicit inverse-stabilization proof.

At the global level, every set of ordinal coordinates is bounded, so the singular obstruction does not transfer unchanged. The real issue is logical size: a virtual domain of class enumerations is not a class of such enumerations. Uniform coding, supported set codes, model-relative class semantics, and the direct common-prefix comparison allow the subject to be studied without making that identification. These distinctions also determine a realistic route to formal verification and a focused list of remaining problems.

#### 111.41 Source 28: assumption and proof-dependency ledger

| Statement                       | Assumptions                                                                  | Important limitation                                                                                                                     |
|---------------------------------|------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------|
| Cutoff thickness                | Infinite initial $\kappa$ ;                                                  | No field closure or regularity of $\kappa$                                                                                               |
| Prefix/order topology agreement | sign-sequence order; ZFC<br>$ X  = \mu$ , $\mu$ -thick, minimal domain $\mu$ | assumed.<br>Not asserted for arbitrary sparse alphabets or every ordinal-length slice.                                                   |
| Ideal continuity criteria       | Admissible ideal contained in $[\mu]^{<\mu}$                                 | Necessity uses spare coordinates outside every control set.                                                                              |
| Maximal inherited group         | Subgroup contains all finitary permutations                                  | Ambient discontinuity alone would not suffice for arbitrary subgroups.                                                                   |
| Self-normalizer                 | Singular $\mu$                                                               | Uses an enlarged bounded set of size greater than cf $\mu$ .                                                                             |
| Forward closure and completion  | Bounded-image partial maps; reserve lemma                                    | Completeness of one uniformity is not completeness of every compatible metric.                                                           |
| Dense complete inverse locus    | cf $\mu = \omega$ for the metric assertion                                   | Does not settle complete metrizability of the full forward space ([merge] settled negatively by source 26: <a href="#">note 70.13</a> ). |
| Canonical group envelope        | Ordinary permutation operations; topology must contain $\tau_b$              | A different topology or group law is a different question.                                                                               |
| Character lower bound           | Singular $\mu$ , ZFC                                                         | Bounds the coarsest group refinement, not all finer topologies.                                                                          |
| Global supported extension      | GBC, specified baseline $b$                                                  | Produces a class of set codes, not all class words as elements.                                                                          |
| Global small-net rigidity       | Uniform family with an internal set of indices                               | Does not apply to arbitrary external sequences in a countable model.                                                                     |

| Statement                       | Assumptions                                               | Important limitation                                                        |
|---------------------------------|-----------------------------------------------------------|-----------------------------------------------------------------------------|
| Unrestricted class lexicography | Given class well-orders and numerical label order         | Does not assert that every class well-order has type $\text{Ord}$ .         |
| Full external universe model    | External strongly inaccessible $\Theta$                   | Conditional modeling approach, not an existence theorem in the base theory. |
| Lean simplicity interface       | Nonempty convex set, or an explicit cut-existence premise | Not a standalone proof of universal small-cut filling.                      |

## 111.42 Source 28: source audit and provenance

The repository was inspected at the pinned revision

`7ff7736ecf3a0adc8536b2d083cf819e1ba39ace`.

The recursive tree response was too large to inspect exhaustively. The focused inspection read the merged-report README and the complete sign-sequence simplicity source. It did not recheck every theorem in the 116-page merged report and did not run a repository-wide build ([merge] the README said 116 pages at `7ff7736ec`, where the article already had Parts I–VIII). The two inspected paths are

`Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/README.md`  
`Algebra/SurrealNumbers/Surreal/Foundations/SignSequenceSimplicity.lean`.

The Lean file’s inspected Git blob is

`3bf0fb22cb5a5c50b05360fd8e5dbeafb104e959`.

The README describes the merged report as AI-assisted, unrefereed, and not formalized, and records its source and review history. We preserve that distinction rather than upgrading a research report into a formal verification claim.

The available prior manuscript `Surreal_Lexicographic_Orders_Prefix_Completions.tex` was read in substantial source ranges covering its definitions, set-level completion and continuity proofs, global prefix arguments, and research questions. In particular, its questions about the bounded subgroup’s normalizer and the full singular space’s complete metrizability were checked directly. The former is answered here in the specified natural permutation action; the latter remains a question of this manuscript.<sup>26</sup> The prior draft `Surreal_Well_Orders_Further_Study.tex` supplies the cut-reconstruction and prefix-non-rigidity context [41]; no claim is made that every continuation draft has been merged into the pinned repository.

The interpretation taxonomy, basic spectra, cutoff thickness mechanism, bounded continuity criteria, distinction between forward and Dedekind completion, and global prefix framework are inherited or reproved background. The ideal formulation, maximality theorem, singular self-normalizer, one-sided closure/completion analysis, dense inverse locus, canonical group envelope, and exact character analysis are the principal developments presented here. This is a provenance distinction relative to inspected material, not a historical-priority claim.

Primary external sources were checked for the Kanovei–Shelah indexing construction, generalized descriptive-set-theoretic context, and the distinction between elementary comprehension and stronger

<sup>26</sup>[merge] Answered negatively in ZFC by source 26, which source 28 did not see (theorem 69.18; note 70.13). The two delivery files named here are sources 24 and 13 of this report.

class recursion. None is cited as a source of the new normalizer or group-envelope proofs. The bibliography is internal to the standalone LaTeX source, so rebuilding does not require an external database or network access.

### 111.43 Source 28: finite regression checks and reproducibility

The accompanying standard-library Python program checks finite mechanisms that are vulnerable to composition-order and indexing errors: convexity of prefix cylinders, the identity relating conjugated stabilizers to images of control sets, the two forward/inverse group-uniformity identities, extension of finite partial injections, the predecessor-based common-prefix definition, and the reversal between enumeration lexicography and relation-bit lexicography in a two-label example. It records counts and the precise tested size ranges in `data/finite_checks.json`.

The recorded run passed on 16,072 prefix cylinders, 470,323 conjugation identities, 940,646 group-uniformity identities, 1,799 partial-injection extensions, and 15,018 independent common-prefix comparisons, together with the relation-code counterexample. The prefix tests range over all permutations through size 7; the algebraic pair tests range through size 5.

These tests do not prove singular-cardinal or class-theoretic assertions. Every finite injection from a finite set to itself is surjective, and finite permutations cannot distinguish bounded control from arbitrary small-set control at a singular cardinal. The normalizer theorem, the diagonal character bound, the missing-label completion boundary, and the global size restrictions are established by the written arguments, not by extrapolating finite experiments.

The package contains `article.tex`, the compiled `article.pdf`, a build script, the test program and recorded output, a source-audit note, and a checksum manifest.<sup>27</sup> A rebuild requires a LaTeX installation with the packages in the preamble; Python 3 is needed only for the optional regression tests. No font files, generated auxiliary TeX files, or copies of external copyrighted papers are distributed.

### 111.44 Source 29: formalization without paradoxes

The choice of foundation is part of the statement of the problem. The preceding results suggest four workable approaches, each useful for a different portion of the theory.

#### 111.44.1 Four routes and their scope

| Framework                 | What it treats directly                                                                                             | Boundary that must remain explicit                                                                                                                   |
|---------------------------|---------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------|
| ZFC with set bounds       | Birthday fragments, fixed strata, binary codes, countable topology, and every specified set-word construction       | A class is represented schematically by a formula; there is no internal quantifier over all definable classes or universal truth predicate.          |
| GBC with supplied classes | Global enumerations, numerical class carriers, uniform families, raw comparison, and set-valued class constructions | The full collection of class relations is not an ordinary class. A history supplied as a class parameter is different from a theorem that it exists. |

<sup>27</sup>[merge] Shipped as `code/28-envelope-finite_checks.py`, `data/28-envelope-finite_checks.json`, `code/28-envelope-build.sh` (it changes into `code/` and builds nothing there) and `28-envelope-SOURCE_AUDIT.md`; source, PDF and checksum manifest (7/7 verified) are in arrival commit 79049d58c.

| Framework                           | What it treats directly                                                                                                                    | Boundary that must remain explicit                                                                                                                                                |
|-------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Higher-order class theory           | Collections whose members are classes, and maps or completions on these collections                                                        | The additional sort and its comprehension axioms must be specified. <b>KM</b> strengthens class comprehension but still does not make proper classes members of ordinary classes. |
| External or universe-relative model | All available objects of a specified model can be studied as external sets; type universes separate carriers from collections of relations | Internal size, external size, internal well-foundedness, and external correctness must not be identified. Enlarging the universe changes the object.                              |

For a ZFC-only development, the first milestone should be fully set-sized: fix  $\theta$  and  $\alpha$ , construct  $\mathbf{No}_{<\theta}$  and  $\mathcal{W}_\alpha(\mathbf{No}_{<\theta})$ , and prove the desired theorem uniformly in those parameters. Statements about all set ordinals then form ordinary first-order theorems. A statement about all *definable class* well-orders is instead a schema, unless one moves to a specified external model with a satisfaction relation available outside it. Coding formulas alone does not supply an internal satisfaction predicate for arbitrary formulas of the same universe.

For GBC, the most economical discipline is to keep all relation arguments explicit. The common-prefix comparison in [Note 86.17](#) uses two supplied classes. The branch automorphism in [Theorem 96.7](#) uses two supplied branches and one fixed global scan. The condensation normal form in [Theorem 108.16](#) uses a supplied history. Each can be described by one elementary class formula after its parameters are available.

By contrast, asserting a solution to every elementary recursion with class-valued slices along an arbitrary class well-order is the principle **ETR**, not a routine consequence of the ordinary set recursion theorem [\[22, 27\]](#). The new **CTH**  $\leftrightarrow$  **CWO** equivalence identifies exactly the existence principle for the particular complete condensation histories used here. It neither proves that arbitrary class recursion follows from comparability nor requires such recursion once a history has already been supplied.

#### 111.44.2 What the inspected Lean code already provides

The repository has genuine Lean files supporting the sign-sequence foundation. Their existence and statements were inspected at the pin; they were not rebuilt in this task. All five files below lie in

`Algebra/SurrealNumbers/Surreal/Foundations/.`

| File                                       | Relevant support actually present                                                                                                                                          |
|--------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>SignSequence.lean</code>             | A carrier in <b>Type</b> $(u+1)$ with birthdays in <b>Ordinal</b> . $\{u\}$ , numerical first-disagreement order, bounded birthdays, ordinal embedding, and non-smallness. |
| <code>SignSequenceCut.lean</code>          | Small-cut fillers and separators at a prescribed birthday above the birthdays of the constraints.                                                                          |
| <code>SignSequenceCutOperation.lean</code> | Canonical small-cut operations, birthday bounds, density, and absence of endpoints.                                                                                        |

| File                                     | Relevant support actually present                                                                                                            |
|------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------|
| <code>SignSequenceSimplicity.lean</code> | The unique simplest separator <i>assuming an existing separator</i> ; the existence hypothesis is not an unrestricted cut-existence theorem. |
| <code>SizeObstructions.lean</code>       | A lower-universe indexing discipline for small cuts and impossibility of unrestricted cut filling.                                           |

In particular, the assertion named `existsUnique_simplest_separator` must not be used with its separator-existence premise omitted. The small-cut theory and the non-smallness theorem fit together: allowing every subset of the carrier as a lower cut would demand a point above the entire carrier. The obstruction is a formal mathematical statement, not a limitation to bypass with an unchecked universe coercion [53].

A Lean universe-relative surreal type is also not a paradoxical set of all surreals at its own universe. Its birthdays range over ordinals at a smaller universe, and the carrier lives at the next level. One may form relations or collections in a larger type universe, but then the resulting construction is explicitly relative to those universe parameters. No identification of a type with the totality of all types is involved.

### 111.44.3 A practical sequence of formal milestones

The most useful initial formalization is a generic first-difference library rather than a large class-theory encoding. The following milestones have exact mathematical specifications.

1. **Set ordinal words and explicit termination.** Represent a word with its ordinal domain and a function on that domain. Prove existence of the first disagreement, strict-order transitivity, prefix-free comparison of bijections, and the three orders obtained from termination below, between, or above labels. Keep zero padding as a preorder until the stated quotient or reduced representatives have been constructed.
2. **The native birthday spectrum.** Formalize [Lemma 76.1](#) and [propositions 76.3](#) and [76.4](#). The crucial invariant is that the target prefix contains actual signs, not padded termination symbols. At a limit, take the union of the source prefixes and verify the ordinal identity  $2 \cdot \lambda = \lambda$ . This proves the full spectrum in [Theorem 76.5](#) without any class quantification.
3. **The canonical word factorization.** Formalize [Note 82.9](#) over an arbitrary ordered alphabet split as  $L + R$ . The proof only needs the ordinal initial segment of lower-side entries and its residual tail. The proper-class corollary  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$  can then depend explicitly on supplied local alphabet isomorphisms.
4. **Residual fibers and finite tails.** Prove the exact decomposition over an injective prefix into well-orders of its unused labels, before introducing any cardinal coding. For countable alphabets, formalize  $P_{\omega+n} \cong E_n \times_{\text{lex}} n!$  and the adjacent endpoint pairs. This separates the combinatorial core from the descriptive set theory.
5. **Two named topologies and two named Borel structures.** The discrete coordinate topology and the order topology must be distinct definitions. The theorem that comparison is  $\Delta_2^0$  in one coding must not rewrite the Borel structure of the other. The same discipline applies to the topological product Borel structure and the tensor sigma-algebra generated by measurable rectangles.
6. **Condensation from a supplied history.** Prove the floor identities, finite support, and initiality of the normal-form image with the history as a parameter. Only after these lemmas

are complete should an existence axiom such as CWO or ETR be connected to the construction. This order of development makes the exact logical dependency visible in the theorem statements.

These are proposed modules and proof targets, not newly compiled Lean developments. Their advantage is that most of the difficult mathematics can be checked in set-sized or universe-relative form before the final class-theoretic packaging is attempted.

#### 111.44.4 The restrictions that prevent paradoxes

The restrictions are concrete. A surreal’s sign sequence has a set ordinal domain. A Conway normal form has set support. A member of a GB class is a set. A comparison between two class relations does not create a set of all class relations. A uniformly indexed family has one specified class code. A power collection of classes belongs to a higher sort or to an external model. A class well-order with a proper-class predecessor segment is not assigned a set ordinal rank at that point. Finally, a nonprincipal cut between proper classes is not filled merely because every set-sized cut is filled.

With these conditions retained, the phenomena proved here are compatible rather than contradictory. The same set-prefix tree can support very different class branches, and an ordinary class core can be universal for all ordinary class linear orders while failing to contain the entire higher-order family of global enumerations.

#### 111.45 Source 29: results, dependencies, and verification status

The table records the logical basis and the kind of conclusion. “Extension” means a result established here beyond the inspected source treatment; it is not a claim of historical priority.

| Result                                                     | Basis                            | Status and scope                                                                                                                                        |
|------------------------------------------------------------|----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------|
| Fixed-set cardinality and ordinal cutoff                   | ZFC                              | Inherited; reproved in <a href="#">Note 61.4</a> .                                                                                                      |
| Exact native birthday cube spectrum and hierarchy          | ZF                               | Extension; <a href="#">Theorem 76.5</a> and <a href="#">corollary 76.6</a> .                                                                            |

The principal proof arguments underwent independent internal mathematical review, including the ordinal fusion at limit birthdays, the finite residual capacities, the termination-factorization signs, the proper-class common-prefix cases, the split-space Borel argument, the uniform tree-automorphism construction, and the initiality step in the condensation normal form. This review is evidence of scrutiny, not a substitute for refereeing or a proof-assistant certificate.

The delivered source is a single self-contained LaTeX file with an embedded bibliography. The PDF is compiled from that source. The package also contains build instructions, an audit of the repository and earlier project sources, and a machine-readable provenance manifest.<sup>28</sup> No remote repository was modified, and no new Lean theorem is represented as compiled or verified.

## 111.46 Source 30: small cuts, class comparison, and the inherited tools

### 111.46.1 Sign sequences and set-sized cuts

Write  $\mathbf{No} = \bigcup_{\alpha \in \text{Ord}} \{-, +\}^\alpha$  as a class definition, not a set union. The birthday  $\text{bd}(x)$  is its sign length. For an infinite cardinal  $\kappa$ ,

$$|\mathbf{No}_{<\kappa}| = \sum_{\alpha < \kappa} 2^{|\alpha|} = 2^{<\kappa}.$$

Cardinals are identified with initial ordinals when they serve as coordinate lengths. Ordinal and cardinal multiplication remain different operations.

We use the standard small-cut lemma: for sets  $L < R$  of surreal numbers, there is a simplest separator, whose birthday is at most  $\sup\{\text{bd}(z) + 1 : z \in L \cup R\}$ . The usual sign construction proves this by meeting each lower and upper requirement before or at that bound. It includes empty option sets and gives upper and lower bounds for every set of surreals. These facts and birthday estimates are implemented on the inspected sign carrier [53, 15].

The word *set* is indispensable. Taking all of  $\mathbf{No}$  as lower options would require a surreal larger than itself. A small-cut theorem cannot be generalized to arbitrary class options.

### 111.46.2 Class theory and recursion

We take GB to have ZF as its set part and no choice axiom;  $\text{GBC} = \text{GB} + \text{GC}$  includes set choice. A class has sets as elements. Although the language has class variables, elementary class comprehension permits only set quantifiers in the defining formula, with class parameters.

Ordinary recursion with set values and set-sized initial histories is available with fixed class parameters: solve on each set-sized domain and assemble by uniqueness. A recursion assigning a

<sup>28</sup>[merge] Shipped as 29-birthdays-SOURCE\_AUDIT.txt, 29-birthdays-PROOF\_STATUS.txt, data/29-birthdays-source\_manifest.json and data/29-birthdays-verification.json; source 29 has no executable checks. The manifest also contains three opaque library-file identifiers of the authoring tool for its earlier manuscripts (sources 19–21); they are identifiers, not credentials. Source and PDF are in arrival commit 51b0a69d7.

proper class at each stage is different. ETR supplies additional elementary class-valued recursions; it is not a synonym for ordinary transfinite recursion [22, 24].

A *class well-order* is a strict linear class relation for which every nonempty admitted subclass has a least member. It is *set-like* when each predecessor class is a set. In GBC, for linear class relations, well-foundedness is equivalent to absence of a descending  $\omega$ -sequence. From a nonminimal subclass, choose successively its baseline-least smaller member; ordinary recursion produces such a sequence. Equivalently every nonempty set subset has a least member. This formulation also gives absoluteness for an existing relation between class realizations with the same sets.

### 111.46.3 The choice requirement is exact

*Note 111.27* (Source 30, Theorem 3.1, “Inherited choice equivalence”). *Over GB, the following are equivalent: global choice; a class well-order of  $\mathbf{No}$ ; a set-like class well-order of  $\mathbf{No}$ ; and a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ .* This is source 11’s [theorem 13.1](#) (over GB without set choice); source 30 recalls its argument. ([merge] “Uniformly”, not “coherently”: the orders  $w_\alpha$  need not extend one another, [remark 13.4](#).)

*Source 30’s proof.* We recall the choiceless argument of [39, statement labelled `swo:cf:choice`] ([theorem 13.1](#)). A supplied well-order  $W$  of sign sequences recursively gives well-orders  $w_\alpha$  of  $V_\alpha$ . At successors, the unique ordinal enumeration of the already ordered  $V_\alpha$  identifies its subsets with sign sequences of one fixed length; transport  $W$  to order its power set. At limits compare rank first, then use the existing order on that rank. All stages are sets. Selecting the least element of a nonempty set in a sufficiently large  $w_\alpha$  gives global choice.

Conversely global choice selects a well-order of each birthday layer. Their birthday-ordered concatenation is set-like. The ordinal ranks of a set-like well-order of the proper class  $\mathbf{No}$  form an initial subclass of  $\text{Ord}$ . This range cannot be a set, by class replacement, so it is all of  $\text{Ord}$ . Its inverse is the required bijection. A bijection conversely transports the ordinal order to a set-like one.

This is existence in the class sort, not first-order definability. We sharpen the distinction later. Background and classical choice equivalences appear in [18, 19].

### 111.46.4 Comparing arbitrary class well-orders directly

For class well-orders  $R, S$  on the same labelled class  $X$ , let  $P_R(x) = \{y : yRx\}$  and define

$$x \in C(R, S) \iff P_R(x) = P_S(x) \text{ and } R \restriction P_R(x) = S \restriction P_R(x). \quad (\text{S30.3.1})$$

All equalities expand into quantification over set elements. Elementary comprehension therefore forms this class.

*Note 111.28* (Source 30, Proposition 3.2, “Inherited common-prefix comparison”). *For  $R \neq S$ ,  $C(R, S)$  is their largest common labelled initial segment. Its complement has different least points  $a$  in  $R$  and  $b$  in  $S$ . Comparing  $a$  and  $b$  in the native label order defines a strict linear comparison of class well-orders.* This is [theorems 14.2](#) and [14.7](#).

*Source 30’s proof.* If  $x \in C(R, S)$ , all its predecessors also belong, with the same induced order. Any common labelled initial segment satisfies the formula, proving maximality. Equal residual minima would themselves satisfy the formula, a contradiction. For transitivity,  $C(R, S)$  and  $C(S, T)$  are nested as initial segments of  $S$ . If one is shorter, that earlier disagreement controls the third comparison. If they coincide, use transitivity on the next labels.

No ordinal is assigned to a proper-class prefix. In particular the construction applies to transported orders of type  $\text{Ord} + \text{Ord}$  and their tail rearrangements. This is a comparison formula on class variables; it is not a class containing all the relations as elements.

### 111.46.5 Embedding benchmarks

Write  $\mathbb{B}_\theta = (\{0, 1\}^\theta, <_{\text{lex}})$ . For infinite  $|X| = \mu$ , pair orientations give  $\mathbb{B}_\mu \hookrightarrow \mathcal{W}_\mu(X)$ . Every linear order of cardinality at most  $\mu$  embeds into  $\mathbb{B}_\mu$  by coding its initial segments on a well-ordered list of its labels.

The preceding reports prove the complete fixed-set benchmark ([merge] theorem 6.1):  $|\mathcal{W}(X)| = 2^\mu$ ; all linear orders of size at most  $\mu$  embed; and an ordinal embeds exactly when it is below  $\mu^+$ . At birthday stages the minimal stratum satisfies

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\rho_\kappa}. \quad (\text{S30.3.2})$$

The next section states the precise prefix-coding ingredients needed from this theorem and proves the new residual extensions. An embedding classification does not determine order topology: equimorphic orders may have different endpoints, jumps, and completions. This distinction is central to the later results.

### 111.47 Source 30: formalization without size paradoxes

The distinctions in the theorems suggest a practical formalization architecture. Its purpose is to make a theorem's domain and quantifiers visible in its type, so that an innocent-looking change of representation cannot silently change the mathematics.

#### 111.47.1 Three sound routes, serving different questions

**Set stages in ZFC.** All of the residual coding, countable topology, and Borel results are ordinary set mathematics. Fix  $\mathbf{No}_{<\kappa}$ , an ordinal domain  $\alpha$ , and the relevant set of bijections or relations. Power sets, products, spaces of codes, and quantification over all those codes are legitimate. No inaccessible cardinal, global choice, or class theory is needed. Ordinary choice is used to select well-orderings and codes for a set-indexed collection of residual alphabets.

For this part, a theorem should take an ordinal-indexed domain as data. A bare bijection between that domain and its cardinal does not preserve the first-disagreement order. The singular scheduler and the regular code-sum lemma are precisely the places where erasing the ordinal structure would invalidate the proof.

**Two-sorted GB/GBC.** To study the whole surreal class, express a global enumeration by a formula about one class graph. Express its lexicographic comparison with a second graph by another formula. For a uniform family use one class relation  $F(i, \xi, x)$ , with the index  $i$  ranging over sets. The partial-table extension theorem has the safe shape

$$\forall J \forall p (J \text{ is a class well-order and } p \text{ is a valid set table} \implies \exists W \text{ desired properties}).$$

The proof supplies  $W$  by elementary definitions from its parameters. It never creates a class containing  $J$  or  $W$  as an element.

This route is adequate for the elementary reconstruction and approximation theorems. The present arguments use set-valued recursions with set-sized initial histories. More general class recursions, whether their values or dependency histories are proper classes, require separately stated principles such as ETR. Class forcing is another area where strength must be specified: the unrestricted class forcing theorem is equivalent over GBC to  $\text{ETR}_{\text{Ord}}$  [24]. That theorem is background for a future forcing analysis, not an assumption hidden in our extension arguments.

**A containing universe or an external model.** An actual topology on a collection of classes, an automorphism group of that collection, or an intersection over all class realizations is cleanly formulated in a metatheory in which the model  $(M, \mathcal{C})$  is a set. Then  $\mathcal{C}$  and its subcollections are ordinary sets there. State explicitly whether a support, sequence, or isomorphism is internal to  $M$  or merely exists externally.

For example, a model-internal set may be externally countable without belonging to any prescribed small internal rank. Conversely the whole internally proper surreal class is a set externally. Allowing its whole relation table as an external support makes the observation topology discrete, destroying the density result. This is a change of topology, not a contradiction.

One may alternatively posit a third sort of collections of classes, with explicitly stated axioms. Merely passing from GB to Kelley–Morse does not do that: KM strengthens class comprehension but still does not make proper classes elements of ordinary classes. A higher sort must be introduced as such. There is no need for it in the set theorems or in the elementary class formulas proved here.

### 111.47.2 Why an exhaustive same-level evaluator is impossible

The pair construction gives an immediate diagnostic for an incorrect size claim. Suppose one class relation  $F(\alpha, \xi, x)$  uniformly listed every global enumeration as  $E_\alpha$  for  $\alpha \in \text{Ord}$ . Use the normalized pairs  $u_\alpha < v_\alpha$  from [note 102.15](#), and form by elementary comprehension

$$A = \{\alpha : E_\alpha(2 \cdot \alpha) = u_\alpha\}.$$

At position  $2 \cdot \alpha$ , the pair enumeration  $E_A$  is  $v_\alpha$  if  $E_\alpha$  is  $u_\alpha$ , and is  $u_\alpha$  otherwise. In either case they differ. Thus  $E_A$  is omitted.

Under global choice a purported exhaustive class of set indices can be reindexed by  $\text{Ord}$  (with repetition if the index domain is a set), giving the same contradiction. There is therefore no uniform exhaustive same-level evaluator. This familiar diagonal argument is entirely compatible with [note 102.16](#): that theorem recovers each individually supplied class from a corresponding enumeration; it does not list all classes.

Likewise, enumerating formulas is not an automatic escape. For a fixed formula, satisfaction in a given set structure is available. A uniform predicate evaluating every formula in the whole universe supplies additional truth strength; Tarski’s theorem prevents it from being definable in the same language. Stronger class theories can supply truth for a fixed language, without thereby listing all available classes. A metatheoretic schema of separate definitions does not itself supply one uniform internal evaluator.

### 111.47.3 The Lean interface actually present in ProveIt

The inspected files lie under

Algebra/SurrealNumbers/Surreal/Foundations/.

Their source, rather than a proposed module name in a report, is the basis for the following inventory.

| Source file                    | Existing declaration and mathematical role                                                                                                                                                                                                    |
|--------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>SignSequence.lean</code> | <code>SignSequence.Type(u+1)</code> has a birthday in <code>Ordinal.{u}</code> and a zero-extended sign function. <code>birthdays_bounded</code> bounds small families; <code>not_small</code> proves the carrier is not small at level $u$ . |

| Source file                                | Existing declaration and mathematical role                                                                                                                                        |
|--------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>SignSequenceCut.lean</code>          | <code>exists_cut_separator_of_birthday_lt</code> supplies a separator of a prescribed birthday above all option birthdays; <code>small_cut_fillers</code> realizes small cuts.    |
| <code>SignSequenceCutOperation.lean</code> | <code>birthday_cut_le_iSup</code> controls the simplest cut; <code>exists_separator_of_small_sets</code> requires explicit <code>Small.{u}</code> witnesses for both option sets. |
| <code>SizeObstructions.lean</code>         | <code>SmallCutData</code> and <code>HasSmallCutFillers</code> express the smallness boundary; <code>noUnrestrictedCuts</code> rules out unrestricted cut realization.             |

These declarations are in the namespace `Surreal.Foundations`, with carrier-specific results in `Surreal.Foundations.SignSequence`. Their universe-relative form is mathematically essential. The fact that all surreals at one level can be treated as a type at a higher level does not make that type small at the original level. A proof of small-cut filling must retain its smallness hypotheses.

We inspected these declarations but did not rebuild the repository or extend its Lean development. No theorem in the new residual, topology, or reconstruction sections is being reported as Lean-verified. The following is an implementation plan, with proof obligations, rather than claimed existing code.

#### 111.47.4 A dependency-respecting implementation plan

1. **Separate the representations.** Define different types for a well-order relation, a bijective ordinal enumeration, a partial injection, and a relation table with its scan. Define conversion maps explicitly. The first-disagreement theorem should say which order each conversion preserves. It should not install one undifferentiated order instance on every code.
2. **Formalize prefix-free binary coding.** Prove the sign code  $- \mapsto 00$ ,  $+ \mapsto 11$ , termination  $\mapsto 01$  is prefix-free and order-preserving. State the concatenation theorem with ordinal sums of code lengths. Its regular-cardinal specialization and its constant-length padding specialization should be separate lemmas.
3. **Verify the singular scheduler.** Give the max-coordinate schedule its actual ordinal order type and prove that the first occurrence of a row precedes every larger-index row. Establish exhaustiveness, injectivity, and first-disagreement preservation separately. This is the most delicate set-theoretic component of the embedding proof.
4. **Use residual alphabets as dependent data.** After a prefix  $p$ , the remaining alphabet is  $X \setminus \text{ran}(p)$ . A selected code depends on that set. The proof that equal prefixes select equal codes is as important as the existence of the codes. The upper and lower embeddings can then be assembled block by block.
5. **Name all three topologies.** On fixed countable enumerations, distinguish the full discrete-product topology, the lexicographic order topology, and the pulled-back relation-table topology. Their Borel sigma-algebras agree in some cases and diverge in others. Using the wrong ambient topology would turn a false continuity statement into an apparently routine proof goal.
6. **Formalize the finite-tail decomposition first.** The order equivalence  $P_{\omega+n} \cong E_n \times n!$  is a small interface from permutation combinatorics to topology. Build the split-order Borel lemma and its countable-fiber exception formula above this interface.

7. **Develop class results through set nodes.** Formalize the partial-table rank extension for sets. Then use a supplied model of class theory, or an explicit universe-relative surrogate, to prove the branch and stabilization statements. Pair coding and its decoder are elementary and make a suitable first reconstruction theorem.

This order of work provides useful certified results before requiring a full formal theory of arbitrary class realizations. Finite testing of a scheduler or a code checks indexing conventions, but cannot replace the proofs of regularity, class replacement, or absence of exhaustive evaluators.

#### 111.47.5 Assumption ledger

| Result or construction                                   | Foundation used                                                                                                               |
|----------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------|
| Fixed-stage residual embeddings and finite-tail topology | ZFC; ordinary choice for set-indexed code selections. Regularity and strong-limit hypotheses occur exactly where stated.      |
| Every fixed type at $\kappa < \aleph_\omega$             | ZFC, without CH or GCH. All smaller infinite cardinals are regular, and larger residual alphabets use the native padded code. |
| The GCH classification of every fixed type               | ZFC+GCH. It is a conditional classification, not a ZFC assertion that all singular residual cardinals are strong limit.       |
| Any class well-order of <b>No</b> iff global choice      | GB without prior set choice; inherited theorem with explicit set-valued rank recursion.                                       |
| Common-prefix class comparison                           | Elementary class comprehension with supplied well-orders; no class ordinal or ETR is introduced.                              |
| Partial-table extension, closure, and canonical scan     | GBC with a supplied baseline. All recursive stages used here are sets.                                                        |
| Labelled realization reconstruction                      | Elementary coding internally; an external set metatheory for comparison of realization collections.                           |
| Universal baseline across all realizations               | Countable set model, plus Williams's minimum-realization theorem.                                                             |
| Pure-order invisibility of ETR                           | Conditional on the stated countable GBC+ETR realization; uses a full truth predicate and Tarski's theorem.                    |
| Actual topologies on admitted classes                    | External set-sized models, with the allowed supports specified as internal.                                                   |

#### 111.48 Source 30: verification and the scope of the conclusions

The mathematical review was organized around independent failure modes: ordinal length rather than cardinal length; the change of residual alphabet after a prefix; topology versus a particular measurable presentation; class-valued versus set-valued recursion; and internal versus external collections. The final regular, singular strong-limit, mixed-block, finite-tail, table-extension, and reconstruction arguments received separate proof review. Review is additional scrutiny, not a substitute for a formal proof or external peer review.

The archive includes a small executable check of the finite mechanisms: the three scans of six labelled orders, prefix-free sign coding, pair orientations, and the finite partial-table extension criterion. It exhaustively compares acyclicity of partial orientations with existence of an extending

permutation on carriers through size five. The resulting record is included.<sup>29</sup> These checks validate finite conventions only; no finite test establishes the transfinite scheduler, Borel nonmeasurability, class replacement, or the model-theoretic conclusions.

The classifications proved here concern precisely the representations and hypotheses stated. GCH gives a full fixed-type embedding classification at infinite cardinal birthday cutoffs. The unconditional theorem already covers every fixed type at each infinite  $\kappa < \aleph_\omega$ , and every residual block above the birthday cutoff. Only the regime of singular non-strong-limit residual cardinals at most  $\kappa$  remains outside the stated exact formulas. Even a complete embedding classification leaves the topological distinctions at  $\omega + 1$  and  $\omega + 2$  visible. At the global level, relation tables can make all types locally indistinguishable while labelled enumeration availability recovers the entire class universe. Both phenomena are compatible because they retain different information.

### 111.49 The finite checks of sources 19–30 as shipped

[merge] Ten of the twelve sources ship a standard-library Python program and its recorded output; sources 21 and 29 ship none (source 29 ships a provenance manifest and build metadata instead). All check finite mechanisms only; none verifies a transfinite, class-theoretic or cardinal statement, as each source says. At placement (2e06337d5) every program was rerun on a copy with Python 3.14.4 on Windows and reproduced its record exactly apart from line endings: the programs write CRLF on Windows and the records have LF, so compare with `diff -strip-trailing-cr`. The delivered checksum manifests of sources 22, 23, 24, 25, 26 and 28 were verified and are not shipped; source 29’s manifest hashes (its sixteen repository files, the three earlier manuscripts and its six deliverables) were verified as well.

| Src. | Program and record                                                                                              | Recorded checks                                                                                                                                          | Output                                                                         |

Run them on copies, never in the report directory, and always name the output file. From the report directory, with an empty scratch directory `$$`:

```
cp code/19-residual-check_restrictions.py "$$/ " && python "$$/19-residual-
check_restrictions.py"
python code/20-limits-finite_diagnostics.py --output "$$/20.json"
python code/22-unranked-finite_checks.py --output "$$/22.json"
python code/23-termination-finite_checks.py --output "$$/23.json"
python code/24-completions-finite_checks.py --output "$$/24.json"
python code/25-symmetries-finite_checks.py --output "$$/25.json"
python code/26-nonborel-finite_checks.py --output "$$/26.json"
python code/27-scans-finite_checks.py --output "$$/27.json"
python code/28-envelope-finite_checks.py --output "$$/28.json"
python code/30-tables-verify_finite.py --output "$$/30.json"
```

and compare with the records in `data/` (source 19's run writes `$$/restriction_checks.json`). The delivered build scripts `code/19-residual-build.sh`, `code/22-unranked-build.sh`, `code/23-termination-build.sh`, `code/24-completions-build.sh`, `code/25-symmetries-build.sh`, `code/26-nonborel-build.sh`, `code/28-envelope-build.sh` and `code/30-tables-build.sh` compile L<sup>A</sup>T<sub>E</sub>X sources that are not shipped (and some of them run their checker with a relative output path first); they build nothing in this layout and are kept as delivered.

## 112 What this Part answers

[merge] Dated notes, 3 October 2026, in the form of [section 50](#); where the question index of [section 113](#) (dated 2 October 2026) or an earlier status section says otherwise, these notes supersede it.

- (a) *Source 18's research question 113.89,  $\omega$ -nonstandard class models:* **answered**, three times independently. The external order is  $\sigma(\mathcal{F} \cup \{I_\infty\})$  (theorem 109.1; note 109.13; note 109.33); its external finite-condensation blocks have the types  $1, 2, 6, \dots, \omega, \omega^*, \mathbb{Z}$  in the arrangement of corollary 109.18; it has the first-order theory of the standard factorial shuffle, as has the external order of every set-sized GBC model (theorem 109.9); it realizes types the standard shuffle omits (corollary 109.10, note 109.21); the common theory is decidable (corollary 109.22) and has  $2^{\aleph_0}$  countable models, of which the standard shuffle is prime (corollary 109.11 and theorem 109.12).
- (b) *Source 11's research question 113.3, exact recursion strength of iterated residual decompositions, and the related questions of sources 13, 15, 16 and 18 (research questions 113.30, 113.48, 113.64 and 113.86), of source 20 (research question 113.111), of source 23 (research question 113.147) and of source 19 (research question 113.104):* answered in part, in the form of canonical condensation histories with the nested-representative limit. A supplied history on the schedule  $W + 1$  always terminates (theorem 108.1); over GBC the existence of such histories for every input is equivalent to strong comparability of class well-orders (theorem 108.19), and every point then has a finite polynomial address (theorem 108.16), the canonical notation that research question 113.30 asks for, for the orders that have a terminating history. The limit convention is canonical (corollary 108.14); no nontrivial retained class is a fixed point of the operator (the remark after theorem 108.1). Open: whether ETR is necessary (equivalently for this operator, whether CWO implies ETR; Hamkins and Woodin's Question 7 is not settled), the strength over GB without global choice, and source 15's first question whether GB codes all finite condensations uniformly. The block-index half of research question 113.3 was answered by Part IX. *Dated note, 4 October 2026 (batch 96):* the strength over GB without global choice is answered: the equivalence with CWO holds over GB (section XVI.12 (a)).
- (c) *Source 23's research question 113.148, which orders eventually collapse:* answered for supplied histories (each collapses at the stage  $W + 1$ , theorem 108.1); in a full model the exact heights are  $\min\{\alpha : \theta \leq \kappa^\alpha\}$ , every height below  $\kappa^+$  occurs, and no single schedule bounds them all (corollary 108.3).
- (d) *Source 20's research question 113.112, alternative limits:* answered in part: keeping the canonical quotient maps gives exactly the nested-representative limit, and source 23's union of equivalences is the same history (corollary 108.14).
- (e) *Source 12's research question 113.17, automorphisms and finite condensation:* answered in part, for countable models. In the  $\omega$ -standard case the automorphism group is that of the coloured rational quotient (source 18's corollary 58.9; source 21's note 109.30); in the nonstandard case it is a semidirect product over the  $I_\infty$ -blocks (source 21's group description after note 109.35). Automorphisms of the pure order act on enumeration structure beyond relabelings: one moves an order without a greatest element to one with a greatest element (corollary 109.31). Uncountable realizations remain open (source 21's research question 113.125).
- (f) *Source 11's research question 113.4, what the bare order defines:* a further part. In the external order of every set-sized GBC model the singleton blocks and the finite-tail permutation blocks are first-order definable (proposition 109.7); existence of a greatest element is not invariant (corollary 109.31).
- (g) *Source 11's research question 113.8, source 12's research question 113.18, and the open item "what the unlabelled external order type remembers" of section 50 (e):* answered in part for the pure order. Among countable models it remembers exactly whether  $\omega$  is standard (theorem 109.1); its first-order theory is the same for all set-sized models (theorem 109.9). Expansions by the set-like predicate, labels or baselines are not classified here (source 20's

research questions 113.109 and 113.110, source 19’s research question 113.102).

- (h) *Source 17’s research question 113.77, the condensed unrestricted order*: answered in part, for countable models: its finite-condensation quotient is  $\mathbb{Q}$ , with the colour arrangement of corollary 109.18 in the nonstandard case. For the coarser condensation by set-sized residuals, source 20’s quotient is dense without endpoints but has an unfilled cut of character  $(\omega, \omega)$  (theorem 107.6).
- (i) *Uniform coding of the unrestricted order* (no earlier question): an interval  $[R, S]$  is exhaustively coded by a uniform set-indexed family exactly when its residual  $Y(R, S)$  is a set (theorem 107.4), and no uniform class-indexed family is dense in the raw comparison (theorem 107.8).

## Part XV

# Countable global choice and surreal coding over Zermelo set theory

[merge] (3 October 2026, batch 89.) This Part prints source 31, batch-89 manuscript 01 (section 1.10), whole and in its own order. It read this report at 2b7b388ba, with Parts I–XIV, and starts from three of its labels: the equivalence of global choice with well-orders of **No** over GB (theorem 13.1), source 12’s full-class model at an inaccessible cardinal (theorem 21.1), and source 28’s question on separating Class Replacement from uniform set choice (research question 113.209). Its two halves have different logical settings, as its introduction says.

- Sections XV.2 to XV.5: first-order Zermelo set theory with Choice, ZC (and ZC<sub>F</sub> with Foundation), with a selector  $c$  and Separation for formulas that mention it. A selector on  $D$ -small sets and uniform injections into  $D$  are interconvertible by uniform definitions (theorem XV.3.3); bounded trace compression needs no Collection (theorem XV.4.1); selection from nonempty countable sets is not conservative over ZC or ZC<sub>F</sub> (theorem XV.5.1), while without expanded Separation it is (proposition XV.5.5).
- Sections XV.6 to XV.11: in an external ZFC universe, the full-class rank models  $\mathcal{M}_\lambda = (V_\lambda, \mathcal{P}(V_\lambda))$  at every limit  $\lambda > \omega$ : exact thresholds for ordinal and birthday enumeration of the sign carrier, for universal set coding and ordinal abstraction, and for Class Replacement on each set domain; the cardinalities of internal proper classes; separating heights. This extends Part V’s inaccessible model (section 21) to every limit height.
- Section XV.12: consequences for this report’s questions and a formalization architecture; sections XV.13 and XV.14: the axiom ledger and source audit (source 31’s Appendices A and B); section XV.15: what the Part answers.

Its twelve research questions are printed with the other sources’ in the questions part (section 113.26), its title page and abstract in Appendix C; appendix D maps its numbered statements.

*The dependency on Glazer’s countermodels.* Theorem XV.5.1 derives a contradiction from Glazer’s obstruction sentence through an abstract interface (section XV.5.1) and takes from Glazer’s paper that the base theory does not refute that sentence. That the interface matches the obstruction of Glazer’s Propositions 3.8 and 4.11 exactly has not been reviewed here; source 31 itself asks for expert review (section XV.14). The theorem is printed as claimed, conditional on that interface.

*Numbering.* The sections of this Part are numbered XV.1–XV.15, so that the questions part and the appendices keep their numbers (Sections 113–115, Appendices A–D). Sections XV.1–XV.12

are source 31's Sections 1–12, and its statement  $k.m$  is printed as  $XV.k.m$ ; the [merge] paragraphs inside them add no numbered statement. Its equations (1)–(10) are tagged (S31.1)–(S31.10).

*Notation* (section 1.3.3 lists every renaming).  $\mathbf{Z}$  is Zermelo set theory and  $\mathbf{ZC}$  adds Choice; neither has classes or Replacement.  $\mathbf{GC}_{\leq\omega}$  is a selector on nonempty countable sets, not this report's  $\mathbf{GC}$ .  $X \mapsto D$  means that an injection exists (source 31's  $X \hookrightarrow D$ ;  $\hookrightarrow$  keeps its meaning of order embedding).  $\mathcal{M}_\lambda = (V_\lambda, \mathcal{P}(V_\lambda))$  has all external subclasses as classes;  $\kappa = |\lambda|$ , which is the cutoff only when  $\lambda$  is a cardinal;  $S_\lambda = \bigcup_{\alpha < \lambda} \alpha^2$  is the sign carrier, the set  $\mathbf{No}_{<\lambda}$  without its field structure. The threads of lemma XV.3.1 form the set  $\text{Thr}_X$  (source 31's  $\mathcal{T}_X$ ).

## XV.1 The problem and the contributions

Global choice makes a single selection simultaneously throughout the universe. Ordinary Choice supplies selections for each set-sized family. With Replacement available, these principles often have the same consequences about sets. Removing Replacement changes the problem: a family described by a formula and indexed by  $\omega$  need not itself be a set. A uniform selection from that family can then produce information that ordinary Choice cannot assemble.

Glazer proved that global choice with expanded Separation is not conservative over  $\mathbf{ZC}$ , both with and without Foundation [70]. We use the countable-family incidence obstruction in his Propositions 3.8 and 4.11; we do not reconstruct his symmetric-extension countermodels. Our contribution to that argument is to show that a selector on countable inputs already supplies the uniform presentations needed for its contradiction.

The relevant ProveIt source is the report on surreal well-orders [69]. Its Theorem 13.1, label `swo:cf:choice` (theorem 13.1), gives over  $\mathbf{GB}$  the equivalence between global choice, class well-orders of  $\mathbf{No}$ , set-like such well-orders, and an Ord-enumeration of  $\mathbf{No}$ . Its Question `swo:ge:n10` (research question 113.209) asks how image bounding and uniform choice separate over weaker class theories. We analyze particular mechanisms in that question; the question's other reconstruction and extension schemes remain open.

The two parts of the article are related, but their logical settings differ. The countable-selection theorem is a theorem about a first-order theory with an additional operation symbol. The rank-model results are semantic classifications of specific two-sorted structures with all external subclasses admitted. No identification of these two settings is assumed.

### XV.1.1 The localized theorem

Write  $\mathbf{GC}_{\leq\omega}$  for a total operation  $c$  satisfying

$$X \neq \emptyset \wedge X \mapsto \omega \implies c(X) \in X.$$

Separation must be allowed to mention  $c$ . The main refinement is

$$\boxed{\mathbf{ZC} + \mathbf{GC}_{\leq\omega} + \mathbf{Sep}(c) \text{ is not conservative over } \mathbf{ZC}.}$$

The corresponding statement with Foundation also holds. Moreover, replacing “at most countable” by “countably infinite” does not restore conservativity. The proof is in section XV.5.

There is a genuine obstacle to the naive proof. Repeatedly deleting the selected element for  $\omega$  steps need not exhaust a countable set. A selector can list one infinite part first and leave another part untouched. Nor may we simply continue through all countable ordinals: the relevant ordinal types need not exist in Zermelo set theory. We instead collect all compatible partial well-orders inside a fixed power set and then normalize the resulting order against a single set of order codes.

### XV.1.2 The exact classification

For a limit ordinal  $\lambda > \omega$ , put

$$S_\lambda = \bigcup_{\alpha < \lambda} {}^\alpha 2, \quad \text{bd}(s) = \text{dom}(s).$$

Here  $\text{bd}(s)$  is the ordinal length, or birthday, of a binary sign sequence. The following table previews the classification. Every cardinal condition is evaluated in the external ZFC universe.

| Principle in $\mathcal{M}_\lambda$                                                                                     | Exact condition on the height                               |
|------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------|
| Global choice; a birthday-monotone set-like well-order of $S_\lambda$                                                  | Every limit $\lambda > \omega$                              |
| A class bijection $\text{Ord} \longleftrightarrow S_\lambda$                                                           | $\lambda = \kappa$ is a cardinal and $2^{<\kappa} = \kappa$ |
| Such a bijection with nondecreasing birthdays                                                                          | $\lambda = \kappa$ is a strong-limit cardinal               |
| A class injection $V_\lambda \hookrightarrow S_\lambda$ ; equivalently, every set well-order has an ordinal order type | $\lambda = \kappa = \beth_\kappa$                           |
| Class Replacement on every ordinal domain                                                                              | $\lambda$ is an uncountable regular cardinal                |
| Full Class Replacement                                                                                                 | $\lambda$ is strongly inaccessible                          |

The fourth row is an equivalence *within this family of full-class rank models*. It is not asserted over every weak class theory. The table also concerns the sign-sequence carrier; at arbitrary cutoffs we do not assert closure under the surreal field operations.

### XV.1.3 What is new, what is inherited, and what remains open

The bounded proof of the well-ordering theorem used below is classical in method. Its application to a uniform presentation theorem, and thence to the countable-input refinement, is the main additional deduction. Targeted searches did not find that refinement explicitly stated; this is not a proof of priority. Restricted global-choice principles have an established literature, including Enayat's treatment of global finite choice [71].

The distinction between well-orders and ordinal order types without Replacement is also established. Hamkins discusses ordinal abstraction and the example  $V_{\omega_1}$  in his account of Rin's work [63, 72]. Carneiro's discussion addresses set-like class orders without Replacement [74]. The contribution of our second part is the simultaneous exact classification of the displayed coding and replacement properties, including their different thresholds and explicit separating heights. The usual global-choice equivalences over GB are collected in [19]; the beth-fixed-point background also has prior discussion [75].

## XV.2 Axioms, classes, and bounded constructions

### XV.2.1 The first-order base theory

Following Glazer's convention, Z comprises Extensionality, Empty Set, Pairing, Union, Power Set, Infinity, and the Separation schema. Including Empty Set explicitly is harmless; the other usual formulations derive it. Set Choice is added to obtain ZC. We write  $\text{ZC}_F$  when Foundation, in the form that every nonempty set has an  $\in$ -minimal member, is added. No form of Replacement or Collection is part of these base theories.

All occurrences of  $X \mapsto D$  mean that there exists a *set graph* of an injection. A set well-order is a strict linear order on a set such that every nonempty subset has a least member. We do not replace its underlying set by an ordinal unless that replacement has been justified.

When a class operation  $c$  is named,  $\text{Sep}(c)$  means Separation for every formula of the language containing  $c$ , with set parameters allowed. A formula defining a unique set-valued operation gives a definitional expansion: formulas using the new operation can be translated into the original expanded language. Consequently, such a definition transports Separation, but does not introduce Replacement.

### XV.2.2 Fixed bounds

Fix a well-ordered set  $(D, <_D)$ , and define

$$\text{Small}_D(X) \iff X \mapsto D.$$

A  $D$ -restricted selector chooses from every nonempty  $D$ -small set. For definiteness it returns  $\emptyset$  elsewhere. Its restriction to the subsets of a fixed  $D$ -small set  $X$  can be represented by a set:

$$\{(A, x) \in \mathcal{P}(X) \times X : A \neq \emptyset \text{ and } c(A) = x\}.$$

This follows by Separation. The restriction's being a set does not imply that the family of all such restrictions, as  $X$  varies, is a set.

We shall also use the set of codes

$$\mathcal{C}_D = \mathcal{P}(D) \times \mathcal{P}(D \times D). \quad (\text{S31.1})$$

A code records both a carrier and a relation. Recording the carrier is essential: the empty relation alone cannot distinguish different singleton orders. Ordinary Choice supplies one fixed well-order  $<_D$  of  $\mathcal{C}_D$ . No choice of a code for each  $X$  has yet been made.

### XV.2.3 A bounded-existence convention

Every set introduced in the first part will have an explicit containing set. For example, a proposed graph from  $X$  to  $D$  is separated from  $X \times D$ ; a family of relations on  $X$  is separated from  $\mathcal{P}(X \times X)$ . Cartesian products themselves exist by the ordinary Pairing, Union, Power Set, and Separation construction.

These bounds are more than presentation details. A statement of the form  $\forall n \in \omega \exists! X \varphi(n, X)$  need not provide a set containing all the values  $X$ . On the other hand, if a containing set  $B$  is already known, then its graph is a subset of  $\omega \times B$ , and Separation suffices. Our argument repeatedly uses the second situation while avoiding the first.

## XV.3 Uniform presentations from restricted selection

### XV.3.1 A selector-compatible well-order

**Lemma XV.3.1** (Bounded well-order construction). *Let  $X$  be a set and suppose  $c(A) \in A$  for every nonempty  $A \subseteq X$ . In  $Z + \text{Sep}(c)$  there is a unique well-order  $W_X$  of  $X$  satisfying*

$$a = c(X \setminus \text{Pred}_{W_X}(a)) \quad (a \in X). \quad (\text{S31.2})$$

*The relation  $W_X$  is uniformly definable from  $X$  and  $c$ . No ordinal collapse, Replacement, or Foundation is used.*

*Proof.* Call  $(A, R)$  a *thread on  $X$*  if  $A \subseteq X$ ,  $R$  well-orders  $A$ , and

$$a = c(X \setminus \text{Pred}_R(a)) \quad (a \in A).$$

The ambient set in this equation is always  $X$ , even for a proper partial domain  $A$ . The set  $\text{Thr}_X$  of threads is separated from  $\mathcal{P}(X) \times \mathcal{P}(X \times X)$ .

We first prove that any two threads  $(A, R)$ ,  $(B, T)$  are comparable by initial segment. Let  $C \subseteq A \cap B$  consist of those  $x$  whose predecessor sets in the two orders are equal and on whose predecessor set the two orders agree. If  $x \in C$  and  $yRx$ , then  $yTx$ , and agreement below  $x$  implies agreement of the predecessor sets and orders below  $y$ . Thus  $y \in C$ . The symmetric statement holds, so  $C$  is an initial segment of both orders, with the same order on it.

If both threads continue beyond  $C$ , let  $a$  and  $b$  be the respective first points beyond it. Their predecessor sets are exactly  $C$ , whence

$$a = c(X \setminus C) = b.$$

The predecessor orders agree, so this common point belongs to  $C$ , a contradiction. One thread is therefore an initial segment of the other.

Separate from  $X$  the union  $A_*$  of all thread domains, and from  $X \times X$  the union  $R_*$  of their relations. Comparability makes  $R_*$  a linear order on  $A_*$ . To verify well-ordering, let  $Y \subseteq A_*$  be nonempty. Choose  $y \in Y$  and a thread containing  $y$ . Let  $z$  be the least element of the nonempty intersection of its domain with  $Y$ . Any other thread is an initial segment or an extension of this one; its new points cannot lie below  $z$ . Thus  $z$  is least in  $Y$  for  $R_*$ .

Every thread containing a point  $a$  has the same predecessors of  $a$  as the union. Consequently  $(A_*, R_*)$  is itself a thread. If  $A_* \neq X$ , append  $c(X \setminus A_*)$  to its end. The resulting well-order is a thread with a larger domain, contradicting the definition of  $A_*$ . Hence  $A_* = X$ , proving existence. Two full-domain threads must coincide by initial-segment comparability, proving uniqueness.  $\square$

*Remark XV.3.2* (Why ordinary iteration is insufficient). Let  $X = \omega \times \{0, 1\}$ . A selector on subsets of  $X$  can select the least available  $(n, 0)$  whenever any such point remains. Successive finite deletions then visit only  $\omega \times \{0\}$ . The compatible well-order can have type  $\omega + \omega$ , so its first  $\omega$  positions need not enumerate  $X$ . The next theorem produces an injection into  $\omega$  without asserting that this particular well-order has a countable ordinal representative in the weak theory.

### XV.3.2 Normalizing against one set of order codes

**Theorem XV.3.3** (Uniform presentation theorem). *Fix  $(D, <_D)$  and a well-order  $\prec_D$  of  $\mathcal{C}_D$ . Over  $\mathbf{Z}$  with Separation in the relevant expanded language, the following existence principles are interconvertible by uniform definitions:*

- (i) *a selector  $c$  for every nonempty  $D$ -small set;*
- (ii) *a class assignment  $X \mapsto i_X$  which supplies a set injection  $i_X : X \rightarrow D$  for every  $D$ -small set  $X$ .*

*In  $\mathbf{ZC}$ , the needed order  $\prec_D$  exists by ordinary Choice.*

*Proof.* Assume (i). Every subset of a  $D$ -small  $X$  is  $D$ -small, so lemma XV.3.1 constructs  $W_X$ . Form by Separation

$$\mathcal{A}_X = \{(A, R) \in \mathcal{C}_D : R \text{ well-orders } A \text{ and } (X, W_X) \cong (A, R)\}.$$

This set is nonempty. Indeed, an existing injection  $u : X \rightarrow D$  transports  $W_X$  to its image; both the image and the transported relation are separated from  $D$  and  $D \times D$ . This argument uses the existence of a particular  $u$  only to prove nonemptiness. It does not choose such a  $u$  uniformly.

Let  $(A_X, R_X)$  be the  $\prec_D$ -least code in  $\mathcal{A}_X$ . There is a unique order isomorphism

$$i_X : (X, W_X) \longrightarrow (A_X, R_X),$$

because a well-order has no nonidentity order automorphism. For completeness, two isomorphisms would have a least point of disagreement; their values there have the same predecessor set and therefore are equal, a contradiction. The isomorphism graph is a subset of  $X \times D$ . The assertions defining the least code and its unique isomorphism constitute a uniform definition of  $i_X$ . Set its value to  $\emptyset$  on nonsmall inputs.

Conversely, assume (ii). For nonempty  $D$ -small  $X$ , the image  $i_X[X]$  is a nonempty subset of  $D$ . Choose the unique element of  $X$  mapped to its  $\prec_D$ -least member. This uniformly defines a selector. All image and inverse graphs here have displayed set bounds.

In either direction, the new operation has a unique set value specified by a formula in the old expanded language. Substitution of this definition translates each instance of Separation involving the new operation into an available instance of Separation. This verifies the assertion about the whole expanded theories, not just about an isolated operation.  $\square$

*Remark XV.3.4* (Uniformity is not compatibility under restriction). The theorem does not say that  $i_Y = i_X \upharpoonright Y$  when  $Y \subseteq X$ . Nor does it assert a definitional equivalence that recovers an original selector after a round trip. It gives uniform constructions establishing equivalence of the two existence principles, with a fixed set of code-ordering parameters.

**Corollary XV.3.5** (Uniform countable enumeration). *Under  $ZC + GC_{\leq \omega} + Sep(c)$ , a single class definition assigns to every nonempty countable set  $X$  a set surjection  $e_X : \omega \rightarrow X$ .*

*Proof.* Apply [theorem XV.3.3](#) with  $D = \omega$ . Let  $m_X = \min i_X[X]$ , and define

$$e_X(n) = \begin{cases} i_X^{-1}(n), & n \in i_X[X], \\ i_X^{-1}(m_X), & n \notin i_X[X]. \end{cases}$$

The graph is a subset of  $\omega \times X$ , and its range is  $X$ .  $\square$

## XV.4 Incidence coding without Collection

The next theorem captures what a uniform presentation makes possible. Its hypothesis is weaker than requiring a different incidence trace for every label: equal traces need only determine the same target value.

**Theorem XV.4.1** (Bounded trace compression). *Work in  $Z$  with Separation for all the named class parameters. Let  $I, D, T$  be sets. Suppose:*

- (a)  $i \mapsto X_i$ , for  $i \in I$ , is a class assignment of sets, and a uniform class definition gives set injections  $u_i : X_i \rightarrow D$ ;
- (b)  $A$  is a class,  $E(x, a)$  a class relation, and  $F : A \rightarrow T$  a class surjection;
- (c) whenever  $a, b \in A$  satisfy

$$\forall i \in I \forall x \in X_i (E(x, a) \leftrightarrow E(x, b)),$$

one has  $F(a) = F(b)$ .

Then there is a set partial surjection

$$Q : \mathcal{P}(I \times D) \rightarrow T. \quad (\text{S31.3})$$

If  $\mathcal{P}(I \times D)$  is well-orderable, then  $T \hookrightarrow \mathcal{P}(I \times D)$ . In particular this last conclusion holds in ZC.

*Proof.* For  $a \in A$ , define its trace by Separation from  $I \times D$ :

$$H_a = \{(i, d) \in I \times D : \exists x \in X_i [u_i(x) = d \wedge E(x, a)]\}. \quad (\text{S31.4})$$

For each  $i$  and  $x \in X_i$ , injectivity gives

$$E(x, a) \iff (i, u_i(x)) \in H_a.$$

Thus  $H_a = H_b$  implies the hypothesis in (c) and hence  $F(a) = F(b)$ . Now separate from  $\mathcal{P}(I \times D) \times T$  the relation

$$Q = \{(H, t) : \exists a \in A [H = H_a \wedge F(a) = t]\}. \quad (\text{S31.5})$$

It is single-valued by the preceding observation and surjective onto  $T$  because  $F$  is. To get an injection in the other direction, well-order  $\mathcal{P}(I \times D)$ , and assign to each  $t$  its least  $Q$ -preimage. The resulting graph is again a subset of a fixed set product.  $\square$

**Corollary XV.4.2** (Compression from a restricted selector). *In ZC +  $\text{GC}_{\leq D}$  +  $\text{Sep}(c)$ , the same conclusion holds when (a) is replaced by the assumption that every  $X_i$  injects into  $D$ .*

*Proof.* Use [theorem XV.3.3](#) to define  $u_i = i_{X_i}$ .  $\square$

#### XV.4.1 The logical point of the compression theorem

Neither  $\{X_i : i \in I\}$ , nor  $\bigcup_{i \in I} X_i$ , nor the collection of traces  $\{H_a : a \in A\}$  was obtained by Replacement. The first two may fail to be sets. The third can, when needed, be separated from  $\mathcal{P}(I \times D)$ . The proof does not first collect the class of labels and then take its image. It directly defines a bounded relation whose fibres are determined by the trace.

Empty rows  $X_i = \emptyset$  cause no problem: their injection has empty graph and contributes no coordinate. This is a small advantage of formulating the theorem using injections instead of surjections onto the rows.

The target-separation condition also permits quotient labels. A class may have many labels describing the same trace, provided their target values agree. Thus the method applies to incidence presentations with redundant codes, not just to extensional representations of individual objects.

#### XV.4.2 What ordinary set Choice already provides

If the family of rows is an actual set, ordinary Choice supplies simultaneous injections. To see the bounded reason, let  $U$  be the union of that family. Every candidate injection into  $D$  is a subset of  $U \times D$ . The sets of candidate injections therefore form a subfamily of  $\mathcal{P}(\mathcal{P}(U \times D))$ . Choice on this set-sized family provides a selection. Consequently, the new phenomenon concerns class assignments whose values have no common set bound. It is not a failure of ordinary countable choice inside ZC.

## XV.5 Countable global selection is nonconservative

### XV.5.1 The external input from Glazer

We use the following precise interface to Glazer’s countermodel theorem [70, Propositions 3.8 and 4.11]. There is a pure set-theoretic obstruction sentence  $\Theta$ , with separate versions for  $\mathbf{ZC}$  and  $\mathbf{ZC}_F$ , realized in his respective models. Its definable data include countable sets  $X_n$ , an extensional incidence class on their class union, and a class surjection onto a set carrier  $T$  satisfying

$$T \not\rightarrow \mathcal{P}(\omega).$$

Extensionality of incidence means that equal traces imply equal labels and hence equal target values. The inequality is the part of his cardinal obstruction used here.

This formulation suppresses unnecessary ordinal representatives. If a target is given by a prewell-order on a set  $B$ , its quotient can be represented as a subset of  $\mathcal{P}(B)$ : separate the equivalence classes from that power set. The argument therefore does not assume that a von Neumann  $\omega_2$  exists internally. The published construction, rather than any new forcing assertion in this article, supplies the countermodels.

[merge] *Status of the interface.* The two paragraphs above are source 31’s statement of what it uses from [70, Propositions 3.8 and 4.11]. This write has not checked them against Glazer’s paper: whether his obstruction supplies countable rows  $X_n$ , an extensional incidence class and a class surjection onto a set  $T$  with  $T \not\rightarrow \mathcal{P}(\omega)$  in exactly this form is unreviewed, and source 31 names expert review of the localized theorem as the next step (section XV.14). Theorem XV.5.1 and its corollaries are printed as claimed, conditional on this interface.

### XV.5.2 The refinement

**Theorem XV.5.1** (Countable-input nonconservativity). *Let  $\mathbf{T}$  be either  $\mathbf{ZC}$  or  $\mathbf{ZC}_F$ . Add a total unary operation  $c$ , allow Separation to mention it, and require only*

$$\forall X [X \neq \emptyset \wedge X \rightarrow \omega \rightarrow c(X) \in X].$$

*This extension is not conservative over  $\mathbf{T}$  for sentences of the original language  $\{\in\}$ . In particular, it proves the negation of the appropriate Glazer obstruction sentence  $\Theta$ , while  $\mathbf{T}$  does not.*

*Proof.* Assume  $\Theta$  in the expanded theory. Apply theorem XV.3.3 with  $D = \omega$  to obtain, uniformly in  $n$ , injections  $u_n : X_n \rightarrow \omega$ . The countable rows and incidence data supplied by  $\Theta$  satisfy theorem XV.4.1. Thus

$$T \rightarrow \mathcal{P}(\omega \times \omega).$$

The standard pairing bijection  $\omega \times \omega \longleftrightarrow \omega$  induces a bijection of their power sets. We obtain  $T \rightarrow \mathcal{P}(\omega)$ , contradicting  $\Theta$ .

The base theory has a model satisfying  $\Theta$  by the cited countermodel theorem, so it cannot prove  $\neg\Theta$ . No step of the additional uniformization or compression argument used Foundation; applying the relevant version of the input proves both cases.  $\square$

*Remark XV.5.2* (Metatheory). The positive implication  $\Theta \rightarrow \perp$  is a derivation in the specified expanded weak theory. The nonderivability statement uses the published countermodel result. Glazer states that his model-construction theorems are established in  $\mathbf{ZF}$ ; our refinement inherits that input. This is not an assertion that  $\mathbf{ZC}$  proves its own consistency. Readers preferring conditional consistency language may assume  $\text{Con}(\mathbf{ZF})$ ; no claim of an optimal metatheoretic bound is needed here.

[merge] (4 October 2026, batch 90.) Glazer’s Oberwolfach abstract *A hypertalk* (Oberwolfach Reports 22 (2025), Report No. 2/2025, pp. 106–107) reports a parallel phenomenon without Foundation: the classification of connected one-dimensional manifolds, not necessarily second countable or set-sized, is not a theorem of ZFC without Foundation but becomes provable when Global Choice is added. He asks whether  $\text{ZFC} - \text{Fnd} + \text{GC}$  proves that every topological manifold is a set. Part XII of *polish-models-of-omnific-arithmetic* (its source 18, batch-90 manuscript 03; AI-assisted, unrefereed, not formalized) prints that question for connected Hausdorff real class manifolds of dimension at least two (its Question 165.6, `pma:gcm:q:glazer`), and proves, without Global Choice, that a connected real class manifold is a set when its carrier has an ordinal exhaustion, a compatible real class metric, or a class injection into or surjection from some  $\mathbf{No}^m$ ; the question itself stays open. Neither that part nor source 31 uses the other’s theorems.

**Corollary XV.5.3** (A single infinite input cardinality suffices). *The nonconservativity conclusion remains true if the selector is required to choose only from sets in bijection with  $\omega$ .*

*Proof.* Let  $c_\infty$  select from countably infinite sets. If  $\emptyset \neq X \rightarrow \omega$ , then  $X \times \omega$  is countably infinite. Indeed, it injects into  $\omega \times \omega$ , and after fixing one element of  $X$ , it contains a copy of  $\omega$ . The ordinary set Cantor–Bernstein theorem, provable by the bounded finite-path construction, gives the bijection. Define

$$c(X) = \pi_1(c_\infty(X \times \omega))$$

for these inputs, and  $c(X) = \emptyset$  otherwise. This is a countable-set selector. Separation for it translates into Separation for  $c_\infty$ , so [theorem XV.5.1](#) applies.  $\square$

**Corollary XV.5.4** (Any fixed infinite bound). *Suppose a fixed well-ordered  $D$  contains a set copy of  $\omega$ . A selector on all nonempty sets embeddable into  $D$ , with expanded Separation, already implies the countable-input conclusion.*

*Proof.* Every countable set embeds into  $D$ . Restrict the selector’s specified behavior to those inputs and apply [theorem XV.5.1](#).  $\square$

### XV.5.3 The exact role of expanded Separation

**Proposition XV.5.5** (An uninteracting selector is conservative). *If the Separation schema is not extended to the new symbol, adjoining the selector requirement alone is conservative over  $\text{ZC}$ , and likewise over  $\text{ZC}_F$ .*

*Proof.* Use the ordinary external ZFC metatheory for this model-theoretic argument. Every set-sized model  $M$  of the base theory can be expanded by selecting an  $\in^M$ -member of each internally nonempty set. External Choice makes these selections on the external set  $M$ . The resulting operation satisfies even unrestricted global selection in the expanded structure. All original axioms still hold because their schemas do not mention the new operation. Thus every base model has an expansion, and completeness gives conservativity for original-language sentences.  $\square$

Expanded Separation is therefore part of the mathematical content of [theorem XV.5.1](#). Merely writing a choice operation into a formal language is not the same assertion.

## XV.6 Full-class rank models and the sign carrier

From this section onward, work in an external universe satisfying ZFC. Fix a limit ordinal  $\lambda > \omega$ . The set sort of  $\mathcal{M}_\lambda$  is  $V_\lambda$ , and its class sort consists of every external subset of  $V_\lambda$ . Ordered pairs and finite tuples are encoded in the usual way. Since  $\lambda$  is a limit, any finite rank increase remains below  $\lambda$ ; hence every relation or function on this domain can be represented by a class of coded tuples.

**Proposition XV.6.1** (Available axioms).  *$\mathcal{M}_\lambda$  satisfies  $\text{ZC}_F$  on its set sort, elementary class comprehension, Separation with arbitrary class parameters, and global choice. Its internal ordinals are precisely the ordinals below  $\lambda$ .*

*Proof.* Transitivity and limit height give Extensionality, Pairing, Union, Power Set, Infinity, and Foundation. Every external subset of a set  $a \in V_\lambda$  again belongs to  $V_\lambda$ , proving Separation even with arbitrary class parameters. External Choice gives a choice function on a set-sized family  $a$ ; its graph has rank bounded by the ranks of  $a$  and its union, plus a finite amount, so belongs to  $V_\lambda$ . Thus internal set Choice holds.

Every extension of a formula on the domain is an admitted class, giving class comprehension. External Choice also selects one member of every nonempty element of the external set  $V_\lambda$ ; its graph is an admitted class and witnesses global choice. Transitivity and the actual well-foundedness of membership identify the internal ordinals with  $\lambda$ .  $\square$

### XV.6.1 Sign sequences and bounded birthdays

Each binary function on an ordinal  $\alpha < \lambda$  has rank between  $\alpha$  and  $\max(\omega, \alpha) + m$  for an absolute finite coding constant  $m$ , after harmless adjustment for finite  $\alpha$ . It therefore belongs to  $V_\lambda$ . Conversely, the domain of any internally represented ordinal-length binary function is an ordinal below  $\lambda$ . The internal sign-sequence class is exactly  $S_\lambda$ .

The following boundedness criterion will be used repeatedly:

$$B \subseteq S_\lambda \text{ is an internal set} \iff \sup\{\text{bd}(s) : s \in B\} < \lambda. \quad (\text{S31.6})$$

For the reverse implication, uniformly bounded lengths give a fixed rank bound on all the coded functions and on their collection. For the forward implication, the rank of the internal set bounds the ranks, and therefore the lengths, of its members. In particular,  $S_\lambda$  is an internal proper class.

This identification is about the sign presentation and its birthday filtration. For example, at a noncardinal cutoff, operations on two sign sequences may produce a sequence whose length reaches the cutoff. Accordingly, no theorem below treats every  $S_\lambda$  as a real-closed field or as a model of all surreal arithmetic.

### XV.6.2 Set-like well-orders at every height

**Proposition XV.6.2** (Choice orders without ordinal enumeration). *For every limit  $\lambda > \omega$ ,  $V_\lambda$  has a rank-monotone set-like class well-order, and  $S_\lambda$  has a birthday-monotone set-like class well-order. These orders give a least element to every nonempty admitted class, not only to every internal nonempty set.*

*Proof.* Externally choose a well-order of each rank layer of  $V_\lambda$ , and order first by rank, then by the selected layer order. Every nonempty subclass has a least occurring rank and then a least element on that layer. The predecessors of a given point are contained in a fixed rank segment, so form an

internal set. The construction for  $S_\lambda$  is identical, with birthday layers  ${}^a2$ . Its predecessors have bounded birthday, and equation (S31.6) applies.  $\square$

One must not infer that either of these orders has type  $\text{Ord}^{\mathcal{M}_\lambda}$ . Such an inference requires both the availability of ordinal representatives for predecessor orders and a justification that the resulting enumeration has the appropriate range. We determine exactly when the corresponding statements hold.

[merge] At a strongly inaccessible  $\kappa$ ,  $\mathcal{M}_\kappa$  is source 12's model  $\mathcal{M}$  of section 21, and the identification of the internal sign-sequence class with  $S_\kappa = \mathbf{No}_{<\kappa}$  is clause (i) of theorem 21.1; source 09's universe enlargement (section 22) and the universe sections of Part IX (section 57) also work at an inaccessible height. This section and the next five drop inaccessibility. Proposition XV.6.2 gives a set-like class well-order of  $S_\lambda$  at every height, which by theorem XV.7.2 need not have type  $\text{Ord}$ ; over GB, which has class Replacement, the two are equivalent (theorem 13.1 and the dated note after it).

## XV.7 Ordinal enumeration and birthday order

For an infinite cardinal  $\kappa$ , write

$$2^{<\kappa} = \sup_{\mu < \kappa, \mu \text{ a cardinal}} 2^\mu.$$

Our use of cardinal equalities in this and the following sections is entirely external.

**Lemma XV.7.1** (Size of the sign carrier). *Let  $\lambda > \omega$  be a limit ordinal and  $\kappa = |\lambda|$ . Then*

$$|S_\lambda| = \begin{cases} 2^{<\kappa}, & \lambda = \kappa, \\ 2^\kappa, & \kappa < \lambda. \end{cases} \quad (\text{S31.7})$$

*Proof.* The layers have size  $2^{|\alpha|}$ , and distinct layers are disjoint. For  $\lambda = \kappa$ , their cardinal sum is  $\kappa \cdot 2^{<\kappa} = 2^{<\kappa}$ . Here  $2^{<\kappa} \geq \kappa$ : at a successor cardinal this follows from Cantor's theorem at the predecessor cardinal; at a limit cardinal it follows by taking the supremum of the successor cardinals below it.

If  $\kappa < \lambda$ , the birthday  $\kappa$  layer is present and has size  $2^\kappa$ . Every layer has at most this size, and there are  $\kappa$  layers, giving the matching upper bound.  $\square$

[merge] The case  $\lambda = \kappa$  is the count  $|\mathbf{No}_{<\kappa}| = 2^{<\kappa}$  of section 7 (before corollary 7.1), proved there by the same sum.

**Theorem XV.7.2** (Bare ordinal enumeration). *There is an admitted class bijection  $\text{Ord}^{\mathcal{M}_\lambda} \longleftrightarrow S_\lambda$  if and only if  $\lambda$  is a cardinal  $\kappa$  satisfying  $2^{<\kappa} = \kappa$ . The same condition characterizes a class injection  $S_\lambda \hookrightarrow \text{Ord}^{\mathcal{M}_\lambda}$ .*

*Proof.* All external functions on the relevant carriers are admitted class functions. The assertion is therefore cardinal equality with  $|\lambda|$ , or the corresponding cardinal inequality. At a noninitial  $\lambda$ , lemma XV.7.1 and Cantor's theorem rule it out. At an initial  $\kappa$ , the same lemma gives exactly the displayed condition. An injection of  $\lambda$  into  $S_\lambda$  is always available by taking the all-zero sequence at each birthday, so injection and bijection have the same threshold.  $\square$

**Definition XV.7.3.** An ordinal birthday enumeration is a class bijection  $e : \lambda \rightarrow S_\lambda$  satisfying  $\xi < \eta \Rightarrow \text{bd}(e(\xi)) \leq \text{bd}(e(\eta))$ .

**Theorem XV.7.4** (Birthday enumeration threshold). *An ordinal birthday enumeration exists if and only if  $\lambda$  is a strong-limit cardinal.*

*Proof.* Such an enumeration is in particular a bare enumeration, so [theorem XV.7.2](#) implies  $\lambda = \kappa$  is a cardinal. Fix  $\alpha < \kappa$  and choose a sign sequence of birthday  $\alpha + 1$ . It occurs at some position  $\xi < \kappa$ . Monotonicity places every sequence of birthday  $\alpha$  before that position. Hence

$$2^{|\alpha|} \leq |\xi| < \kappa.$$

Thus  $\kappa$  is strong limit.

Conversely, suppose  $\kappa$  is strong limit. For each  $\alpha < \kappa$ , externally well-order  ${}^\alpha 2$  in its initial cardinal order type  $\theta_\alpha = 2^{|\alpha|} < \kappa$ . Concatenate these orders in increasing birthday. For every  $\beta < \kappa$ , the ordinal sum of the layers up through  $\beta$  has cardinal at most

$$\max(\aleph_0, |\beta|, 2^{|\beta|}) < \kappa.$$

As  $\kappa$  is an initial ordinal, each such partial sum is below  $\kappa$ . Their supremum is therefore at most  $\kappa$ . It is at least  $\kappa$ , since there is a nonempty layer for every birthday. The concatenated order has type exactly  $\kappa$ , giving the required enumeration. No regularity of  $\kappa$  was used.  $\square$

*Remark XV.7.5.* A birthday-monotone *set-like well-order* exists at every limit height by [proposition XV.6.2](#); the extra demand in [theorem XV.7.4](#) is that its order type be the internal Ord. The difference is visible even at  $\omega_1$  under CH, as shown in [section XV.11](#).

## XV.8 Universal set coding and ordinal abstraction

Recall the external beth hierarchy:

$$\beth_0 = \aleph_0, \quad \beth_{\alpha+1} = 2^{\beth_\alpha}, \quad \beth_\delta = \sup_{\alpha < \delta} \beth_\alpha \quad (\delta \text{ limit}).$$

For an uncountable initial cardinal  $\kappa$ ,

$$|V_\kappa| = \beth_\kappa. \tag{S31.8}$$

Indeed,  $|V_{\omega+\alpha}| = \beth_\alpha$  by induction, and  $\omega + \kappa = \kappa$ . In particular, one must not substitute this formula without adjustment at  $\lambda = \omega + \omega$ , where the cardinality is  $\beth_\omega$ .

**Lemma XV.8.1** (Growth facts). *For an uncountable cardinal  $\kappa$ ,  $\beth_\kappa \geq \kappa$ , and  $\beth_\kappa$  is a strong-limit cardinal. If  $\beth_\kappa = \kappa$ , then  $|V_\alpha| < \kappa$  for every  $\alpha < \kappa$ .*

*Proof.* The beth sequence is strictly increasing and continuous. At the limit index  $\kappa$  its supremum has cardinal at least  $\kappa$ . If  $\mu < \beth_\kappa$ , some  $\beth_\beta$  exceeds  $\mu$ , with  $\beta + 1 < \kappa$ ; hence  $2^\mu \leq \beth_{\beta+1} < \beth_\kappa$ . This proves the strong-limit assertion. In the fixed-point case, the rank-cardinality formula, or its monotone upper bounds for small ranks, puts every  $|V_\alpha|$  below  $\beth_\kappa = \kappa$ .  $\square$

**Theorem XV.8.2** (Universal coding threshold). *For a limit ordinal  $\lambda > \omega$ , the following are equivalent:*

- (i) *there is a class injection  $V_\lambda \hookrightarrow S_\lambda$ ;*
- (ii) *there is a class bijection  $V_\lambda \longleftrightarrow S_\lambda$ ;*
- (iii) *there is a class bijection  $V_\lambda \longleftrightarrow \lambda$ ;*
- (iv)  $\lambda = \kappa = \beth_\kappa$ .

*Proof.* All the functions in question are external functions between sets, represented internally as classes. Because  $S_\lambda \subseteq V_\lambda$ , (i) and (ii) are equivalent by external Cantor–Bernstein.

First suppose  $\lambda$  is not an initial ordinal, and put  $\kappa = |\lambda| < \lambda$ . If  $\kappa = \omega$ , then  $\lambda \geq \omega + \omega$ , so

$$|V_\lambda| \geq \beth_\omega > 2^\omega = |S_\lambda|.$$

If  $\kappa > \omega$ , then  $\kappa + 2 < \lambda$ , because  $\lambda$  is a limit. By equation (S31.8),

$$|V_\lambda| \geq |V_{\kappa+2}| = 2^{2^{\beth_\kappa}} > 2^\kappa = |S_\lambda|.$$

Thus neither (i) nor (iii) can hold at a noninitial height.

Now let  $\lambda = \kappa$ . If  $\beth_\kappa > \kappa$ , the strong-limit property in lemma XV.8.1 gives

$$|S_\kappa| = 2^{<\kappa} \leq 2^\kappa < \beth_\kappa = |V_\kappa|.$$

Both (i) and (iii) fail. If  $\beth_\kappa = \kappa$ , then  $\kappa$  is strong limit, so  $|S_\kappa| = \kappa = |V_\kappa|$ . All three coding statements hold.  $\square$

**Definition XV.8.3** (Ordinal abstraction). OA asserts that every internal set well-order is isomorphic, by an internal set graph, to an internal von Neumann ordinal.

**Theorem XV.8.4** (Ordinal abstraction threshold).  $\mathcal{M}_\lambda \models \text{OA}$  if and only if  $\lambda = \kappa = \beth_\kappa$ .

*Proof.* Assume first that  $\lambda = \kappa = \beth_\kappa$ . Every internal set  $a$  has size below  $\kappa$ , by lemma XV.8.1. An internal well-order on  $a$  is externally a genuine well-order: every external subset of  $a$  is internal. Let its external order type be  $\alpha$ . Since  $|\alpha| = |a| < \kappa$  and  $\kappa$  is initial,  $\alpha < \kappa$ . Its isomorphism graph has bounded rank and belongs to  $V_\kappa$ . Thus the collapse is internal.

Conversely, suppose first that  $\lambda$  is not initial. The ordinal  $\kappa = |\lambda|$  belongs to  $V_\lambda$ . Transport the order  $\lambda$  to the carrier  $\kappa$  by an external bijection. The resulting relation is a subset of  $\kappa \times \kappa$ , so has rank below  $\lambda$ . It is an internal well-order of external type  $\lambda$ , which has no internal ordinal representative. This refutes OA.

Finally, let  $\lambda = \kappa$  and suppose  $\beth_\kappa > \kappa$ . Continuity of the beth hierarchy gives some  $\beta < \kappa$  with  $\beth_\beta > \kappa$ ; otherwise its supremum would be at most  $\kappa$ . A rank segment below  $\kappa$  therefore contains an internal set of size at least  $\kappa$ . Choose an external subset  $a$  of that set of size  $\kappa$ , and transport the order  $\kappa$  to  $a$ . Both  $a$  and the relation are internal by rank boundedness. This well-order has type  $\kappa$ , again with no internal ordinal representative.  $\square$

### XV.8.1 Why this does not prove Replacement

At a singular beth fixed point, every internal set well-order has an ordinal type and the entire set universe has a class bijection with Ord. Nevertheless, a class function on a small ordinal can have unbounded-rank values. An external class bijection does not imply that the images of all of its set-sized domain restrictions are internal sets. The next section makes this obstruction exact.

## XV.9 The exact domain size for Class Replacement

**Definition XV.9.1.** For an internal set  $a$ , let  $\text{CR}(a)$  assert that the range of every admitted class function  $F : a \rightarrow V_\lambda$  is an internal set. Let  $\text{CR}(\text{Ord})$  assert  $\text{CR}(\alpha)$  for every internal ordinal  $\alpha$ . Full CR asserts  $\text{CR}(a)$  for every internal set.

**Lemma XV.9.2** (The domain-size criterion). *For every  $a \in V_\lambda$ ,*

$$\mathcal{M}_\lambda \models \text{CR}(a) \iff |a| < \text{cf}(\lambda). \quad (\text{S31.9})$$

*The same condition characterizes full-class Collection on the domain  $a$ .*

*Proof.* If  $|a| < \text{cf}(\lambda)$ , the ranks of the values of any function  $F : a \rightarrow V_\lambda$  form an externally bounded subset of  $\lambda$ . Its range therefore has rank below  $\lambda$ , so is internal.

If  $|a| \geq \text{cf}(\lambda)$ , choose externally a surjection  $p : a \rightarrow \text{cf}(\lambda)$  and a cofinal map  $g : \text{cf}(\lambda) \rightarrow \lambda$ . The admitted class function  $g \circ p$  has an unbounded set of ordinal values. That range is not an internal set, refuting  $\text{CR}(a)$ .

For Collection, a total class relation on  $a$  has an external witness selection by ambient Choice. When  $|a| < \text{cf}(\lambda)$ , these selected witnesses have bounded rank and give a collecting set. In the other direction, the functional relation just constructed has unique witnesses and no internal collecting set.  $\square$

**Theorem XV.9.3** (Replacement thresholds). *For every limit ordinal  $\lambda > \omega$ ,*

$$\begin{aligned} \mathcal{M}_\lambda \models \text{CR}(\omega) &\iff \text{cf}(\lambda) > \omega, \\ \mathcal{M}_\lambda \models \text{CR}(\text{Ord}) &\iff \lambda \text{ is an uncountable regular cardinal,} \\ \mathcal{M}_\lambda \models \text{CR} &\iff \lambda \text{ is strongly inaccessible.} \end{aligned}$$

*Proof.* The first assertion is [lemma XV.9.2](#) with  $a = \omega$ .

For the second, if  $\lambda$  is regular initial, every  $\alpha < \lambda$  has size below  $\text{cf}(\lambda) = \lambda$ . Conversely, if  $\text{cf}(\lambda) < \lambda$ , then  $\text{cf}(\lambda)$  is itself an internal ordinal and its domain violates [lemma XV.9.2](#). The only remaining possibility is  $\text{cf}(\lambda) = \lambda$ , which says that  $\lambda$  is an initial regular cardinal.

For full Replacement, the second assertion first forces regular cardinal height. If that regular cardinal  $\kappa$  is not strong limit, choose an infinite cardinal  $\mu < \kappa$  with  $2^\mu \geq \kappa$ . The internal set  $\mathcal{P}(\mu)$  has size at least  $\text{cf}(\kappa) = \kappa$ , so violates [lemma XV.9.2](#). Conversely, at a strongly inaccessible  $\kappa$ , induction on  $\alpha < \kappa$  gives  $|V_\alpha| < \kappa$ : the successor step uses strong limit and the limit step uses regularity. Every internal set has size below  $\text{cf}(\kappa)$ , and [lemma XV.9.2](#) proves full Class Replacement.  $\square$

[merge] The inaccessible case of the third equivalence is the classical fact that source 12’s model uses (“regularity and the strong-limit property ensure the required closure of set operations and class Replacement”, [section 21](#)). The first equivalence makes exact that section’s warning that  $V_{\beth_\omega}$  “lacks the regularity used in Replacement”: there  $\text{cf} \lambda = \omega$ , so Class Replacement fails already on the domain  $\omega$  ([section XV.11](#)).

**Corollary XV.9.4** (Separating the two requirements). *Within the structures  $\mathcal{M}_\lambda$ , the conjunction of ordinal-domain Class Replacement and ordinal birthday enumeration is equivalent to full Class Replacement. The same is true with ordinal birthday enumeration replaced by ordinal abstraction or universal set coding.*

*Proof.* The first conjunction says exactly that the height is regular and strong limit. For the second, a beth fixed point is strong limit, and regularity again gives strong inaccessibility. Every inaccessible cardinal is a beth fixed point: induction gives  $\beth_\alpha < \kappa$  for  $\alpha < \kappa$ , and continuity gives  $\beth_\kappa = \kappa$ .  $\square$

**Remark XV.9.5** (Ordinal domains are not all well-orderable domains). The distinction in [theorem XV.9.3](#) concerns *ordinal domains*. It must not be confused with Replacement on every

well-orderable set. Freire and Hamkins prove that the latter implies full Replacement over Zermelo set theory with Foundation, without assuming Choice [73]. An internal well-ordered carrier may have no internal ordinal representative, precisely as [theorem XV.8.4](#) shows.

*Remark XV.9.6* (Full classes versus definable classes). The inaccessible threshold characterizes Replacement for *all external class functions* admitted in  $\mathcal{M}_\lambda$ . It is not a classification of heights satisfying the first-order Replacement schema for formulas of the pure membership language. Such heights are usually discussed through worldly rank segments; the class parameter restriction changes the problem. No result about first-order Replacement at all singular heights is asserted here.

## XV.10 The sizes of internal proper classes

The available classes form an external set, but many are proper classes relative to the internal set sort. This distinction is useful rather than paradoxical.

**Theorem XV.10.1** (Proper-class cardinal spectrum). *A class  $C \subseteq V_\lambda$  is an internal proper class exactly when it is unbounded in rank. Its possible external cardinalities are precisely*

$$\{\theta : \theta \text{ is a cardinal and } \text{cf}(\lambda) \leq \theta \leq |V_\lambda|\}. \quad (\text{S31.10})$$

*Proof.* A rank-bounded subclass is an external subset of some  $V_\alpha$  and therefore belongs to  $V_\lambda$ . Conversely, an element of  $V_\lambda$  bounds the ranks of all of its members. An unbounded subclass must have at least  $\text{cf}(\lambda)$  elements. A cofinal sequence of ordinals below  $\lambda$  realizes that lower bound.

For any cardinal  $\theta$  in the displayed interval, choose an external subset  $B \subseteq V_\lambda$  of size  $\theta$ , and adjoin a fixed cofinal set of ordinals of size  $\text{cf}(\lambda)$ . The union is rank-unbounded and still has size  $\theta$ . It is an admitted proper class of the required cardinality.  $\square$

**Corollary XV.10.2** (Two different limitation-of-size conditions). *In  $\mathcal{M}_\lambda$ :*

- (i) *every proper class admits an injection from Ord if and only if  $\text{cf}(\lambda) = |\lambda|$ ;*
- (ii) *every proper class is class-bijective with Ord if and only if  $\lambda$  is strongly inaccessible.*

*Proof.* For (i), compare the least possible size  $\text{cf}(\lambda)$  with  $|\text{Ord}^{\mathcal{M}_\lambda}| = |\lambda|$ . For (ii), the universal class itself first forces  $|V_\lambda| = |\lambda|$ , which by [theorem XV.8.2](#) forces a beth-fixed-point cardinal height  $\kappa$ . The minimum proper-class size then forces  $\text{cf}(\kappa) = \kappa$ , hence strong inaccessibility. At an inaccessible height both the minimum and maximum sizes equal  $\kappa$ , so all proper classes have the required bijections.  $\square$

At a noninitial height, condition (i) is not the same as regular cardinal height. For example  $\lambda = \omega_1 \cdot 2$  has  $\text{cf}(\lambda) = |\lambda| = \omega_1$ , but fails ordinal-domain Class Replacement since  $\omega_1$  is an internal ordinal domain. This example separates cardinal comparability from internal image bounding.

## XV.11 Explicit separating models

### XV.11.1 Global choice without any ordinal sign enumeration

Take  $\lambda = \omega + \omega$ . Then

$$|\text{Ord}^{\mathcal{M}_\lambda}| = \aleph_0, \quad |S_\lambda| = 2^{\aleph_0}, \quad |V_\lambda| = \beth_\omega.$$

Global choice and birthday-monotone set-like well-orders exist, but even a class injection  $S_\lambda \rightarrow \text{Ord}$  is impossible. Class Replacement on  $\omega$  fails, witnessed by the class function  $n \mapsto \omega + n$ , whose range

is unbounded in  $\lambda$ . Thus a global selector, including its countable restriction, need not supply any countable image-bounding principle.

### XV.11.2 Ordinal sign enumeration without birthday enumeration

Assume CH and take  $\lambda = \omega_1$ . Then  $2^{<\omega_1} = 2^{\aleph_0} = \omega_1$ , so a class bijection  $\omega_1 \longleftrightarrow S_{\omega_1}$  exists. But there are  $\omega_1$  sequences of birthday  $\omega$ . A birthday-monotone enumeration would have to place all of them before any sequence of birthday  $\omega + 1$ . No position below  $\omega_1$  has that many predecessors.

Ordinal-domain Class Replacement holds by regularity, but full Class Replacement and ordinal abstraction fail. This refines the role of the established  $V_{\omega_1}$  example by separating arbitrary sign enumeration from enumeration that respects the birthday filtration.

### XV.11.3 Birthday enumeration without universal set coding

Take  $\kappa = \beth_\omega$ . This is a singular strong-limit cardinal of cofinality  $\omega$ . Hence ordinal birthday enumeration of  $S_\kappa$  exists. But

$$|V_\kappa| = \beth_\kappa > \beth_\omega = \kappa = |S_\kappa|.$$

Universal set coding and ordinal abstraction fail. This example requires no continuum hypothesis and no inaccessible cardinal.

### XV.11.4 Universal coding and ordinal abstraction without Replacement

Define externally

$$\kappa_0 = \omega, \quad \kappa_{n+1} = \beth_{\kappa_n}, \quad \kappa = \sup_{n < \omega} \kappa_n.$$

The sequence is strictly increasing, so  $\text{cf}(\kappa) = \omega$ . Continuity gives  $\beth_\kappa = \sup_n \beth_{\kappa_n} = \sup_n \kappa_{n+1} = \kappa$ . This is the first beth fixed point reached above the starting value. Consequently

$$V_\kappa \longleftrightarrow S_\kappa \longleftrightarrow \kappa$$

by class bijections, and every internal set well-order has an internal ordinal type. Nevertheless the admitted class function  $n \mapsto \kappa_n$  has unbounded range. Even  $\text{CR}(\omega)$  fails.

No first-order definability assertion about this particular sequence is needed for the example: every external class function is admitted in the structure. This makes its failure of *Class* Replacement immediate and avoids confusing the two replacement schemas.

### XV.11.5 The inaccessible case

If a strongly inaccessible  $\kappa$  exists, all properties in the main classification table hold in  $\mathcal{M}_\kappa$ . In particular, every internal proper class has external cardinality  $\kappa$ , and its class functions on internal sets have internally bounded images. This is the setting in which the rank-model examples in the inspected ProveIt report are placed. ([merge] This report: [sections 21, 22 and 57.](#))

| Height                         | GC  | bare sign<br>enumeration | birthday<br>enumeration | universal<br>set coding | full CR |
|--------------------------------|-----|--------------------------|-------------------------|-------------------------|---------|
| $\omega + \omega$              | yes | no                       | no                      | no                      | no      |

## XV.12 Consequences for surreal foundations and formalization

### XV.12.1 A precise extension of the ProveIt questions

The classification explains why a proof formulated over GB cannot simply be read over ZC with class comprehension. Three jobs must be separated:

1. *Selection*: choose a local presentation or local order.
2. *Collapse and coding*: represent that presentation by an available ordinal or sign sequence.
3. *Image bounding*: ensure that the values obtained over a set domain still form an internal set.

The first part of this article shows that selection restricted to countable inputs already has non-conservative consequences when combined with expanded Separation. The second shows that even unrestricted selection leaves collapse and image bounding at distinct thresholds in full-class rank models.

These are concrete answers about the mechanisms named in the repository’s weak foundations agenda ([merge] [research question 113.209](#); the questions [research questions 113.161](#) and [113.185](#) of sources 24 and 26 ask about the same resources). They do not prove that its supported-prefix extension, small-net rigidity, or inverse-reconstruction schemes are each equivalent to a particular row of our table. Establishing those equivalences would require encoding the exact input and output types of each scheme in a common weak base.

### XV.12.2 A formalization architecture with an explicit trust boundary

A proof assistant development can formalize the first part without implementing all the symmetric-extension machinery. The natural target is a theorem about models of a specified first-order theory, with Glazer’s obstruction isolated as an input interface. Its parameters would be formulas defining the class family, incidence relation, label domain, and target map, together with their required properties. The formal theorem would show that no expanded model can satisfy both that interface and countable selection with the relevant Separation instances.

The thread construction should be represented by a bounded object:  $\text{Thr}_X \subseteq \mathcal{P}(X) \times \mathcal{P}(X^2)$ . The main lemmas are initial-segment comparability, well-foundedness of its union, maximality, rigidity of well-orders, and correctness of least-code normalization. The compression theorem then needs only injectivity of each row presentation and target separation by traces. This organization makes accidental appeals to Replacement visible.

For the second part, use a universe separation: the metatheory has an actual set  $V_\lambda$ , and its class sort is another set  $\mathcal{P}(V_\lambda)$  in the larger universe. Internal “set” and external “set” are distinct predicates. No term denoting a set of all sets or a set of all actual surreal numbers is required. The sign carrier is explicitly the set  $\bigcup_{\alpha < \lambda} {}^\alpha 2$  in the metatheory.

A first machine-checked milestone should be the domain-size criterion [lemma XV.9.2](#), followed by the sign-cardinality formula and the two enumeration thresholds. These use ordinary external cardinal arithmetic and rank bounds. The ordinal-abstraction theorem adds the distinction between an internal well-order relation and its external order type.

### XV.12.3 Why no experimental computation is offered as proof

Finite experiments with selectors can illustrate the thread construction, but cannot verify non-conservativity, lack of ordinal collapse, or Class Replacement. The mathematical verification here consists of displayed set bounds and independent checks of the proofs. The supplied source is an

ordinary LaTeX article, not a proof-assistant certificate. A later formal development should report separately the checked uniformization theorem and any assumed countermodel construction.

## XV.13 Axiom ledger and proof dependencies

[merge] Source 31's Appendix A.

| Construction or result           | Existence bound or main argument                                    | Logical setting                         |
|----------------------------------|---------------------------------------------------------------------|-----------------------------------------|
| Thread collection $\text{Thr}_X$ | Subset of $\mathcal{P}(X) \times \mathcal{P}(X^2)$                  | $\mathbf{Z} + \mathbf{Sep}(c)$          |
| Union thread $W_X$               | Domain subset of $X$ , relation subset of $X^2$                     | Initial-segment comparison; no collapse |
| Uniform injection $i_X$          | Least code in $\mathcal{C}_D$ ; graph subset of $X \times D$        | One fixed code well-order               |
| Trace $H_a$                      | Subset of $I \times D$                                              | Expanded Separation                     |
| Partial surjection $Q$           | Subset of $\mathcal{P}(I \times D) \times T$                        | Target determined by trace              |
| Countable nonconservativity      | Uniformization and compression contradict the published obstruction | Glazer countermodel input               |
| Sign enumeration thresholds      | Cardinal count and ordinal sums of birthday layers                  | External ZFC, full classes              |
| Universal set coding and OA      | $ V_\kappa  = \beth_\kappa$ , bounded rank of internal relations    | External ZFC, full classes              |
| Replacement on $a$               | All $ a $ -sized rank sets bounded iff $ a  < \text{cf}(\lambda)$   | External ZFC, full classes              |
| Proper-class size spectrum       | Rank-unbounded subsets and cofinal sets                             | External ZFC, full classes              |

The main derivation has the following dependency order. First prove the bounded thread lemma. Then prove least-code uniformization. Use the uniform injections to form bounded traces and the partial surjection. Finally instantiate the published obstruction. The rank-model part is independent of that nonconservativity argument; its common inputs are the rank-boundedness criterion and external cardinal arithmetic.

## XV.14 Source audit and research status

[merge] Source 31's Appendix B.

### XV.14.1 The inspected repository snapshot

The report was inspected at commit

2b7b388ba81a3355b19a7c2d2fe797e92f572355.

Its path is

Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/article.tex.

The corresponding Git blob is 05807d292fbed8b68aa5744b502fece703057c74. The source is a merged research report. We inspected its relevant foundations statements and proof passages; no repository-wide correctness audit is claimed. No repository files were modified. The exact replacement-free classification developed here was not found in the inspected passages and targeted searches.

[merge] The commit 2b7b388ba is “Catalogue batches 81 to 86”; the blob 05807d292 is this article as written by 07ee2b30c (batch 83), with Parts I–XIV, unchanged until this write.

### XV.14.2 Status of the principal assertions

**Proved refinement.** The countable-input and exactly-countably-infinite-input nonconservativity statements follow from the fully displayed uniformization argument and Glazer’s published countermodels.

**Proved structural results.** The full-class rank-model spectra, domain-size criterion, and separation examples are proved here in external ZFC. Several ingredients and motivating examples are classical or already discussed in the cited literature.

**Not claimed.** There is no claimed new solution of the entire surreal transfer problem, no classification for arbitrary definable-class realizations, no proof of the finite-input conservativity boundary, and no machine-checked formalization.

**Novelty qualification.** The article provides a concrete additional theorem and an exact synthesis. Targeted literature and repository checks support its relevance but do not establish that every formulation is historically new. Expert review of the localized nonconservativity statement would be the next scholarly step.

## XV.15 What this Part answers

[merge] Dated notes, 3 October 2026, in the form of [section 50](#).

- (a) *Source 28’s research question 113.209, the weakest class-theoretic assumptions for the supported-prefix extension, small-net rigidity and inverse-reconstruction schemes, and whether their uses of Class Replacement and uniform set choice separate sharply:* answered in part. Source 31 separates three mechanisms: selection, collapse and coding, and image bounding ([section XV.12](#)). Selection restricted to countable inputs, with Separation for the selector, is already nonconservative over ZC and ZC<sub>F</sub> ([theorem XV.5.1](#), through the Glazer interface; countably infinite inputs suffice, [corollary XV.5.3](#)), and conservative without expanded Separation ([proposition XV.5.5](#)). In the full-class rank models global choice holds at every height, while ordinal coding and image bounding have different exact thresholds ([theorems XV.7.2, XV.7.4, XV.8.2, XV.8.4 and XV.9.3](#)), Class Replacement on a set holds exactly below the cofinality of the height ([lemma XV.9.2](#)), and ordinal-domain Class Replacement together with birthday enumeration, ordinal abstraction or universal coding is full Class Replacement ([corollary XV.9.4](#)). Open: the minimal assumptions of each of the three schemes, which source 31 restates as [research question 113.242](#); it proves no equivalence of a scheme with a row of its table. The sibling questions [research questions 113.161 and 113.185](#) of sources 24 and 26 ask about the same resources and stay open.
- (b) *Source 12’s full-class model* ([theorem 21.1](#), a theorem, not a question): extended from inaccessible  $\kappa$  to every limit height for global choice, ordinal and birthday enumeration of the

sign carrier, universal set coding, ordinal abstraction, Class Replacement on each set domain and the sizes of proper classes ([theorem XV.10.1](#) and [corollary XV.10.2](#)); the warning about  $V_{\sqcup_\omega}$  in [section 21](#) is made exact. The external identification of the set-like and unrestricted orders in clauses (ii)–(iv) of [theorem 21.1](#) is not extended ([research question 113.241](#)).

- (c) *The base theory of [theorem 13.1](#):* in  $\mathcal{M}_\lambda$ , global choice and set-like class well-orders of the sign carrier exist at every height, but an Ord-enumeration exists only when  $\lambda = \kappa$  with  $2^{<\kappa} = \kappa$  ([proposition XV.6.2](#) and [theorem XV.7.2](#)); the equivalence of [theorem 13.1](#) uses the class Replacement of GB (the dated note after it). No earlier question asked this.
- (d) *Not settled:* Hamkins’s question whether universality of the surreal line is a weak global choice principle ([section 1.7](#) (f)); Hamkins’s surreal transfer question [76], on which source 31 asks [research question 113.244](#); the questions listed as not affected in [section 113.25](#) (q).

[merge] *New against the repository* (source 31 claims no priority for any formulation): the uniform presentation theorem and uniform countable enumeration ([theorem XV.3.3](#) and [corollary XV.3.5](#)), bounded trace compression ([theorem XV.4.1](#) and [corollary XV.4.2](#)), the countable-input nonconservativity theorem and its corollaries ([theorem XV.5.1](#) and [corollaries XV.5.3](#) and [XV.5.4](#), conditional on the Glazer interface), the conservativity of an uninteracting selector ([proposition XV.5.5](#)), choice orders without ordinal enumeration at every height ([proposition XV.6.2](#)), the bare, birthday, universal-coding and ordinal-abstraction thresholds ([theorems XV.7.2](#), [XV.7.4](#), [XV.8.2](#) and [XV.8.4](#)), the domain-size criterion and the Replacement thresholds ([lemma XV.9.2](#), [theorem XV.9.3](#), and [corollary XV.9.4](#)), the proper-class spectrum ([theorem XV.10.1](#) and [corollary XV.10.2](#)) and the separating heights of [section XV.11](#). *Inherited or re-proved:* the method of [lemma XV.3.1](#) (a bounded proof of the well-ordering theorem), the available axioms ([proposition XV.6.1](#)), the case  $\lambda = \kappa$  of [lemma XV.7.1](#) ([section 7](#)), the beth facts ([lemma XV.8.1](#)), the inaccessible case of [theorem XV.9.3](#) ([section 21](#)), ordinal abstraction and the example  $V_{\omega_1}$  (Hamkins, Rin), set-like orders without Replacement (Carneiro) and well-ordered Replacement (Freire and Hamkins, [remark XV.9.5](#)).

## Part XVI

# Definable class well-orders beyond Ord: arithmetic, histories over GB, fixed points and definability ceilings

[merge] (4 October 2026, batch 96.) This Part merges four manuscripts of batch 96 ([section 1.11](#)), written independently on 4 and 5 October 2026 in answer to one request: how far definable class well-orders reach beyond Ord, what their arithmetic is, how they can be named, and how the subject can be formalized. They are this report’s sources 32–35, batch-96 manuscripts 08–11: source 32 (“Beyond Ord”, definability ceilings and truth jumps), source 33 (“Beyond Ord”, definability heights), source 34 (“Beyond Ord”, canonical arithmetic and the limits of notation; the base) and source 35 (fixed-point completion and the limits of uniform definability). All four read this report with Parts I–XV, exactly as it stood before this write ([section 1.11](#)); their subject continues Part IX’s canonical blocks and histories ([sections 52](#) and [53](#)) and Part XIV’s complete condensation histories ([section 108](#)).

*The question answered.* Source 29 proved over GBC that strong comparability CWO of class well-orders and the existence CTH of canonical condensation histories are equivalent ([theorem 108.19](#)), and

this report listed the same question over GB without global choice as open (note 108.4, section 112 (b), research question 113.111). Sources 34 and 35 answer it independently: the equivalence holds over GB with ZF sets and no form of choice (theorem XVI.5.8 and note XVI.5.19). The only use of global choice in source 29’s argument was the well-foundedness of the polynomial order  $P(\Gamma)$  (note 108.15); both sources prove it without choice (theorem XVI.4.2 and note XVI.4.4). Neither proves CWO or CTH in GB, and whether CWO implies ETR (Hamkins and Woodin’s Question 7) stays open. The places that listed the question carry dated notes of this write.

*Arrangement.* Sections XVI.1–XVI.10 are source 34’s Sections 1–10, in its order and whole. Each is followed by subsections that print the corresponding material of source 35, then source 32, then source 33, each source’s sections whole and in their own order where possible. Source 34’s research agenda (its Section 11) is printed with the other three sources’ questions in section 113.28; section XVI.11 collects the four sources’ ledgers, checks and source audits (source 34’s Appendix A and the appendices of the others), and section XVI.12 records what the Part answers. A statement proved again by the same argument is a numbered *Note* that gives the source’s statement, number and differences, with the statement it repeats; a proof that differs is printed as a marked route (“Source 35’s proof”); results of one source are printed in full. Where a source re-proves a result of Parts I–XV the Note names the earlier label. Every result, proof, example, remark, question and limitation of the four sources is printed; text written for the merge is marked [merge].

*Three stale or answered items* are kept on record with their proofs (Vladimir’s standing rule of 4 October 2026). Source 32’s claim to answer this report’s termination question repeats source 20’s theorem 108.1 (remark XVI.1.1). Source 33’s Remark 5.5 and its research question 12.7 leave open whether its finite-digit map has initial image; it always has, because the map is the normal-form map of Part XIV (remark XVI.5.29). Sources 32 and 33 ask for the strength of tower existence (their questions 12.1 and 12.6); it is CWO, over GBC by source 29 and over GB by sources 34 and 35, so only  $\text{CWO} \Rightarrow \text{ETR}$  remains (section 113.28). Source 35’s question 10.6, a choice-free completion theorem, is answered here positively from source 34’s choice-free set-subset criterion (theorem XVI.6.21).

*Numbering.* The sections of this Part are numbered XVI.1–XVI.12, so that the questions part and the appendices keep their numbers (Sections 113–115, Appendices A–D), as in Part XV. Numbered statements are XVI. $k.m$ ; appendix D maps every numbered statement of the four sources to its place here. Source 34’s displayed equation ( $k$ ) is tagged (S34. $k$ ), source 35’s (S35. $k$ ), source 32’s (S32. $k$ ), and source 33’s equation ( $s.k$ ) (S33. $s.k$ ).

*Notation* (section 1.3.4 lists every renaming).  $\Omega$  is the presentation (Ord,  $<$ ), never a set ordinal or a surreal.  $A^{[B]}$  is the finite-support power (source 34’s macro `\Pow`, printed `\fsp`; sources 32 and 33 write  $A^B$ , printed  $A^{[B]}$  where the operands are class orders), and  $P(\Gamma) = \Omega^{[\Gamma]}$  is the polynomial order of Parts IX and XIV.  $\mathbf{E}$  is the hereditary term order (source 34’s and source 35’s  $\mathcal{E}$ ; this report’s  $\mathcal{E}_\kappa$  and  $\mathcal{E}$  are different objects) and  $\mathbf{E}(A)$  its version over a base  $A$ .  $A \hookrightarrow B$  is an order embedding,  $A \preceq_{\text{init}} B$  an initial one,  $A \not\hookrightarrow B$  the absence of an embedding.

## XVI.1 The question and the contribution

There are two quite different senses in which an ordering can be longer than all ordinals. An ordinary set cannot carry a well-order longer than every ordinal: its order type is itself an ordinal. A proper class can carry such an ordering, and can carry many different ones. For example, tagging each ordinal with 0 and putting a new tagged endpoint above all of them gives  $\Omega + 1$ . Putting one entire tagged copy of the ordinals after another gives  $\Omega + \Omega$ . The endpoint or the first point of the second copy has a proper class of predecessors. That is the precise structural change.

The purpose of this paper is not to postulate an absolute ordinal above all ordinals. It is to organize the well-orders already expressible as class relations, determine which operations are legitimate, and identify what limits their notation. A formula defining a relation, a proof that it is well-ordered, an isomorphism to another presentation, and a uniform procedure ranging over all definitions are different mathematical objects. Much of the difficulty lies in keeping these objects separate.

### XVI.1.1 Relation to the inspected ProveIt material

We inspected the ProveIt repository at commit `e1d2f3048b947801873a6e9ddc4e03736234b328`. The principal source is the consolidated report *Lexicographic Orders of Well-Orderings of the Surreal Numbers*, especially its treatment of canonical blocks, polynomial presentations, and Source 29’s canonical-history equivalence [77]. Its status ledger explicitly leaves the theory over GB open after establishing the corresponding equivalence over GBC. The present paper supplies the missing choice-free polynomial argument and checks the remaining dependencies. The theorem applies to arbitrary supplied class well-orders, not only to a surreal carrier.

[merge] Source 34 read this report at commit `e1d2f3048`, where `article.tex` (blob `72eee5cc8`) is the text of Parts I–XV that this write extends. Its “Source 29’s canonical-history equivalence” is [theorem 108.19](#), and “its status ledger explicitly leaves the theory over GB open” refers to [note 108.4](#), to item (b) of [section 112](#) and to [research question 113.111](#). The third row of the table below is [theorem XVI.5.8](#).

The repository also contains work on omnific notation and definable surreal numbers. Those directions concern additional algebraic structures or definability of individual numbers. Here the objects are order presentations. In particular, a formal symbol  $\Omega$  in this paper does not designate a surreal larger than every ordinal surreal. There is no such surreal in the usual class of surreal numbers, since each surreal is set-coded and has an ordinal birthday.

| Result                                              | Status in this paper                                            | Foundational scope                                                    |
|-----------------------------------------------------|-----------------------------------------------------------------|-----------------------------------------------------------------------|
| Set-like boundary and one-step division by $\Omega$ | Established structure; included with proofs                     | GB                                                                    |
| Finite-support power is a class well-order          | Choice-free refinement of the repository proof                  | GB; full subclass-minimum definition                                  |
| Canonical histories $\iff$ CWO                      | Repository equivalence lowered from GBC to GB                   | Arbitrary class carriers                                              |
| Hereditary $\Omega$ normal forms                    | Proper-class development of a standard ordinal-notation pattern | Explicit finite syntax; GB suffices                                   |
| Uniform-family diagonal and truth-relative growth   | Proved synthesis; priority not asserted                         | Supplied uniform family; full truth required for truth specialization |
| Definable spectral cofinality                       | Proved external model-theoretic synthesis                       | Transitive $\beta$ -model; named global well-order                    |

The most direct answer to a repository open question is the change of base theory in the third row. The other developments provide a systematic framework for constructing, interpreting, and bounding long notations. The much broader problem of whether strong class-well-order comparability implies ETR is not solved here. Hamkins and Woodin formulate that question explicitly; the sources checked during preparation did not provide a verified later resolution [27, Theorem 6 and Question 7]. This is a dated literature-status statement, not a proof that no resolution exists.

### XVI.1.2 What “farther” will mean

For class well-orders  $A, B$ , write  $A \hookrightarrow B$  if there is a class order embedding and  $A \preccurlyeq_{\text{init}} B$  if an embedding has an initial range, allowing the whole range. We use  $A \cong B$  for a class isomorphism. The claim that  $B$  is strictly longer than  $A$  is strongest when  $A$  embeds as a proper initial segment of  $B$ . A construction that contains  $A + 1$  as a suborder also proves  $B \not\hookrightarrow A$ , even when initial-segment comparability is unavailable. We specify which conclusion is proved rather than silently identifying the two relations.

In a sufficiently large external universe, a class model can itself be set-sized. Its internally proper class orders then have ordinary external ordinal lengths. This supplies precise numerical calibrations, but those external ordinals are not new ordinals of the original model.

### XVI.1.3 Source 35: scope, results, and their provenance

There is a coherent arithmetic of well-ordered classes that continue past the order  $\text{Ord}$ . Its objects should be understood as ordered presentations, and its equality should be understood as the existence of an appropriate class isomorphism. This immediately permits  $\text{Ord} + 1$  without asserting the existence of a set ordinal larger than every ordinal. The new final point is a tagged set in a class carrier; its predecessor class is proper. This distinction is the starting point for everything that follows.

The question “how far beyond  $\text{Ord}$ ?” has several answers. Explicit finite syntax reaches sums, products, class powers, and an exponential fixed point containing every finite tower of  $\text{Ord}$ -powers. Given a fixed point, one can construct another strictly above it. A uniformly coded family with a supplied well-ordered index class always has a strict upper bound for ordinary suborder embeddability, so no such family is cofinal among all class well-orders. In ambient ZFC, for strongly inaccessible  $\kappa$ , the full two-sorted model based on  $V_\kappa$  has external upper boundary  $\kappa^+$ , while a family restricted to first-order definitions occupies a bounded part of that spectrum. None of these statements identifies a last class ordinal.

The main results fall into three groups. First, we give an explicit arithmetic with proofs requiring only predicative class comprehension and class Replacement. Second, we connect the repository’s canonical condensation machinery with fixed-point completion. Third, we quantify the obstruction to one all-purpose definable notation system. The axioms used in the second and third groups are specified separately: an explicit constructor being elementary is a much weaker assertion than every class well-order having a comparable canonical presentation.

#### XVI.1.3.1 What is inherited, and what is developed here

The relevant ProveIt source is the maintained *surreal-well-orders* article, inspected at commit `f158f27b46bd1efb5a771ffc3c07e64eea970501`, dated 4 October 2026 [78]. Its polynomial orders and canonical histories are directly relevant even though the surrounding report also studies lexicographic orders of labelled well-orders. This paper studies the individual well-order presentations themselves.

| Topic                | Inspected prior development                                          | Role in this article                                     |
|----------------------|----------------------------------------------------------------------|----------------------------------------------------------|
| Set-interval blocks  | Repository Theorem 52.3 gives an elementary canonical decomposition. | Reproved briefly and expressed as division by $\Omega$ . |
| Polynomial histories | Repository Theorem 53.4 gives explicit histories for $P(\Gamma)$ .   | Used as the arithmetic model for normal forms.           |

| Topic                       | Inspected prior development                                                                                   | Role in this article                                                                                                   |
|-----------------------------|---------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------|
| Finite normal forms         | Repository Theorem 108.16 obtains an initial polynomial image from a supplied history.                        | Proof checked and included, with its choice assumptions isolated.                                                      |
| Comparability and histories | Repository Theorem 108.19 proves $\text{CWO} \leftrightarrow \text{CTH}$ over $\text{GBC}$ .                  | Strengthened to $\text{GB}$ using the new direct minimization proof.                                                   |
| Class epsilon notation      | Class-order notation for $\varepsilon_{\text{Ord}+1}$ occurs in Rathjen’s work, as recorded by Jeon [89, 88]. | A hereditary $\Omega$ -polynomial presentation is developed explicitly, without a priority claim for epsilon notation. |
| Fixed-point completion      | Not located in the inspected repository development.                                                          | A local equivalence and the global principle $\text{FPE}$ are proved here.                                             |
| Uniform definability        | General truth and coding obstructions are classical.                                                          | A strict successor-sum bound and a fixed-complexity separation theorem are proved here.                                |

The repository identifies its relevant additions as unrefereed and not machine formalized. We therefore supply proofs of the machinery needed for the extensions, rather than treating a manuscript label as a proof certificate. The results called extensions are new relative to the inspected development; this statement is deliberately narrower than a claim of first discovery in the literature. In particular, the article does not claim a solution to the general reverse-mathematical problem asking whether  $\text{CWO}$  implies  $\text{ETR}$ .

### XVI.1.3.2 A precise reading of the choice-free improvement

The repository explicitly retains the question of the strength of canonical histories over  $\text{GB}$  without Global Choice. The improvement proved below addresses this boundary: the same four-way characterization already holds over  $\text{GB}$ . This identifies the history principle with strong comparability in that weaker base. It does *not* prove either principle outright in  $\text{GB}$ , give a complete independence classification, or remove Choice from every theorem about orders of the entire surreal carrier. Transporting arbitrary proper carriers to one fixed carrier is a separate use of Global Choice.

Over  $\text{GBC}$ , the key local result concerning fixed points can be read independently of any universal comparison principle. For a supplied well-order  $W$ , one specific initial embedding  $W \preceq_{\text{init}} P(W)$  is enough to construct a fixed-point extension of  $W$ . Conversely, a fixed-point extension provides this embedding. Thus a question about completing one order has a concrete structural certificate.

[merge] Source 35 read this report at commit `f158f27b4`, with the same `article.tex` (blob `72eee5cc8`) and `README` as source 34. Its “repository Theorems 52.3, 53.4, 108.16 and 108.19” are [theorems 52.3](#), [53.4](#), [108.16](#) and [108.19](#), with these numbers; “its Part XIV explicitly leaves the corresponding question over  $\text{GB}$  without Global Choice open” refers to [note 108.4](#) and [section 112](#) (b). Its attribution of class epsilon notation to Rathjen through Jeon’s note is recorded as source 35 states it; the status of its 2026 citations is in [section 1.11](#).

### XVI.1.4 Source 32: the question and the scope of the answer

The expression “longer than  $\text{Ord}$ ” becomes meaningful as soon as one stops requiring every predecessor segment of a well-order to be a set. For example, take two disjoint copies of  $\text{Ord}$ , place the first entirely before the second, and compare ordinals normally within each copy. Every nonempty admitted subclass has a least point, but the first point of the second copy has a proper class of predecessors. This is a legitimate class well-order, not a new von Neumann ordinal.

We write

$$\Omega = (\text{Ord}, <)$$

for this *order presentation*. An expression such as  $\Omega^{[\Omega]}$  will denote a specifically defined class of sets with a specifically defined ordering. It will never mean that  $\text{Ord}$  has become an element of the set universe. Likewise, a variable  $W$  denotes a supplied class relation and its domain, not an element of a class of all proper-class order types.

There are three different questions behind the user’s problem. Which long orders have explicit definitions in a weak class theory? Which recursive operations can that theory perform along those orders? And, relative to a specified model and a specified meaning of “definable”, which external ordinal lengths can its class presentations realize? These questions have different answers. A large presentation need not support strong recursion, and an externally available isomorphism need not be an admitted class.

#### XVI.1.4.1 Main results and their provenance

The constructions of sums, products, and finite-support powers in [section XVI.3.4](#) are presentation-level extensions of ordinary ordinal arithmetic. The set-like boundary and the distinction between arbitrary and initial embeddings are foundational facts, not proposed discoveries. The repository already develops least-representative set-interval blocks and explicit polynomial condensation examples [\[79, 80\]](#). We reprove the ingredients needed here and use them to sharpen the structural picture.

The principal additional results proved in this manuscript are the uniform diagonal theorem ([note XVI.7.14](#)), the conditional termination bound for general condensation ([note XVI.5.20](#)), and the definability-ceiling and exact truth-presentation theorems ([theorems XVI.8.9](#) and [XVI.8.12](#)). These are mathematical contributions of this treatment in the sense that complete arguments are supplied here. Their historical novelty has not been established. The condensation theorem answers the repository’s termination question under an explicit recursion hypothesis, while leaving the exact strength of hierarchy existence open.

*Remark XVI.1.1* ([merge]; source 32’s termination theorem is source 20’s). The sentence of source 32 above, “The condensation theorem answers the repository’s termination question under an explicit recursion hypothesis, while leaving the exact strength of hierarchy existence open”, is stale on both counts, and is kept on record with the following correction. This report proved the termination theorem before source 32 was written: source 20’s [theorem 108.1](#) (Part XIV) shows over GB that a supplied nested history of  $W$  on the schedule  $W + 1$  ends in the singleton of the least point, and names elementary transfinite recursion along  $W + 1$  as a sufficient existence hypothesis; source 29 proves it again ([note 108.11](#)), and so do sources 34 and 35 ([lemma XVI.5.2](#) and [note XVI.5.13](#)). Source 32’s [note XVI.5.20](#) is the same theorem for its hierarchies of equivalence relations, which define exactly the same stages as nested histories ([remark XVI.5.24](#)). The question source 32 read (23-termination-RESEARCH\_STATUS.md, source 23’s status file, unchanged since it was staged) predates Part XIV; source 32 did not read Part XIV, whose status note records it as answered. The “exact strength of hierarchy existence” is answered as well: over GBC it is strong comparability CWO (source 29, [theorem 108.19](#)), and over GB likewise ([theorem XVI.5.8](#) and [note XVI.5.19](#)). Only whether CWO implies ETR remains open ([section 113.28](#)). Source 32 itself asserts no priority (its research status and [section XVI.11.3](#)).

The repository inspection was targeted rather than exhaustive. The relevant research-status file explicitly distinguishes its GBC polynomial examples from a general termination theorem. The merged report identifies the source as manuscript 23, with its condensation material incorporated

into the larger surreal well-order study [79, 80]. We do not certify the other manuscripts in that collection.

#### XVI.1.4.2 Conventions about foundations

Our default theory is GBC: Gödel–Bernays class theory with Global Choice and a ZFC set part. Every member of a class is a set. A class relation can therefore be coded by a class of ordered pairs or tuples of sets. Class parameters in elementary comprehension are allowed, but quantification over classes inside that comprehension is not.

When a statement is made in a model  $(M, \mathcal{X})$ , “class” means an element of the admitted class collection  $\mathcal{X}$ . This is especially important for well-foundedness and isomorphisms. Sections [section XVI.8.6](#) and [section XVI.8.7](#) explicitly change viewpoint to an external ZFC metatheory with a strongly inaccessible cardinal. Their ordinal spectra are external sets of ordinals; they are not same-level class quotients in GBC.

### XVI.1.5 Source 33: the problem and the principal results

#### XVI.1.5.1 What does “longer than Ord” mean?

Write

$$\Omega = (\text{Ord}, \in)$$

for the class well-order of all set ordinals. The symbol  $\Omega$  is an abbreviation for an order presentation, *not* a new set and not an ordinal of the same universe. The tagged disjoint union  $\Omega + 1$  is a perfectly legitimate class well-order. Its last point has a proper class of predecessors. This is precisely why the usual theorem assigning an ordinal to every *set* well-order does not collapse  $\Omega + 1$  to a set ordinal or to  $\Omega$ .

There are several different questions hidden in the request to go beyond Ord:

- (i) Which longer orders can be constructed by explicit formulas?
- (ii) Which arithmetic operations preserve class well-foundedness?
- (iii) When can two arbitrary class well-orders be compared by an initial embedding?
- (iv) How does the answer depend on allowed parameters, truth predicates, and the surrounding class model?
- (v) Can all relevant orders be organized into one uniform notation system?

The answers are not interchangeable. In particular, constructing  $\Omega^{[\Omega]}$  is much easier than producing a uniform comparison procedure for arbitrary class well-orders. The literature on class recursion makes this separation explicit [27, 22, 84].

#### XVI.1.5.2 A map of the results proved here

The article’s main statements are the following.

##### Structural and definability results.

**Canonical division.** Every class well-order  $W$  has a canonical presentation

$$W \cong \Omega \cdot Q + \alpha,$$

where  $Q$  is a class well-order and  $\alpha$  is a set ordinal ([note XVI.3.11](#)).

**Finite digits.** An exhausting, uniformly supplied set-interval condensation tower indexed by  $\Gamma + 1$  yields an order embedding

$$W \longrightarrow \Omega^{[\Gamma]}$$

whose values have finite support ([theorem XVI.5.27](#)).

**Definability diagonal.** At every fixed finite syntactic level  $n$ , a parameter-free-in- $(\in, G)$  order  $D_n$  dominates every set-parameter  $\Sigma_n(G)$  presentation, and  $D_n$  embeds into none of those orders ([theorem XVI.7.20](#)).

**External height.** Over  $V_\kappa$  with  $\kappa$  inaccessible, the supremum  $\delta_G$  of the  $G$ -definable well-order types satisfies

$$\kappa < \delta_G < \kappa^+, \quad \text{cf}(\delta_G) = \omega, \quad \delta_{G,T} > \delta_G$$

when  $T$  is truth for  $(V_\kappa, \in, G)$  ([note XVI.8.16](#) and [theorem XVI.8.19](#)).

The most important common mechanism is *uniformity*. A class-indexed family of class relations is usable when one class of tuples gives all its sections. A metatheoretic collection of individually definable relations does not automatically have such a code. The difference accounts both for positive constructions and for diagonal obstructions.

### XVI.1.5.3 Relationship with ProveIt and the literature

The targeted repository review used the main README, the surreal research catalogue, and the guide to `Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/` [82, 83, 80]. The latter guide describes twenty-three merged manuscripts and an 860-page report. It explicitly separates unrefereed research text from formalized Lean results. Its later parts already contain class-order and transfinite condensation material. Therefore neither the existence of orders beyond Ord nor the general idea of an arbitrarily long condensation hierarchy is claimed here as a new contribution to the repository.

This manuscript takes a different organizing route: intrinsic class-order arithmetic, canonical division, finite digits, and the relationship between syntactic complexity and attainable order lengths. Its proofs are self-contained except for clearly cited foundational background. The repository review was targeted, not a line-by-line audit of the full merged report, and it does not establish absence of overlapping arguments elsewhere in the repository.

Three literature interfaces matter particularly. First, class comparison is part of the reverse mathematics of elementary transfinite recursion [27]. Second, truth predicates and their iterations are genuine class-existence principles rather than harmless uniform notation [22, 24]. Third, unrolling and class-theoretic potentialism supply ways to study external order heights while retaining the distinction between sets and classes [35, 84, 28]. The results below are not presented as solutions of the published comparison/recursion problems.

[merge] (4 October 2026.) Source 33's description of the guide was accurate at its reading (README blob d2e24b58, unchanged from e50dde15b to this write); with this Part the report merges twenty-seven manuscripts. The finite-digit embedding announced in the box above is in fact initial: it is the normal-form map of Part XIV ([remark XVI.5.29](#)).

## XVI.2 Foundations: classes, definability, and well-foundedness

### XVI.2.1 The base theories and the object language

We use the two-sorted formulation of Gödel–Bernays theory. Sets are members of classes; proper classes are not members of other classes. Elementary comprehension permits formulas with set quantifiers and supplied class parameters. Class Replacement says that the image of a set under a class function is a set. The notation **GB** here includes the usual ZF set axioms but does not assume Global Choice; none of the choice-free proofs below needs a choice axiom for arbitrary sets. **GBC** adds a global choice function, equivalently in this setting a set-like global well-order. The letter  $G$  will denote such a well-order when one is used.

A class relation on  $X$  is represented by a class of coded pairs of sets. One relation suffices to code a family: its section at a set index  $i$  is a class. This does not turn the family into a class whose members are themselves proper classes. Appended endpoints and sums use tagged sets, such as  $(0, x)$  and  $(1, \emptyset)$ . An arbitrary carrier can already equal the whole universe, so an untagged “new set outside the carrier” is not a legitimate general construction.

**Definition XVI.2.1** (Class well-order). A class well-order is a strict linear order  $<_W$  on a class  $X$  such that every nonempty admitted subclass of  $X$  has a least member. A relation is *set-like* if the predecessors of each individual point form a set.

The word “admitted” refers to the class part of the model. An internal class well-order is not automatically externally well-founded when the model is set-sized. A transitive model of class theory is a  $\beta$ -model if its assertions of class well-foundedness are externally correct. We invoke this extra hypothesis when taking external order types.

Over **GBC**, class well-foundedness is equivalent to the absence of a set-coded infinite descending sequence. Given a subclass without a least point, use  $G$  to select a predecessor repeatedly; ordinary recursion on  $\omega$  and Class Replacement produce a descending set sequence. Conversely, the range of a descending sequence has no least member. This standard distinction is discussed in [22, 27]. Over **GB** alone we retain the subclass-minimum definition and do not use the reverse implication without an additional selection argument.

**Lemma XVI.2.2** (A first-order criterion for linear orders). *In **GB**, a class linear order is a class well-order if and only if every nonempty set subset of its domain has a least point. Consequently a common class linear order has absolute well-foundedness between two **GB** realizations with the same sets.*

*Proof.* Only the reverse implication needs proof. Suppose a nonempty admitted subclass  $C$  has no least point. Below any  $x \in C$ , take the least ordinal  $\rho$  such that  $C_{<x} \cap V_\rho$  is nonempty, and then take the order-least point of that set. The hypothesis supplies this latter minimum, so the selected predecessor is unique. Starting from any one point of  $C$ , ordinary set-valued recursion yields an infinite descending sequence. Its range is a set subset with no least point, a contradiction. The criterion quantifies only over sets and the given relation; hence it is unchanged in a same-set class extension.  $\square$

This lemma is specific to linear orders: their set-sized restrictions provide unique choices. It does not silently identify the set-subset criterion with absence of descending sequences in arbitrary choiceless settings.

## XVI.2.2 Four meanings of definable

The formulas defining a class order can have no parameters, set parameters, ordinal parameters, or specified class predicates. These give different spectra. An order defined from a truth class is not thereby definable in the pure language of set theory. Nor does the fact that each member of an external list is definable give one formula that evaluates every definition in that list.

The principal elementary constructions preserve their input parameters. If  $A$  and  $B$  are defined using  $p$ , their tagged sum, product, and finite-support power are defined using  $p$ . Our hereditary  $\Omega$  system uses no extra predicate: its terms are finite trees with ordinal labels. The diagonal theorem later uses a uniform relation already supplied, while its truth specialization explicitly enlarges the language.

For a ZFC-only presentation, each such construction can be read as a metatheoretic scheme about specified defining formulas. Statements quantifying over all classes, such as CWO, require a class theory or an external interpretation. A universal internal predicate that evaluates every pure set-theoretic definition cannot be assumed.

## XVI.2.3 Induction is not the same as class-valued recursion

Induction along a supplied class well-order is elementary: if the class of failures of an elementary property were nonempty, its least member would contradict the induction step. This proves uniqueness and many structural assertions. It does not create an unknown class-valued history. A history satisfying

$$S_i = \{x : \varphi(x, S \restriction i, A)\}$$

is a new class whose sections may all be proper classes. The principle ETR asserts the existence of such solutions along class well-orders. Even a length- $\omega$  class-valued recursion can require more than GBC, as the recursive construction of a full truth predicate shows. In contrast, recursion on a finite tree, or on  $\omega$  with uniquely specified set values, is available in the elementary arguments below.

## XVI.2.4 Source 35: foundations and the meaning of length

### XVI.2.4.1 The base theory and class parameters

Throughout the choice-free results, GB means the two-sorted Gödel–Bernays theory with ZF for sets, elementary class comprehension allowing class parameters, and class Replacement. No form of Choice is built into this notation. We write GBC for its extension by Global Choice. This convention is stated because authors differ on whether the abbreviation GB includes set Choice. KM denotes Kelley–Morse class theory; any additional choice or collection principle will be named when used.

A *class presentation*  $W = (X, <_W)$  consists of a class of sets and a class relation on those sets. In a model  $(M, \mathcal{X})$ , all the classes mentioned belong to  $\mathcal{X}$ . A class is never silently an element of another class. Expressions involving families of classes mean one class of tuples with set-valued indices.

*Note XVI.2.3* (Source 35, Definition 2.1, “Class well-order”). A *class presentation*  $W = (X, <_W)$  is a *class well-order* if  $<_W$  is a strict linear order and every nonempty admitted subclass of  $X$  has a least element. It is *set-like* if, for every  $x \in X$ , the predecessor class  $W_{<x} = \{y \in X : y <_W x\}$  is a set. This is source 34’s [definition XVI.2.1](#); source 35 calls the pair  $(X, <_W)$  a *class presentation*, a class of sets with a class relation.

The word “admitted” matters in model-theoretic discussions. The internal assertion is interpreted using the model’s sets and classes. In an external full model the quantification includes every subset

of the carrier. For fixed relations on a fixed set universe satisfying the usual choice assumptions, well-foundedness has a first-order description by absence of a set-coded descending sequence. Consequently one should not claim that changing only the class collection in two same-set GBC realizations automatically changes well-foundedness. The later formalization section explains the distinct issue of a transitive set model being externally wrong because it is missing a descending sequence as a *set*.

*Note XVI.2.4* (Source 35, Proposition 2.2, “The exact boundary of set-likeness”). *In GB, a set-like class well-order is isomorphic to a set ordinal if its carrier is a set, and to Ord if its carrier is proper. Every proper-class well-order has an initial subclass isomorphic to Ord. If it is not set-like, it has an initial subclass isomorphic to Ord + 1.* This is source 34’s [theorem XVI.3.1](#) (Section XVI.3), by the same proof: the rank  $x \mapsto \text{otp}(W_{<x})$  maps onto an initial subclass of Ord, which is all of Ord for a proper carrier by Class Replacement applied to the inverse; the points with set-sized predecessor classes form the initial copy of Ord, and its first successor caps a copy of Ord + 1. Source 35 adds that the rank function is elementary because the isomorphism certifying each value is a set. Sources 32 and 33 prove it as [notes XVI.2.9](#) and [XVI.2.14](#); in this report it is the class-carrier form of source 11’s canonical initial part ([theorem 15.1](#)) and of the first block of [theorem 52.3](#).

#### XVI.2.4.2 Two notions of comparison

An order embedding is an injective class map preserving and reflecting the strict order. Write  $A \hookrightarrow B$  if one exists. Write  $A \preceq_{\text{init}} B$  if an embedding exists whose image is an initial subclass of  $B$ ; the entire target is allowed. Write  $A \prec_{\text{init}} B$  if its image is proper. When we say that one order is *longer* without further qualification, we mean this proper-initial-segment comparison.

The existence of an arbitrary suborder embedding is weaker as a *witness*: it need not itself identify an initial segment. Under strong class-well-order comparability, the two usual comparisons can be related as for set ordinals. We do not assume that principle while constructing elementary examples. A class isomorphism, denoted  $\cong$ , must be a class available in the chosen formalization.

**Lemma XVI.2.5** (Rigidity and the successor obstruction). *In GB, every order embedding  $f : W \rightarrow W$  of a class well-order into itself is inflationary:  $x \leq_W f(x)$ . There is no embedding  $W + 1 \hookrightarrow W$ . Between two class well-orders there is at most one isomorphism onto an initial subclass.*

*Proof.* If the class of counterexamples to inflationarity is nonempty, let  $x$  be its least element. From  $f(x) < x$  and order preservation,  $f(f(x)) < f(x)$ , contradicting minimality. If an embedding of  $W + 1$  into  $W$  maps its final point to  $a$ , its restriction  $f$  to  $W$  satisfies  $a \leq f(a) < a$ , again impossible. For uniqueness of initial isomorphisms, a least point of disagreement would have two different images with exactly the same predecessor class in the target; strict linearity forbids this.  $\square$

This elementary obstruction replaces several tempting but unjustified appeals to a universal ordinal rank for class well-orders.

[merge] The first two assertions of the lemma are source 34’s [lemma XVI.3.2](#) (Section XVI.3), proved in the same way, and sources 32 and 33’s [notes XVI.2.10](#), [XVI.2.15](#) and [XVI.2.16](#); source 35’s [note XVI.7.7](#) is a second proof of the second. The third, uniqueness of an initial-segment isomorphism, is stated as a lemma only here; source 34 uses it after [corollary XVI.6.8](#) and source 32 notes it after [note XVI.2.10](#). It is printed whole because [theorem XVI.6.17](#) uses it.

### XVI.2.4.3 The symbol $\Omega$ and the absence of a paradox

We use  $\Omega$  as a typographical symbol for the *presentation*  $(\text{Ord}, \in)$  when it occurs in class-order arithmetic. It is not a member of  $\text{Ord}$ . For example, a carrier for  $\Omega + 1$  is

$$(\{0\} \times \text{Ord}) \cup \{(1, 0)\},$$

with every point of the first tagged copy below the final point. The pair  $(1, 0)$  is a set. Its predecessor class is proper. A carrier for  $\Omega \cdot \Omega$  is  $\text{Ord} \times \text{Ord}$ , ordered by the second coordinate first and by the first coordinate within each block. Neither construction asks for a set containing all ordinals.

Similarly,  $\Omega^{[\Gamma]}$  below is a class of *finite set codes*. An exponent label  $i \in \Gamma$  is a set, even when its predecessor class in  $\Gamma$  is proper. The exponent label need not be an ordinal. Finite support is what makes the object a legal set code.

*Remark XVI.2.6* (Set-valued and class-valued recursion). A recursion on  $\omega$  whose next value is a uniquely specified set can be carried out in GB with supplied class parameters. One takes finite approximations and uses class Replacement to obtain the set-coded sequence. A recursion on  $\omega$  whose stages are newly constructed *classes* is different: GB does not in general supply one class coding the entire sequence. The Tarskian recursion for truth is the familiar warning. The finite-trace constructions in this paper repeatedly use the former fact and never assume the latter without a stated principle [24].

### XVI.2.5 Source 32: well-ordering, set-likeness, and comparison

*Note XVI.2.7* (Source 32, Definition 2.1). A class well-order is a strict linear order  $<_W$  on a class  $\text{dom } W$  such that every nonempty admitted subclass of  $\text{dom } W$  has a least element; it is set-like when  $W_{<x} = \{y \in \text{dom } W : y <_W x\}$  is a set for every  $x \in \text{dom } W$ . An embedding preserves and reflects the strict order; an initial embedding additionally has an initial-segment image. One writes  $A \hookrightarrow B$  and  $A \preceq_{\text{init}} B$  only when the witnessing map is an admitted class. This is [definition XVI.2.1](#) with the two comparison relations of source 34's Section 1.2 (XVI.1.2). Source 32 writes  $D_W$  for the domain of  $W$ , printed  $\text{dom } W$  here, because  $D_W$  is the condensation operator of Parts IX and XIV and of Section XVI.5; it writes  $\preceq_e$  and  $\preceq_i$  for  $\hookrightarrow$  and  $\preceq_{\text{init}}$ .

In GBC the apparently second-order well-order condition has an elementary test in the supplied class parameters. The following familiar equivalence is also used in the class-order literature [27].

**Lemma XVI.2.8** (The descending-sequence test). *For a strict linear class order  $W$ , the following are equivalent: every nonempty admitted subclass has a least point; every nonempty set subset has a least point; and there is no set function  $f : \omega \rightarrow \text{dom } W$  with  $f(n+1) <_W f(n)$  for every  $n$ .*

*Proof.* The first assertion implies the second. A descending sequence has a set range with no least point, so the second implies the third. Conversely, let  $S$  be a nonempty admitted subclass with no least point. Fix a set-like global well-order of the universe. Choose its least point in  $S$  as  $f(0)$ ; after choosing  $f(n)$ , choose the globally least element of  $S$  below  $f(n)$  in the  $W$  order. Recursion of length  $\omega$  with set values and class parameters, followed by Class Replacement, gives a set function  $f$ . It is descending. This is ordinary set-valued recursion, not class-valued elementary transfinite recursion.  $\square$

[merge] Source 32's [lemma XVI.2.8](#) is the GBC equivalence already printed in Part IX (source 15's paragraph "Exactly where recursion principles enter" in [section 57.4](#)) and stated by source 33 as [note XVI.2.12](#); source 35 recalls it in Section XVI.8 (its Section 9.3) and source 34 in [theorem XVI.7.4](#)'s preamble. Over GB without global choice, source 34's [lemma XVI.2.2](#) gives the

equivalence of the first two clauses for linear orders; the third clause, absence of descending set sequences, is not claimed there to be equivalent without choice.

Consequently, validity of a supplied class-order presentation can be tested by a first-order formula with its domain and relation as class parameters. This fact will later let us filter invalid fibers of a uniformly presented family without impredicative class comprehension.

*Note XVI.2.9* (Source 32, Theorem 2.3, “The exact set-like boundary”). *Every set-like class well-order is isomorphic either to a set ordinal or to  $\Omega$ . Moreover, every proper-class well-order has a canonical initial segment isomorphic to  $\Omega$ , namely  $I_W = \{x \in \text{dom } W : W_{<x} \text{ is a set}\}$ . This is source 34’s [theorem XVI.3.1](#) and source 35’s [note XVI.2.4](#), by the same rank collapse and the same least point outside  $I_W$ ; source 32 works in GBC, although the proof uses no choice.*

This gives the precise answer to the first threshold question: longer orders are possible exactly because they are not set-like. No additional element of Ord, and no inconsistency, is involved.

*Note XVI.2.10* (Source 32, Lemma 2.4, “No self-compression”). *If  $W$  is a class well-order, no admitted embedding  $W + 1 \rightarrow W$  exists; every admitted self-embedding  $f : W \rightarrow W$  satisfies  $x \leq_W f(x)$ . This is source 34’s [lemma XVI.3.2](#). Source 32’s proof takes the least  $x$  with  $f(x) <_W x$ , puts  $y = f(x)$ , and derives  $y \leq_W f(y)$  from minimality and  $f(y) <_W f(x) = y$  from order preservation; for  $W + 1$ , the image  $a$  of the new point satisfies  $g(a) <_W a$  for the restriction  $g$ .*

Uniqueness of an initial-segment isomorphism follows from the same least-disagreement argument. Existence is another matter: GBC does not permit one simply to collect all class partial isomorphisms and take their union. That proposal uses quantification over classes inside the proposed defining formula. Under ETR, class well-orders are comparable by initial embeddings [27]; our explicit constructions below do not assume this comparison principle.

## XVI.2.6 Source 33: foundations, well-foundedness, and size

### XVI.2.6.1 The base theory and the meaning of a class presentation

Our default base theory is GBC: Gödel–Bernays set theory with global choice, including the usual set axioms of ZFC. Set variables range over sets; class variables range over the available classes. Elementary class comprehension permits formulas with set quantifiers and named class parameters. Class replacement says that the image of a set under a class function is a set.

A *class order presentation* is a pair  $(D, R)$  of classes, with  $R \subseteq D \times D$ . Elements of  $D$  are always sets. A function between presentations is represented by a class graph of ordered pairs of sets. An isomorphism type will be discussed externally or by comparing presentations; we do not form an internal class whose elements are proper-class relations.

Global choice supplies a set-like global well-order  $G$  of  $V$ , which we fix when needed. Its restriction to any nonempty class has a least point. This last assertion follows by choosing one point, intersecting the class with its set-sized  $G$ -initial segment, and applying ordinary set well-ordering.

*Note XVI.2.11* (Source 33, Definition 2.1). *A class well-order is a linear class order for which every nonempty available subclass has a least element; it is set-like if every proper principal initial segment  $D_{<x} = \{y \in D : yRx\}$  is a set. This is [definition XVI.2.1](#); source 33 writes a presentation as a pair  $(D, R)$  of classes.*

There is an important first-order test for this definition. The equivalence below is standard in the class-recursion literature [27, §3]; the proof records exactly the use of choice and replacement needed later.

*Note XVI.2.12* (Source 33, Lemma 2.2, “The descending-sequence test”). *For a linear class order  $R$  on  $D$ , the following are equivalent in GBC: (a) every nonempty available subclass of  $D$  has a least*

point; (b) every nonempty set subset of  $D$  has a least point; (c) there is no set function  $f : \omega \rightarrow D$  with  $f(n+1)Rf(n)$  for all  $n$ . Consequently well-orderhood is expressible by a first-order formula with  $D, R$  as class predicates. This is source 32's lemma XVI.2.8, by the same argument: from a subclass  $C$  without least point, choose  $x_0 \in C$  and then the  $G$ -least member of  $\{y \in C : yRx_n\}$ ; finite approximations define the  $n$ th value by an elementary formula, and Class Replacement on  $\omega$  collects the values into a set function. Source 33 stresses that only an ordinary set-length sequence of sets is constructed, with no class-valued stages. Over GB, (a) $\Leftrightarrow$ (b) is source 34's lemma XVI.2.2. Remark XVI.2.13 (Internal versus external well-foundedness). The word “set” in note XVI.2.12 refers to the sets of the model under consideration. An external descending sequence need not belong to that model. Thus a general transitive class model can misjudge well-foundedness. The inaccessible-rank models used in section XVI.8.8 are verified separately to avoid this problem. We do not silently identify internal well-foundedness with external well-foundedness.

### XVI.2.6.2 Set-like orders stop at Ord

Note XVI.2.14 (Source 33, Proposition 2.4). *A set-like class well-order is isomorphic either to a set ordinal or to  $\Omega$ ; in particular a proper-class set-like well-order has type  $\Omega$ .* This is source 34's theorem XVI.3.1, by the ordinal collapse  $\rho(x) = \text{otp}(D_{<x})$ ; if its range is a proper initial segment of Ord, its least omitted ordinal bounds it, and Class Replacement applied to the inverse makes  $D$  a set.

An order beyond  $\Omega$  therefore needs at least one point with a proper class of predecessors. That requirement is not an inconsistency: it simply places the order outside the set-like case of note XVI.2.14.

### XVI.2.6.3 Embeddings, initial embeddings, and rigidity

Write  $A \hookrightarrow B$  if an available class order embedding  $A \rightarrow B$  exists, and  $A \preceq_{\text{init}} B$  if one exists with initial image. The first relation is enough for our diagonal results. We do not assume, in GBC, that arbitrary class well-orders admit an initial comparison.

Note XVI.2.15 (Source 33, Lemma 2.5, “Inflation of a self-embedding”). *If  $f : W \rightarrow W$  is an order embedding of a class well-order into itself, then  $x \leq_W f(x)$  for every  $x \in W$ .* This is the first assertion of source 34's lemma XVI.3.2, with the same least-counterexample proof.

Note XVI.2.16 (Source 33, Corollary 2.6, “The successor obstruction”). *For every class well-order  $W$ ,  $W \hookrightarrow W + 1$  and  $W + 1 \not\hookrightarrow W$ ; in particular, there is no greatest class well-order under embeddability.* The nonembedding is the second assertion of source 34's lemma XVI.3.2; source 33's proof restricts  $h : W + 1 \rightarrow W$  to  $W$  and applies note XVI.2.15 at  $a = h(\text{top})$ , and the empty  $W$  is immediate.

This proof is useful precisely because it needs neither a universal comparison theorem nor a class recursion along  $W$ .

## XVI.3 The boundary at $\Omega$ and elementary arithmetic

**Theorem XVI.3.1** (The set-like boundary). *In GB, every set-like class well-order is isomorphic either to a set ordinal or to  $\Omega$ . Every proper class well-order  $W$  has a canonical initial copy of  $\Omega$ , consisting exactly of its points with set-sized predecessor classes. If  $W$  is not set-like, it has an initial copy of  $\Omega + 1$ .*

*Proof.* For a set-like order define  $r(x) = \text{otp}(W_{<x})$ . Each value is a set ordinal, and  $r$  is an isomorphism onto an initial subclass of  $\text{Ord}$ . A bounded initial subclass is an ordinal; Class Replacement applied to the inverse map then makes the original carrier a set. An unbounded initial subclass is all of  $\text{Ord}$ .

For general  $W$ , let  $S$  consist of the points with set predecessor classes. It is an initial subclass and is set-like. If  $W$  is proper and  $S$  were a set, the complement would be nonempty and have a least point  $b$ . Its predecessors would be exactly  $S$ , contradicting  $b \notin S$ . Thus  $S$  is proper and has type  $\Omega$ . If its complement is nonempty, its first point caps the claimed initial copy of  $\Omega + 1$ .  $\square$

This theorem excludes a set-valued increasing rank map from a genuinely longer class well-order into  $\text{Ord}$ . It does not exclude class rankings into another long order. In particular, assigning every point the set ordinal “number of its predecessors” would simply assume away the phenomenon being studied.

**Lemma XVI.3.2** (No backward self-embedding). *For a class well-order  $W$ , every class order embedding  $f : W \rightarrow W$  satisfies  $x \leq_W f(x)$ . There is no class order embedding  $W + 1 \rightarrow W$ .*

*Proof.* If  $f(x) <_W x$ , choose the least such  $x$ . Then  $f(f(x)) <_W f(x)$  makes  $f(x)$  an earlier counterexample. For an embedding of  $W + 1$ , let  $a$  be the image of its endpoint. The restriction to  $W$  would imply  $a \leq_W f(a) <_W a$ . The empty order is immediate.  $\square$

### XVI.3.1 Sums and products

Define  $A + B$  by tagged concatenation. Define  $A \cdot B$  on pairs  $(b, a)$ , comparing  $b$  first and then  $a$ ; thus it is  $B$  copies of  $A$ . More generally, a uniformly given family  $(A_b)_{b \in B}$  has a sum  $\sum_{b \in B} A_b$ . For a nonempty subclass of the sum, first choose the least occupied index and then the least point in that fiber. This proves well-ordering in GB without class choice. The coordinate maps prove, with explicit isomorphisms,

$$(A + B) + C \cong A + (B + C), \quad (A \cdot B) \cdot C \cong A \cdot (B \cdot C),$$

$$A \cdot (B + C) \cong A \cdot B + A \cdot C.$$

Commutativity and distribution of  $(A + B) \cdot C$  over its left summands are not asserted; set-ordinal examples refute them.

| Presentation          | Concrete model                                                | Distinguishing feature                                                           |
|-----------------------|---------------------------------------------------------------|----------------------------------------------------------------------------------|
| $\Omega + 1$          | Ordinals followed by a tagged endpoint                        | A proper-class predecessor segment with a final point                            |
| $\Omega \cdot 2$      | Two consecutive ordinal blocks                                | The second block has no last point                                               |
| $\Omega \cdot \omega$ | Countably many ordinal blocks                                 | Has a set-coded countable cofinal sequence                                       |
| $\Omega^2$            | Pairs of ordinals, outer coordinate first                     | Proper-class many ordinal blocks                                                 |
| $\Omega^{[\Omega]}$   | Finite ordinal-coefficient polynomials with ordinal exponents | Contains every $\Omega^\alpha$ , $\alpha \in \text{Ord}$ , as an initial segment |

In the last two lines the superscripts mean the finite-support construction defined below. A cofinal set in  $\Omega \cdot \omega$  does not collapse its carrier to a set: the initial segments bounded by that set can themselves be proper classes.

### XVI.3.2 Canonical division by $\Omega$

**Theorem XVI.3.3** (One-step block decomposition). *Every class well-order  $W$  has a canonical decomposition*

$$W \cong \Omega \cdot Q + \delta,$$

where  $Q$  is a class well-order and  $\delta$  is a set ordinal, possibly zero. The representatives and the isomorphism are elementary in  $W$ , and the construction is valid in GB.

*Proof.* Declare  $x \sim y$  when the closed interval between them is a set. The relation is an elementary, convex equivalence relation. Every block has a least point  $r$ , and each of its points has a set predecessor interval within the block. Its local rank  $\text{otp}([r, x))$  identifies the block with a set ordinal or with  $\Omega$ , by [Theorem XVI.3.1](#).

If a block were a set and not final, the class of points following it would have a least point  $z$ . The interval from the block's minimum to  $z$  would be that set with one point adjoined. This contradicts distinctness of the blocks. Let  $Q$  be the class of least representatives of all proper blocks, with the inherited order. There is at most one set block, and it is final; take its order type as  $\delta$ , or take  $\delta = 0$  if it does not exist. Local ranks give the displayed isomorphism uniformly.  $\square$

This is a canonical decomposition of a supplied order, not an automatic transfinite iteration of decompositions. The question whether all successive quotients can be supplied as one history is the subject of [Section XVI.5](#). The one-step construction and the polynomial examples already appear in [ProveIt \[77\]](#); they are included here to make the refinement self-contained.

[merge] [Theorem XVI.3.1](#) is source 35's [note XVI.2.4](#), source 32's [note XVI.2.9](#) and source 33's [note XVI.2.14](#); [lemma XVI.3.2](#) is source 35's [lemma XVI.2.5](#) (first two clauses), source 32's [note XVI.2.10](#) and source 33's [notes XVI.2.15](#) and [XVI.2.16](#). [Theorem XVI.3.3](#) is the canonical block decomposition of Part IX, proved there three times ([note 52.1](#): source 15's [theorem 52.3](#), source 16's [theorem 52.6](#), source 18's [theorem 52.11](#)), and here again by sources 35, 32 and 33 ([\(S35.8\)](#), [theorem XVI.3.6](#) and [note XVI.3.11](#)); source 34's remainder  $\delta$  is Part IX's  $\theta_R$  and source 35's  $\rho_W$ .

### XVI.3.3 Source 35: arithmetic of presented class well-orders; sums and products

The operations in this section act on *presentations*: a class of set-valued labels together with a class ordering relation. They do not turn proper classes into elements of a larger same-level class. Write  $\Omega$  for the presentation  $(\text{Ord}, <)$ . An expression such as  $\Omega \cdot \Omega$  denotes a specified class order; an equation between such expressions means a class order-isomorphism. All the direct constructions and their well-ordering proofs below work in GB, with the convention that a class well-order gives a least element to every nonempty available subclass. Global Choice is unnecessary for these results.

The repository already develops the ordinal-coefficient polynomial construction  $P(\Gamma)$  and uses it to analyze condensation histories [\[78\]](#). Here we place that construction inside a general arithmetic, allow arbitrary class well-ordered coefficients, and give a choice-free proof of well-foundedness. Class expressions of the form  $\text{Ord}^\Gamma$  also occur in the literature on elementary transfinite recursion [\[24, Section 9\]](#). The finite-support definition makes the meaning and the required resources explicit.

#### XVI.3.3.1 Sums and products

For class well-orders  $A$  and  $B$ , their sum  $A + B$  has the disjointly tagged domain

$$(\{0\} \times A) \cup (\{1\} \times B),$$

with every point of the first copy before every point of the second. Their product  $A \cdot B$  has domain  $A \times B$  and comparison

$$(a, b) < (a', b') \iff b <_B b' \text{ or } (b = b' \text{ and } a <_A a').$$

Thus  $A \cdot B$  consists of copies of  $A$  indexed by  $B$ . A nonempty subclass of the product has a least occupied  $B$ -coordinate, and its fiber there has a least  $A$ -coordinate. This proves the well-ordering claim without a recursion or any choice principle. The sum is even more immediate.

The same argument handles a *supplied uniform family*. More precisely, let  $I$  be a class well-order, let  $D \subseteq I \times V$  be a class, and let a class relation specify a well-order  $A_i$  on each fiber  $D_i$ . The tagged domain  $D$ , with the  $I$ -coordinate compared first, is the sum  $\sum_{i \in I} A_i$ . There is one class of pairs and one class comparison relation. No class whose members are the classes  $A_i$  is being formed. Choosing the least occupied index and then the least point of its fiber proves that this sum is well-ordered.

Reassociation and retagging give explicit isomorphisms

$$(A + B) + C \cong A + (B + C), \quad (\text{S35.1})$$

$$(A \cdot B) \cdot C \cong A \cdot (B \cdot C), \quad (\text{S35.2})$$

$$A \cdot (B + C) \cong A \cdot B + A \cdot C. \quad (\text{S35.3})$$

For example, the product reassociation sends  $((a, b), c)$  to  $(a, (b, c))$ ; both comparisons prioritize  $c$ , then  $b$ , then  $a$ . These verifications use only the displayed definitions, so there is no hidden comparison theorem for arbitrary class orders.

The direction in (S35.3) matters. The other distributive law already fails for set ordinals:

$$(1 + 1) \cdot \omega \cong \omega, \quad 1 \cdot \omega + 1 \cdot \omega \cong \omega + \omega.$$

The familiar noncommutativity of ordinal arithmetic persists as well. It is helpful to record the order of the factors before simplifying an expression.

### XVI.3.4 Source 32: ordinal arithmetic with explicit class presentations; uniform sums and products

#### XVI.3.4.1 Uniform sums and products

A family  $(W_i)_{i \in I}$  of class orders will always be *uniformly coded*: there are classes  $D$  and  $R$  such that

$$\text{dom } W_i = \{x : (i, x) \in D\}, \quad x <_{W_i} y \iff (i, x, y) \in R.$$

This is not a class function whose values are proper classes. Its elements are ordinary set tuples, and it is a legitimate object of GBC.

**Proposition XVI.3.4** (Uniform sum theorem). *If  $I$  is a class well-order and  $(W_i)_{i \in I}$  is a uniformly coded family of class well-orders, then*

$$\sum_{i \in I} W_i$$

*is a class well-order on the pairs  $(i, x)$  with  $x \in \text{dom } W_i$ , ordered first by  $i$  and then within the fiber.*

*Proof.* For a nonempty subclass of the sum, its occupied indices form an admitted nonempty subclass of  $I$ . Take the least occupied index and then the least point in that fiber. Both choices use elementary comprehension and the well-order hypotheses.  $\square$

The binary sum  $A + B$  is the two-fiber special case. The ordinal product  $A \cdot B$  is the sum of copies of  $A$  indexed by  $B$ ; on  $\text{dom } A \times \text{dom } B$ , the *second coordinate has priority*. Rearranging finite tags and tuples gives explicit admitted isomorphisms

$$(A + B) + C \cong A + (B + C), \quad (A \cdot B) \cdot C \cong A \cdot (B \cdot C),$$

$$A \cdot (B + C) \cong A \cdot B + A \cdot C.$$

Commutativity and the other distributive law are not asserted. These are ordinal, not cardinal, operations.

[merge] Proposition XVI.3.4 is the sum argument of source 34's section XVI.3 and of source 35's Section 3.1 (in section XVI.3.3), printed as a numbered statement because sources 32 and 33 cite it so; source 33's note XVI.3.9 is the same proposition.

### XVI.3.5 Source 32: canonical division by $\Omega$ and class cofinality

#### XVI.3.5.1 Set-interval blocks

For  $x, y \in W$ , let  $[x, y]_W$  denote the closed interval between them, regardless of which is smaller. Define

$$x \sim_W y \iff [x, y]_W \text{ is a set.} \quad (\text{S32.5})$$

The predicate on the right is elementary: it asserts the existence of a set with exactly the specified members. In particular, it does not quantify over a collection of proper classes.

*Note XVI.3.5* (Source 32, Lemma 5.1). *The relation  $\sim_W$  is a convex equivalence relation. Each block has a least point, and the induced order inside each block is set-like. Every nonfinal block is proper. Consequently there can be at most one set-sized block, and if it exists it is final.* This is the block lemma of Part IX and Part XIV (source 15's theorem 52.3, source 18's lemma 52.10, source 29's note 108.9), proved inside source 34's theorem XVI.3.3 and as source 35's note XVI.5.11 and source 33's note XVI.3.10, by the same argument: transitivity from the union of two set intervals, set-likeness because the predecessors of  $x$  in its block lie in the set interval from the block's least point  $r$ , and, if a nonfinal block  $B$  were a set, the least point  $z$  after it would satisfy  $[r, z]_W = B \cup \{z\}$ , a set.

Least representatives solve the size problem in forming the quotient. Instead of putting proper-class blocks into another class as elements, form the class of their least points. An original point determines its representative by an elementary formula. The resulting quotient is an ordinary class relation on sets. This is the block-representation method already used in the repository [79]; the following division formulation makes its consequence explicit.

**Theorem XVI.3.6** (Canonical  $\Omega$ -division). *For every class well-order  $W$  there are a canonically presented class well-order  $Q$  and a set ordinal  $\alpha$  such that*

$$W \cong \Omega \cdot Q + \alpha. \quad (\text{S32.6})$$

*Here  $Q$  is the order of least representatives of the proper set-interval blocks;  $\alpha$  is the type of the final set block, or 0 when there is none. The pair is unique up to an admitted isomorphism of  $Q$  and equality of  $\alpha$ .*

*Proof.* By note XVI.3.5, every proper block is set-like and therefore has type  $\Omega$  by note XVI.2.9. The rank of a point  $x$  within its block is the ordinal type of the set of block predecessors of  $x$ . The

formula defining this rank is uniform in the block representative and  $x$ . If a final set block exists, apply the ordinary set-order collapse to it and call its type  $\alpha$ .

Assigning each point its block representative and its local rank gives the required admitted isomorphism. For the empty order take  $Q = 0$  and  $\alpha = 0$ . For a nonempty set order there is just one set block, so  $Q = 0$  and  $\alpha = \text{otp}(W)$ .

To verify uniqueness, observe that in any presentation  $\Omega \cdot Q + \alpha$  the copies of  $\Omega$  are exactly the proper set-interval blocks. Points from distinct copies have a proper interval between them, because it contains a final part of the earlier copy of  $\Omega$ . All intervals within a copy are sets, and the final ordinal  $\alpha$ , when nonzero, is the unique set block. An isomorphism preserves set-sized intervals: images of sets under an admitted class function are sets, and the inverse gives the converse. It therefore induces an isomorphism of the proper-block representative orders and an isomorphism of the final set blocks. Ordinary ordinal uniqueness gives equality of the remainders.  $\square$

[merge] Theorem XVI.3.6 is source 34's theorem XVI.3.3 with the uniqueness clause of source 18's proposition 52.12 (Part IX), proved in the same way: an admitted isomorphism and its inverse preserve set-sized intervals by Class Replacement. Source 33's note XVI.3.11 states the same canonicity. In proposition XVI.3.7, the description of the least cofinal size is source 18's corollary 52.13 in other words; the first clause, an increasing cofinal map  $\Omega \rightarrow W$  when no set is cofinal, is proved here only by source 32 (its recursion along  $\text{Ord}$  uses a set-like global well-order).

The theorem is not a global Cantor normal form theorem. In particular,  $Q$  may be another non-set-like proper-class order, and iterating the quotient construction introduces a separate recursion problem. Nevertheless, it provides a canonical first structural invariant for every supplied  $W$ , with no ETR assumption and no global comparison theorem.

### XVI.3.5.2 Cofinality need not measure class size

A subclass  $C \subseteq W$  is cofinal if every point of  $W$  lies at or below some member of  $C$ . Proper-class well-orders can have a last point, a countable cofinal set, or no set cofinal subset at all. For example,

$$\Omega + 1 \text{ has cofinality } 1, \quad \Omega \cdot \omega \text{ has cofinality } \omega,$$

whereas  $\Omega$  has no set cofinal subset. The hereditary order  $E(\Omega)$  has a countable cofinal set by note XVI.6.24.

**Proposition XVI.3.7** (Set cofinality or an  $\Omega$ -sequence). *If a class well-order  $W$  has no set cofinal subset, it has an admitted increasing cofinal map  $\Omega \rightarrow W$ . If it does have a set cofinal subset, its least possible set cardinality is 1 or an infinite regular cardinal.*

*Proof.* In the first case  $W$  is proper. A set-like global well-order restricted to its domain gives an enumeration  $e : \text{Ord} \rightarrow \text{dom } W$ . Recursively choose  $f(\xi)$  to be the  $W$ -least point strictly above  $e(\xi)$  and all earlier values  $f(\eta)$ ,  $\eta < \xi$ . The collection to be bounded is a set. Since no set is cofinal, a strict upper bound exists. This is set-valued recursion with set histories along  $\text{Ord}$ , available in GBC. The result is increasing and is cofinal because it bounds every value of  $e$ .

In the second case, choose a set cofinal subset  $C$ . Its induced order has a set ordinal type  $\lambda$ . If  $W$  has a greatest point, one point is enough. Otherwise the cofinality of  $W$  equals the ordinary cofinality of  $\lambda$ : a cofinal subset of  $\lambda$  gives one in  $W$ , and any set cofinal in  $W$  maps cofinally into  $C$  by taking least upper bounds in  $C$  point by point. Ordinary ordinal cofinality is an infinite regular cardinal.  $\square$

The first clause does not say that  $W$  has order type  $\Omega$ . A cofinal suborder is not necessarily an initial suborder. In  $\Omega^{[\Omega]}$ , for example, the monomials indexed by ordinal exponents are cofinal, although the whole order is much longer than its initial set-like segment.

### XVI.3.6 Source 33: an explicit arithmetic of class well-orders; uniformly indexed sums

Disjoint tags are implicit in all constructions. Define  $A + B$  by placing every point of  $A$  before every point of  $B$ . Define  $A \cdot B$  on pairs  $(b, a)$ , with  $b \in B$ ,  $a \in A$ , by comparing the  $B$ -coordinate first. Thus  $A \cdot B$  consists of  $B$ -many consecutive copies of  $A$ .

*Note XVI.3.8* (Source 33, Definition 3.1, “Uniform family”). *A family  $(A_i)_{i \in I}$  of class order presentations is uniform if there are classes  $U$  and  $S$  with  $\text{dom}(A_i) = \{x : U(i, x)\}$  and  $x <_{A_i} y \leftrightarrow S(i, x, y)$ ; the index collection  $I$  is itself a class of sets, whose members are codes or labels, not proper classes.* This is source 34’s [definition XVI.7.1](#) (Section XVI.7) and source 32’s uniformly coded families before [proposition XVI.3.4](#).

*Note XVI.3.9* (Source 33, Proposition 3.2). *If  $I$  is a class well-order and  $(A_i)_{i \in I}$  is a uniform family of class well-orders, then the lexicographic sum  $\sum_{i \in I} A_i$  is a class well-order, definable from the given data in GBC.* This is source 32’s [proposition XVI.3.4](#), by the same least occupied index and least point of its fibre; the argument uses no choice (source 34’s [section XVI.3](#)).

The statement includes a subtle restriction: merely being told, for each index, that some class order exists does not supply the uniform pair of predicates  $U, S$ . Even a set-indexed collection of class-valued choices must not be treated as an ordinary set function.

### XVI.3.7 Source 33: canonical division by the order of all ordinals

#### XVI.3.7.1 Set intervals and their blocks

For points  $x, y$  of a class linear order  $W$ , let  $[x, y]_W$  denote the closed interval between them, regardless of their order. Define

$$x \sim_W y \iff [x, y]_W \text{ is a set.} \quad (\text{S33.4.1})$$

Being a set is expressed by the existence of a set with exactly the specified members. Thus [\(S33.4.1\)](#) is an elementary definition from  $W$ .

*Note XVI.3.10* (Source 33, Lemma 4.1). *For a class well-order  $W$ , the relation  $\sim_W$  is a convex equivalence relation. Each block has a least point and is a set-like well-order. Any block that is a set must be the final block of  $W$ .* This is source 32’s [note XVI.3.5](#), with the same proof.

#### XVI.3.7.2 The division theorem

*Note XVI.3.11* (Source 33, Theorem 4.2, “Canonical  $\Omega$ -division”). *Every class well-order  $W$  has a decomposition*

$$W \cong \Omega \cdot Q + \alpha, \quad (\text{S33.4.2})$$

*where  $Q$  is a class well-order and  $\alpha$  a set ordinal. The factors are canonical:  $Q$  is the order of the least points of the proper-class set-interval blocks, and  $\alpha$  the type of the final set-sized block, if there is one, or zero. The decomposition and the displayed isomorphism exist in GBC.* This is source 34’s [theorem XVI.3.3](#) and source 32’s [theorem XVI.3.6](#), including its canonicity: source 33 sends  $x$  to the pair  $(r(x), \rho(x))$  of its block minimum and  $\rho(x) = \text{otp}\{y : r(x) \leq_W y <_W x\}$ , and proves canonicity

by observing that in any presentation  $\Omega \cdot Q + \alpha$  the displayed blocks are exactly the set-interval blocks. Its displayed equation (4.2) is this decomposition.

**Example XVI.3.12.** The canonical decompositions of  $\Omega + \omega$  and  $\Omega^2 + 17$  have  $(Q, \alpha) = (1, \omega)$  and  $(\Omega, 17)$ , respectively. A nonempty set ordinal has  $Q = 0$  and is its own remainder. The empty order has both factors zero.

The theorem is a genuine structural statement about arbitrary class well-orders. It does not assume initial comparability of two unrelated orders, nor does it recursively construct classes along  $W$ . Every point's coordinate is the type of a *set* interval.

### XVI.3.7.3 Why repeated quotients need coherent data

One may iterate the operation of identifying set-interval blocks. At a limit stage, however, knowing only the isomorphism types of the previous quotients is insufficient: one needs to know *which points have already been identified*. The next section makes this precise with an explicit family. It also avoids any implication that the existence of individually described quotients automatically supplies a uniformly coded transfinite iteration.

## XVI.4 Finite-support exponentiation without Global Choice

**Definition XVI.4.1** (Finite-support power). Let  $A$  be a nonempty class well-order with least point  $0_A$ , and let  $B$  be a class well-order. The carrier of  $A^{[B]}$  is the class of finite partial functions  $f : B \rightarrow A \setminus \{0_A\}$ . Missing values mean  $0_A$ . For distinct  $f, g$ , take the greatest point  $b$  in their finite disagreement set and put

$$f < g \iff f(b) <_A g(b).$$

Write  $P(B) = \Omega^{[B]}$ . Its elements are formal polynomials  $\Omega^{b_0}a_0 + \cdots + \Omega^{b_{k-1}}a_{k-1}$ , where  $b_0 >_B \cdots >_B b_{k-1}$  and  $0 < a_i \in \text{Ord}$ .

The superscript  $b_i$  is a point of the exponent order; when interpreting the monomial's predecessor length, it represents the initial segment  $B_{<b_i}$ . A polynomial is a finite set, even when both available coordinates and available coefficients range over proper classes. No class-valued function is being made an element of the carrier. The greatest-disagreement rule is a strict linear order by the ordinary finite lexicographic argument.

**Theorem XVI.4.2** (Choice-free power theorem). *GB proves that  $A^{[B]}$  is a class well-order whenever  $A$  and  $B$  are class well-orders and  $A$  is nonempty.*

*Proof.* Let  $C$  be a nonempty subclass of the power. We construct its least member directly. Regard each polynomial as a finite list of exponent-coefficient pairs in decreasing exponent order. For a chosen prefix  $p$ , let  $C_p$  consist of those members of  $C$  whose lists begin with  $p$ . Maintain two invariants:  $C_p$  is nonempty, and every member of  $C \setminus C_p$  is larger than every member of  $C_p$ . The empty prefix satisfies these conditions.

If  $p$  itself is in  $C$ , it is least in  $C_p$ , since each proper extension has a nonzero next coefficient. It is therefore least in  $C$ , and the construction stops. Otherwise each member of  $C_p$  has a next pair. Among the next exponents choose the  $B$ -least one, say  $b$ . Among the corresponding nonzero coefficients choose the  $A$ -least one, say  $a$ . These are uniquely defined minima of admitted subclasses. Append  $(b, a)$  to  $p$ . The new  $C_p$  is nonempty. A member rejected at this step has a larger next exponent, or the same exponent with larger coefficient; in either case it is larger than every retained member. Thus both invariants persist.

If this process did not stop, ordinary recursion on  $\omega$  would produce a sequence of uniquely defined finite prefixes. All values are sets, so Class Replacement supplies the sequence as a set. Its successive selected exponents strictly decrease in  $B$ , because every retained polynomial lists its support in decreasing order. The range of this sequence would be a nonempty subclass of  $B$  without a least member, contrary to the hypothesis. Hence the process stops and yields the required least member of  $C$ . No choices from unrelated subclasses are made.  $\square$

The difference from the repository proof is exact. A general subclass without a minimum cannot in bare GB simply be turned into a descending sequence by invoking Global Choice. The proof above uses the already supplied well-orders of the coordinates and digits to choose unique minima. This is the dependency removed in the canonical-history theorem.

There is also an independent short route to the same result. For a nonempty set of finite graphs, collect its exponent supports and its digits into sets, including the zero digit. Their induced well-orders have set ordinal types. The given graphs therefore sit inside an ordinary set ordinal power, so that set of graphs has a minimum. [Lemma XVI.2.2](#) upgrades this set-subset assertion to the full class well-order assertion in GB. The explicit greedy proof records a minimum-selection procedure and exposes the same absence of choice directly.

#### XVI.4.1 Arithmetic laws with concrete witnesses

The finite-support construction agrees with ordinary ordinal exponentiation on set ordinals. For a successor exponent, the last coefficient arranges copies of the preceding power; at a limit, every finite support lies below some earlier exponent. These observations give the usual set transfinite proof.

For class well-orders, explicit splitting and flattening of finite graphs prove the following laws without class-valued recursion:

$$A^{[0]} \cong 1, \quad A^{[1]} \cong A, \quad (\text{S34.1})$$

$$A^{[(B+C)]} \cong A^{[B]} \cdot A^{[C]}, \quad (\text{S34.2})$$

$$(A^{[B]})^{[C]} \cong A^{[(B \cdot C)]}. \quad (\text{S34.3})$$

In (S34.2), restrict a finite function to the two tagged pieces; the  $C$  piece is the more significant coordinate. In (S34.3), a finitely supported function with finitely supported values flattens to a finite function on pairs  $(c, b)$ . The greatest differing  $c$ , followed by the greatest differing  $b$ , is exactly the product order. Empty inner functions represent the zero digit. The inverse maps group the finite pairs into their fibers, so these are isomorphisms, not just embeddings.

An initial embedding  $j : B \rightarrow C$  induces an initial embedding  $A^{[B]} \rightarrow A^{[C]}$  by relabelling supports. If  $A$  has at least two points and the image of  $j$  is proper, the latter embedding is proper: the first missing exponent supports a new coefficient-one monomial. This gives a reliable strict-growth rule.

**Proposition XVI.4.3** (The exponent is not a power class). *For every set ordinal  $2 \leq a$ , one has*

$$a^{[\Omega]} \cong \Omega, \quad a^{[(\Omega+1)]} \cong \Omega \cdot a.$$

*By contrast,  $P(\Omega)$  has a proper initial segment of type  $\Omega$  and is strictly longer than it.*

*Proof.* For set  $a$ , any polynomial has a greatest support exponent  $\beta$  unless it is zero. All smaller polynomials have support in  $\beta + 1$  and digits below  $a$ . They therefore form a set. The whole power

is proper, since there are monomials at every ordinal exponent. [Theorem XVI.3.1](#) gives its type  $\Omega$ . Equation (S34.2) gives the second formula. For base  $\Omega$ , the constant polynomials form an initial copy of  $\Omega$ , and the monomial at exponent 1 follows all of them.  $\square$

Thus  $2^{[\Omega]}$  and  $\omega^{[\Omega]}$  do not leap beyond  $\Omega$  under this definition. A notation that presents them as larger has either changed the exponentiation operation or confused order exponentiation with a collection of subsets. Full functions from a proper class are not set-coded elements of an ordinary class; functions of unrestricted support require a different foundation and a separately checked order.

## XVI.4.2 A presentation language and a useful normal-form rule

A safe presentation language begins with  $0, 1$ , set ordinal constants, and  $\Omega$ , and closes under tagged sum, product, finite-support power, and explicitly supplied uniform sums. It can also include the hereditary constructor in the next development. Each expression denotes a concrete class relation. Equalities between expressions are witnessed by class isomorphisms, and the language need not choose a representative of every possible isomorphism type.

For  $f \in P(B)$  with decreasing support  $b_0, \dots, b_{k-1}$ , the strict predecessor class has the canonical presentation

$$(P(B))_{<f} \cong \sum_{i < k} \Omega^{[B_{<b_i}]} \cdot f(b_i). \quad (\text{S34.4})$$

Indeed, partition the predecessors by the first, most significant coordinate at which they fall below  $f$ . At coordinate  $b_i$  the smaller coefficient has  $f(b_i)$  choices in ordinal order, and the lower coordinates form  $\Omega^{[B_{<b_i}]}$ . Concatenating these pieces in decreasing significance proves the formula. It explains exactly what the polynomial notation means as a description of an initial segment.

For example, a point written  $\Omega^{\omega+2} \cdot 3 + \Omega^7 \cdot \omega + 5$  names the initial segment with those three successive terms. It does not claim that the ambient proper class order is a von Neumann ordinal. Constants and finite trees give systematic descriptions, but the comparison of arbitrary formula-defined presentations is not replaced by a universal syntactic normalizer. The diagonal results below show why that stronger objective has a real obstruction.

[merge] [Theorem XVI.4.2](#) removes the one use of global choice in this report's proofs that polynomial orders are well-ordered: source 15's [lemma 53.2](#), source 23's [note 108.6](#) and source 29's [note 108.15](#) each turn a subclass without a least element into a descending sequence by global choice. Source 35 proves the same theorem with a different termination argument ([note XVI.4.4](#) and its proof below); sources 32 and 33 prove it in GBC by the set-support localization of source 34's second route ([notes XVI.4.10](#) and [XVI.4.12](#)). The laws (S34.1)–(S34.3) are source 35's (S35.5) and (S35.6), source 32's [note XVI.4.11](#) and source 33's [note XVI.4.13](#); the initial-embedding rule is source 35's [lemma XVI.4.5](#); the first identity of [proposition XVI.4.3](#) is the third of source 35's [proposition XVI.4.6](#) and source 33's [proposition XVI.4.14](#). Formula (S34.4) is source 35's [note XVI.6.22](#).

## XVI.4.3 Source 35: exponentiation by finite support, cofinality and continuity

Let  $A$  be a nonempty class well-order, with least point  $0_A$ , and let  $B$  be any class well-order. Define  $A^{[B]}$  to be the class of *finite partial functions*

$$p : B \rightarrow A \setminus \{0_A\}.$$

Every such function is a set: its graph contains finitely many ordered pairs of sets. Missing values are read as  $0_A$ . Its finite domain is written  $\text{supp}(p)$ . For distinct  $p, q$ , the finite nonempty set

$$\{b \in \text{supp}(p) \cup \text{supp}(q) : p(b) \neq q(b)\}$$

has a greatest element  $b_*$ . Put

$$p < q \iff p(b_*) <_A q(b_*). \quad (\text{S35.4})$$

The empty graph is the least element. The brackets emphasize this order-theoretic exponentiation; it is not the collection of all class functions  $B \rightarrow A$ , or cardinal exponentiation.

*Note XVI.4.4* (Source 35, Theorem 3.1, “Choice-free finite-support theorem”). *If  $A$  is a nonempty class well-order and  $B$  is a class well-order, then  $A^{[B]}$  is a class well-order. This is provable in GB.* This is source 34’s [theorem XVI.4.2](#), proved independently. Both proofs build the least member of a nonempty subclass  $C$  greedily, appending at each step the least next exponent and then the least next coefficient, and both keep every discarded polynomial above every retained one. They differ in the termination argument: source 34 collects the uniquely specified prefixes into a set sequence by recursion on  $\omega$  and Class Replacement, and derives a descending sequence of exponents; source 35 avoids the  $\omega$ -sequence and considers the class of last exponents of all finite histories obeying the rule, whose least element would have to be followed by a smaller one. Its proof is printed as a second route.

*Source 35’s proof.* The comparison is linear. One way to check transitivity is to put the supports of three polynomials into one finite decreasing list of exponents and compare their coefficient lists lexicographically, starting at the greatest exponent. This is an ordinary finite lexicographic comparison.

Let  $C \subseteq A^{[B]}$  be a nonempty class. Write each polynomial as its finite list of nonzero terms, with exponents strictly decreasing. We construct the beginning of a least member of  $C$ . Start with the empty prefix  $s$ . At every step the survivor class

$$C_s = \{p \in C : p \text{ begins with the list } s\}$$

is nonempty. If  $s$  itself is a polynomial in  $C_s$ , stop. It is the least survivor: every proper extension adds a positive coefficient at a smaller exponent.

Otherwise every survivor has a next term. The class of their next exponents is a nonempty subclass of  $B$ , so choose its *least* element  $b$ . Among survivors having next exponent  $b$ , choose the least next coefficient  $a$  in  $A$ . Append  $(b, a)$  to  $s$ . The new survivor class is nonempty. Moreover, each discarded survivor is greater than every retained survivor: at the first new place of disagreement it has either a larger exponent, or the same exponent and a larger coefficient.

This process must stop after finitely many steps. To see this without making an infinite sequence of choices, consider all *finite histories* obeying the rule. They are set codes, and the condition of being such a history is an elementary formula with the supplied classes as parameters. If no history terminated, the class of last exponents of nonempty histories would be a nonempty subclass of  $B$ . Let  $b$  be its least element and take a history ending in  $b$ . Its next extension exists by the rule, and its new exponent is strictly below  $b$ , since exponents in a polynomial decrease. This contradicts the choice of  $b$ .

At termination, the resulting finite list is a member of  $C$  and is below every polynomial discarded at an earlier step. It is therefore the least member of  $C$ . All selections used designated least elements; Global Choice and elementary transfinite recursion were not used.  $\square$

For set ordinals  $\alpha \geq 1$  and  $\beta$ , this construction has ordinary ordinal type  $\alpha^\beta$ . Indeed, a last exponent splits the order into  $\alpha$  successive copies of the preceding power, and at a nonzero limit every finite support is contained in an earlier exponent segment. These are the usual successor and limit equations, starting with  $\alpha^{[0]} = 1$ . Consequently the construction genuinely extends ordinal exponentiation. The empty base can be treated separately by the usual conventions  $0^0 = 1$  and  $0^\beta = 0$  for  $\beta > 0$ ; it is not needed in the results below.

**XVI.4.3.1 The exponent laws are explicit isomorphisms**

For nonempty  $A$ , splitting a finite support between the two tagged parts of  $B + C$  gives

$$A^{[B+C]} \cong A^{[B]} \cdot A^{[C]}. \quad (\text{S35.5})$$

The right-hand coordinate records the restriction to  $C$ . A difference there is more significant than every difference in  $B$ , exactly as required by the product convention. Joining the two tagged graphs is the inverse map. In particular,

$$A^{[0]} \cong 1, \quad A^{[1]} \cong A, \quad A^{[B+1]} \cong A^{[B]} \cdot A.$$

There is also a flattening isomorphism

$$(A^{[B]})^{[C]} \cong A^{[B \cdot C]}. \quad (\text{S35.6})$$

An element on the left assigns a nonzero finite  $B$ -polynomial  $p_c$  to finitely many  $c \in C$ . Send it to the finite graph on  $B \times C$  whose value at  $(b, c)$  is  $p_c(b)$ . Conversely, slice a finite graph on  $B \times C$  at its finitely many occupied  $C$ -coordinates. Empty slices are omitted. The greatest different  $C$ -coordinate determines the first comparison; inside that slice, the greatest different  $B$ -coordinate determines the second. This is precisely greatest-difference comparison on  $B \cdot C$ . Thus both the bijection and its compatibility with the order are verified directly.

These identities are available even when several operands and their initial segments are proper classes. They require no recursion whose stages would themselves have to be classes. They also do not assert the generally false identity  $(A \cdot B)^{[C]} \cong A^{[C]} \cdot B^{[C]}$ .

**Lemma XVI.4.5** (Preservation of initial embeddings). *An order embedding  $f : B \rightarrow C$  induces an order embedding*

$$A^{[f]} : A^{[B]} \longrightarrow A^{[C]}, \quad A^{[f]}(p)(f(b)) = p(b).$$

*If the image of  $f$  is initial, the induced image is initial. If that image is proper and  $A$  has at least two elements, the induced image is proper as well.*

*Proof.* The map transports a finite support and its coefficients; an embedding preserves the greatest point of a finite difference set. Hence it preserves and reflects comparisons. Suppose the image of  $f$  is initial. Every exponent outside it is above every exponent inside it. A polynomial with an occupied outside exponent is therefore greater than every polynomial supported in the image. The latter polynomials consequently form an initial subclass, and each has a unique finite inverse image under the displayed map. If the exponent image is proper, let  $c_*$  be its least omitted point and let  $1_A$  be the least point of  $A$  above  $0_A$ . The monomial supported at  $c_*$  with coefficient  $1_A$  is the least polynomial outside the induced image. This also proves properness explicitly.  $\square$

The polynomial operation used in the repository is exactly

$$P(B) := \Omega^{[B]}.$$

Its coefficients are the nonzero set ordinals. The lemma shows that  $P$  transports initial embeddings, including their properness. Identity maps and compositions are preserved literally by support transport. This functorial behavior is what makes the fixed-point constructions in the next part possible.

Changing the *base* deserves separate attention. An initial embedding  $A \rightarrow A'$  also gives a coefficientwise order embedding  $A^{[B]} \rightarrow (A')^{[B]}$ , but that particular map need not be initial. Already

for  $2 \subset 3$  and exponent 2, the image contains the monomial at exponent 1 while omitting the constant coefficient 2 below it. One must not infer initiality from coefficientwise inclusion. For set ordinals another initial embedding exists by ordinary ordinal comparison; applying an analogous comparison to arbitrary class orders requires its own justification.

### XVI.4.3.2 What collapses to Ord, and what passes it

A set-like well-order on a proper class has its canonical ordinal-rank isomorphism with  $\Omega$ : each point has a set of predecessors, its rank is a set ordinal, and the range is an initial subclass of Ord that is a proper class. It must therefore be all of Ord. This observation gives useful simplification rules.

**Proposition XVI.4.6** (Set-sized operands at the class boundary). *For set ordinals  $\alpha$  and  $\beta$ ,*

$$\alpha + \Omega \cong \Omega, \quad \alpha \cdot \Omega \cong \Omega \quad (\alpha > 0), \quad \beta^{[\Omega]} \cong \Omega \quad (\beta \geq 2).$$

*Proof.* In  $\alpha + \Omega$ , the predecessor set of a point in the second copy has ordinary type  $\alpha + \gamma$  for some set ordinal  $\gamma$ . In  $\alpha \cdot \Omega$ , the predecessors of  $(a, \gamma)$  have ordinary type  $\alpha \cdot \gamma + a$ . Thus both displayed orders are set-like, and their domains are proper classes under the stated nonemptiness assumption.

For  $\beta^{[\Omega]}$ , a polynomial and all its predecessors have their supports in some set ordinal  $\gamma$ . There are only set-many finite  $\beta$ -valued graphs on  $\gamma$ , so its predecessor class is a set. The monomials with coefficient 1 at successive ordinal exponents show that the whole domain is proper. The same set-like classification applies. More explicitly, the power on exponents below  $\gamma$  has type  $\beta^\gamma$ , and these ordinary ordinals are cofinal in Ord. The resulting identification agrees with ordinary base- $\beta$  evaluation on each finite polynomial.  $\square$

[merge] The third identity is source 34's [proposition XVI.4.3](#); the first two are source 32's remark after [note XVI.4.11](#) and source 33's examples after [note XVI.4.13](#). Source 35's continuity principle (S35.7) is the last clause of source 32's [note XVI.4.11](#). [Proposition XVI.4.7](#) and [lemma XVI.4.8](#) are proved here only by source 35; the second holds over GB as well ([theorem XVI.6.21](#)).

The reversed expressions behave differently. The new endpoint of  $\Omega + 1$  has a proper class of predecessors, and the first point of the second block of  $\Omega \cdot 2$  has the same property. Neither order is isomorphic to  $\Omega$ . Their displayed first copies of  $\Omega$  are proper initial subclasses, so the sense in which they are longer is witnessed directly.

In  $\Omega^{[\Omega]}$ , the constant polynomials form an initial copy of  $\Omega$ . The monomial with coefficient 1 at exponent 1 lies immediately after that whole copy. Moreover,

$$\Omega^{[2]} \cong \Omega \cdot \Omega$$

is a proper initial subclass of  $\Omega^{[\Omega]}$ , by [Lemma XVI.4.5](#). In particular,

$$\beta^{[\Omega]} \cong \Omega \quad \text{for every set } \beta \geq 2, \quad \Omega^{[\Omega]} \not\cong \Omega.$$

The size of the coefficient collection changes the construction: allowing all set ordinals as coefficients introduces proper-class intervals. There is no legitimate inference that a proper-class base can be replaced by a sufficiently large set base for the *whole* order.

### XVI.4.3.3 Cofinality is a separate invariant

A long class well-order may still have a set of cofinal points. The exponent construction gives exact elementary examples of both possibilities.

**Proposition XVI.4.7** (Cofinality of a limit exponent). *Suppose  $A$  has at least two elements and  $B$  is nonempty with no greatest point. Then  $A^{[B]}$  has a set-sized cofinal subclass if and only if  $B$  does. Whenever these cofinalities are set cardinals, their least possible cardinalities agree.*

*Proof.* Let  $1_A$  be the least nonzero coefficient. The map sending  $b \in B$  to the monomial with coefficient  $1_A$  at exponent  $b$  is strictly increasing and cofinal. Indeed, choose an exponent above the greatest exponent of any given nonzero polynomial; its monomial is larger. A cofinal set in  $B$  therefore gives a cofinal set of the same size in the power.

Conversely, let  $Q$  be a cofinal set of polynomials. Take the greatest support exponent of each nonzero member of  $Q$ . These exponents form a set by Class Replacement. They are cofinal in  $B$ : if all lay below some  $b$ , the monomial at  $b$  would exceed every member of  $Q$ . Their number is at most  $|Q|$ . The two constructions prove both assertions.  $\square$

In particular,  $\Omega^{[\Omega]}$  has no set-sized cofinal subclass, whereas  $\Omega^{[\omega]}$  has cofinality  $\omega$ . The latter is nevertheless longer than every finite power  $\Omega^{[n]}$ : these powers are proper initial subclasses, and the monomials at the finite exponents give a cofinal sequence. If the exponent instead has a greatest point,  $\Omega^{[B]}$  has no cofinal set. For any proposed set of polynomials, their coefficients at that point have a common ordinal bound; a larger coefficient there produces a polynomial above the entire set. Thus passing from  $\Omega^{[\omega]}$  to  $\Omega^{[\omega+1]}$  changes the availability of a set-sized cofinal sequence. Cofinality and initial-segment length measure different features.

#### XVI.4.3.4 Continuity and bounded interpretations

Continuity is meaningful for a given uniform system. Suppose  $(B_i)_{i \in I}$  is uniformly presented,  $I$  is a nonempty class well-order, the domains are nested, and each earlier order is an initial subclass of every later one. Then

$$B = \bigcup_{i \in I} B_i, \quad A^{[B]} = \bigcup_{i \in I} A^{[B_i]}. \quad (\text{S35.7})$$

The first union is well-ordered: given a nonempty subclass, take one of its points in a stage and take its least point inside that stage. All points outside the stage are later. For the second equality, the finitely many exponents of a polynomial lie together in a single stage. This proves continuity directly from finite support.

In particular, if  $B$  is nonempty and has no greatest point,

$$A^{[B]} = \bigcup_{b \in B} A^{[B_{<b}]}$$

Some of the orders  $B_{<b}$  may be proper classes; nevertheless this family is elementary and uniform. These assertions do not supply an unspecified family of class stages, or a supremum of every class well-order. The existence and coding of the diagram precede the union.

There is another useful verification principle when a notation system consists of finite trees carrying ordinal labels.

**Lemma XVI.4.8** (Bounded-specialization principle). *Work in GBC. Let  $T$  be an elementary class of finite ordinal-labelled terms with a class linear order. Suppose that, for arbitrarily large set ordinals  $\kappa$ , all terms whose labels are below  $\kappa$  admit a common strictly order-preserving interpretation into a set ordinal. Then  $T$  is a class well-order.*

*Proof.* If a nonempty subclass had no least element, Global Choice would produce a descending  $\omega$ -sequence in it. Its terms use only a set of ordinal labels, whose union is bounded by some set ordinal. Choose a larger  $\kappa$  with the asserted interpretation. The entire sequence then maps to a descending sequence in one set ordinal, a contradiction.  $\square$

For nested ordinal-coefficient polynomials, the relevant interpretation substitutes an ordinary ordinal  $\kappa$  for the formal symbol  $\Omega$ , with every coefficient below  $\kappa$ . Ordinary base- $\kappa$  comparison verifies order preservation on the bounded terms. This principle explains how set-ordinal mathematics can verify a class notation system locally without collapsing its global order type to a set ordinal. For the finite-support operation itself, [Note XVI.4.4](#) is stronger in its axiomatic economy, since its direct least-element argument already works without Global Choice.

All comparisons made in this section have explicit witnesses. No step assumes that arbitrary class well-orders are comparable by initial embeddings. That additional issue belongs to the foundational analysis, rather than to the elementary support calculations.

#### XVI.4.4 Source 32: finite-support exponentiation and familiar expressions

Let  $A$  have a least point  $0_A$  and at least two points. Define  $A^{[B]}$  to be the class of finite partial functions

$$f : \text{dom } B \rightarrow \text{dom } A \setminus \{0_A\},$$

read as total functions with default value  $0_A$ . For distinct  $f, g$ , their finite set of differing coordinates has a greatest point  $b$ . Declare

$$f < g \iff f(b) <_A g(b). \quad (\text{S32.1})$$

The empty function is the zero point. Only finitely many nonzero digits are stored, so every element is a set even when both parameters have proper-class domains.

**Lemma XVI.4.9** (Set-sized digit representation). *For ordinary ordinals  $a \geq 2$  and  $b$ , finite-support functions  $b \rightarrow a$  with the order (S32.1) have order type  $a^b$  in ordinary ordinal arithmetic.*

*Proof.* Use ordinary transfinite induction on the set ordinal  $b$ . At zero there is one function. At  $b = c + 1$ , grouping by the digit at  $c$  gives  $a$  successive copies of the order at  $c$ , hence type  $a^c \cdot a$ . At a nonzero limit, every finite support lies below some  $c < b$ , and these smaller orders are nested initial segments. Their union has type  $\sup_{c < b} a^c = a^b$ . This also proves that the digit order is a well-order and that the displayed embeddings at smaller exponent bounds are initial. The same induction identifies the rank of a digit function with the finite sum  $\sum a^{\beta_i} d_i$  in decreasing order of its occupied exponents.  $\square$

*Note XVI.4.10* (Source 32, Theorem 3.3, “Explicit class exponentiation in GBC”). *For class well-orders  $A$  and  $B$ , with  $A$  having at least two points, the finite-support presentation  $A^{[B]}$  is a class well-order. Its construction and proof require no ETR axiom.* This is source 34’s [theorem XVI.4.2](#), in GBC. Source 32’s proof is source 34’s second route with descending sequences in place of set subsets: a descending set sequence uses a set of exponents and a set of digits, whose collapses to ordinals translate it into a descending sequence in an ordinary ordinal power ([lemma XVI.4.9](#)), and [lemma XVI.2.8](#) converts this into class well-foundedness. That conversion is where global choice enters; over GB, [lemma XVI.2.2](#) replaces it.

*Source 32’s proof.* Linearity and transitivity can be checked on the finite union of the supports of any three functions, using the corresponding finite lexicographic comparison. Suppose there were a descending set sequence of functions. The union of its finite supports is a set  $S \subseteq \text{dom } B$ , and the set of all its coefficient values together with  $0_A$  is a set  $T \subseteq \text{dom } A$ . The induced well-orders on  $S$  and  $T$  have ordinary ordinal types  $b$  and  $a$ . If  $T$  contains only zero, there cannot be a strict descent. Otherwise  $a \geq 2$ , and replacing coordinates and digits by their ranks translates the sequence into a descending sequence in the set well-order from [lemma XVI.4.9](#). This is impossible. Apply [lemma XVI.2.8](#).  $\square$

The same *set-support localization* argument is useful more generally: a purported countable obstruction to a finite-coded class construction often uses only a set of labels. One can then reduce the obstruction to ordinary set mathematics without collapsing the entire proper-class order.

*Note XVI.4.11* (Source 32, Theorem 3.4, “Exponent laws by explicit maps”). *For the preceding presentations,  $A^{[0]} \cong 1$ ,  $A^{[1]} \cong A$ ,*

$$A^{[B+C]} \cong A^{[B]} \cdot A^{[C]}, \quad A^{[B \cdot C]} \cong (A^{[B]})^{[C]}. \quad (\text{S32.2})$$

*If  $j : B \rightarrow C$  is an initial embedding, pushing supports forward along  $j$  gives an initial embedding  $A^{[B]} \rightarrow A^{[C]}$ , proper when  $j$  is proper. If  $B$  has no greatest point,  $A^{[B]}$  is the union of its initial suborders supported in  $B_{<b}$ , for  $b \in B$ . These are source 34’s (S34.1)–(S34.3) and the initial-embedding paragraph after them, source 35’s lemma XVI.4.5 and (S35.7), and source 33’s note XVI.4.13, proved by the same splitting, grouping and support transport; source 32 assumes  $A$  has at least two points.*

We deliberately avoid the assertion that initial embeddings in the *base* always induce initial embeddings of powers. Even for ordinary finite ordinals that assertion is false: the digit subset for  $2^2$  inside the base-3 presentation of  $3^2$  is not an initial segment.

#### XVI.4.4.1 Which familiar expressions really get longer?

For every set ordinal  $\alpha$  and every nonzero set ordinal  $a$ ,

$$\alpha + \Omega \cong \Omega, \quad a \cdot \Omega \cong \Omega.$$

Indeed, the orders on the left are proper and set-like, so note XVI.2.9 applies. By contrast,  $\Omega + 1$  is not set-like, and  $\Omega \cdot 2$  consists of two genuinely successive proper-class blocks.

For every set ordinal  $a \geq 2$ ,

$$a^{[\Omega]} \cong \Omega. \quad (\text{S32.3})$$

To see set-likeness, a predecessor of a given finite-support function can use no exponent above its greatest occupied exponent. The available exponents are therefore bounded by a set ordinal, and the coefficient alphabet is a set. There are only a set of possible predecessors. The order is proper because there is a distinct monomial at each ordinal exponent. Again note XVI.2.9 applies.

This absorption fails for a proper-class base. In  $\Omega^{[\Omega]}$ , the monomial at exponent 1 has all ordinal constants as predecessors. Thus  $\Omega^{[\Omega]}$  is not set-like. The constructions provide, among many others,

$$\Omega, \quad \Omega + 1, \quad \Omega \cdot 2, \quad \Omega^2, \quad \Omega^{[\Omega]}, \quad \Omega^{[\Omega^{[\Omega]}]}, \quad \dots$$

The displayed tower steps are connected by explicit proper initial embeddings. No universal comparison theorem is needed to certify their increase.

#### XVI.4.5 Source 33: finite-support exponentiation and first landmarks beyond Ord

Suppose  $A$  is a class well-order with least point  $0_A$ . Define  $A^{[B]}$  to be the class of finite partial functions

$$p : B \rightarrow A \setminus \{0_A\}.$$

Missing values are read as  $0_A$ . The empty function is zero. For distinct  $p, q$ , let  $b$  be the *greatest* exponent at which they differ and set

$$p < q \iff p(b) <_A q(b).$$

The greatest differing exponent exists because the union of the two supports is finite. This is reverse lexicographic comparison on the exponent positions, not comparison at the first difference.

*Note XVI.4.12* (Source 33, Theorem 3.3, “Arithmetic closure”). *If  $A, B$  are class well-orders and  $A$  is nonempty, then the finite-support presentation  $A^{[B]}$  is a class well-order. For set ordinal bases and exponents, it is the usual ordinal power. No elementary transfinite recursion principle is needed for its construction or well-foundedness.* This is source 34’s [theorem XVI.4.2](#) in GBC, proved as source 32’s [note XVI.4.10](#): a descending set sequence uses a set  $S$  of exponents and a set  $C$  of coefficients, whose collapses to ordinals  $\beta$  and  $\alpha$  send it to a descending sequence in the finite-support presentation of  $\alpha^\beta$ ; if  $C$  contains only zero all the polynomials are equal. The last assertion is source 32’s [lemma XVI.4.9](#). Source 33 adds that for a one-point base the construction has one point and that zero bases follow the conventions  $0^0 = 1$ ,  $0^B = 0$  for nonempty  $B$ .

For a one-point base, the construction always has one point. We use the usual separate conventions  $0^0 = 1$  and  $0^{[B]} = 0$  for nonempty  $B$  when zero bases occur. All substantial uses below have base at least two.

*Note XVI.4.13* (Source 33, Proposition 3.4, “Explicit arithmetic laws”). *The following isomorphisms are supplied by definable coordinate maps:  $(A + B) + C \cong A + (B + C)$ ,  $(A \cdot B) \cdot C \cong A \cdot (B \cdot C)$ ,  $A \cdot (B + C) \cong A \cdot B + A \cdot C$ , and, for nonempty  $A$ ,  $A^{[B+C]} \cong A^{[B]} \cdot A^{[C]}$  and  $(A^{[B]})^{[C]} \cong A^{[B \cdot C]}$ .* These are the identities of source 34’s [section XVI.3](#) and (S34.2) and (S34.3), source 35’s (S35.3), (S35.5) and (S35.6) and source 32’s [note XVI.4.11](#), by the same retagging, splitting and flattening.

There is no general commutativity and no general distributive law on the other side. For instance,  $1 + \Omega \cong \Omega$  but  $\Omega + 1 \not\cong \Omega$ . Also  $(1 + 1) \cdot \Omega \cong \Omega$ , whereas  $1 \cdot \Omega + 1 \cdot \Omega \cong \Omega \cdot 2$ .

#### XVI.4.5.1 First landmarks beyond Ord

**Proposition XVI.4.14.** *For every set ordinal  $a \geq 2$ ,*

$$a^{[\Omega]} \cong \Omega.$$

*Consequently,*

$$2^{[\Omega+1]} \cong \Omega \cdot 2, \quad 2^{[\Omega \cdot 2]} \cong \Omega^2.$$

*Proof.* A polynomial below a given element of  $a^{[\Omega]}$  cannot use an exponent greater than the largest exponent of that element. All such polynomials therefore belong to a set of finite functions from one bounded ordinal into the set  $a$ . Hence  $a^{[\Omega]}$  is set-like. It is a proper class because every ordinal can occur as the exponent of a monomial with coefficient one. Apply [note XVI.2.14](#). The remaining identities follow from [note XVI.4.13](#).  $\square$

[merge] The first identity of [proposition XVI.4.14](#) is source 34’s [proposition XVI.4.3](#) and source 35’s [proposition XVI.4.6](#); the two consequences  $2^{[\Omega+1]} \cong \Omega \cdot 2$  and  $2^{[\Omega \cdot 2]} \cong \Omega^2$  are printed only by source 33 (the first is the case  $a = 2$  of source 34’s  $a^{[\Omega+1]} \cong \Omega \cdot a$ ).

Thus the symbols  $\Omega + 1$ ,  $\Omega \cdot 2$ ,  $\Omega^2$ ,  $\Omega^\omega$ , and  $\Omega^{[\Omega]}$  admit completely explicit meanings. Later we construct a coherent fixed point above finite towers of powers of  $\Omega$ . None of these expressions turns  $\Omega$  into a set ordinal.

*Remark XVI.4.15* (Not cardinal exponentiation). The class  $A^{[B]}$  just defined contains *finite* function codes. It is not the collection of all class functions  $B \rightarrow A$ . The latter would generally be a higher-order collection, not a class of sets in GBC. Likewise, arbitrary infinite-support reverse lexicographic orders need not be well-founded; a support convention is part of a definition, not a cosmetic choice.

## XVI.5 The canonical-history theorem over GB

The repository already proves a substantial theorem over GBC: canonical terminating condensation histories, strong comparability of class well-orders, and certain initial-segment polynomial representations are equivalent [77]. Its proof constructs canonical floor maps and finite normal forms. We retain that construction and its attribution. The contribution here is a sharper foundation: the choice-free polynomial well-order theorem proved above removes the only use of Global Choice in the arbitrary-carrier argument. Consequently the equivalence holds over GB, including when the set universe does not satisfy Choice. This answers the repository's remaining question about the GB version for the precise limit convention below. It does not establish the converse from comparability to ETR discussed by Hamkins and Woodin [27].

Throughout this section a class well-order means that every nonempty admitted subclass has a least element. We do not substitute the potentially weaker absence of a set-coded descending  $\omega$ -sequence over a choiceless base. All constructions use elementary comprehension and Class Replacement. In particular, a supplied history is a single class relation, not a collection whose members are classes.

### XVI.5.1 Histories and their termination bound

Let  $W = (X, <_W)$  be a nonempty class well-order with minimum  $m$ . For a nonempty subclass  $A \subseteq X$  containing  $m$ , let  $D_W(A)$  be the class of least representatives for the equivalence relation

$$x \sim_A y \iff [\min_W(x, y), \max_W(x, y)]_W \cap A \text{ is a set.}$$

The preceding block decomposition applies to the induced order on  $A$ . In particular, a block followed by another block has type Ord.

Let  $\Gamma = (I, <_\Gamma)$  be another nonempty class well-order. Form  $\Gamma + 1$  with a tagged new final stage  $*$ . Write  $i^+$  for the immediate successor of  $i \in I$  in this extended order. A nonzero limit stage is a noninitial stage without an immediate predecessor; it may have a proper class of predecessors.

**Definition XVI.5.1** (Canonical history). A canonical history of  $W$  on  $\Gamma + 1$  is one class relation  $H$  with slices

$$H_{\min \Gamma} = X, \quad H_{i^+} = D_W(H_i), \quad H_\lambda = \bigcap_{i < \lambda} H_i \quad \text{at nonzero limits } \lambda.$$

It is terminating if  $H_* = \{m\}$ . The principle CTH asserts that every nonempty class well-order  $W$  has a canonical history on its own input-order schedule  $W + 1$ .

The displayed intersection is elementary: membership says that every earlier set-valued stage label satisfies the appropriate slice predicate. Elementary induction along the supplied schedule shows that the slices are decreasing and contain  $m$ . The history's existence, however, is not supplied by that induction.

**Lemma XVI.5.2** (Termination on the input schedule). *In GB, any supplied canonical history on  $W + 1$  terminates. More precisely,*

$$H_x \subseteq \{m\} \cup \{y \in X : x \leq_W y\} \quad (x \in X).$$

*Proof.* Induct along  $W$ , using the given history as a class parameter. The first-stage claim is immediate. At the successor  $x = t^+$ , the inductive bound has removed all points below  $t$  except  $m$ .

If  $t \neq m$  remains, it is the second point of  $H_t$ , so its two-point interval with  $m$  causes its deletion by  $D_W$ . This proves the successor bound. At a nonzero limit  $x$ , each  $m \neq y < x$  lies below some  $t < x$ , and is absent from  $H_t$  by induction.

If  $W$  has a last point  $\ell$ , its slice is contained in  $\{m, \ell\}$ ; the final successor leaves only  $m$ . Otherwise every nonminimal point is excluded by some later stage, hence from the final intersection.  $\square$

This is the repository's supplied-history termination argument [77]. It is consistent with  $W$  being isomorphic to its first condensation: the slices are actual nested subclasses, so repeated abstract order types do not prevent the specified limit intersection from shrinking.

## XVI.5.2 Canonical floors and finite addresses

**Lemma XVI.5.3** (Floors at all stages). *For each stage  $i$  and point  $x \in X$ , there is a greatest retained point at most  $x$ :*

$$p_i(x) = \max_W \{a \in H_i : a \leq_W x\}.$$

*The maps are uniformly elementary in  $H, W$ , nondecreasing in  $x$ , and for  $i \leq j$  satisfy*

$$p_j(x) \leq_W p_i(x), \quad p_j(p_i(x)) = p_j(x), \quad p_i(p_j(x)) = p_j(x).$$

*At every nonzero limit  $\lambda$ , the floors of each fixed  $x$  stabilize before  $\lambda$  at  $p_\lambda(x)$ .*

*Proof.* At the first stage the floor is  $x$ . Suppose  $p_i(x) = a$ , and let  $b$  be the least representative of  $a$ 's block in  $H_i$ . A representative strictly between  $b$  and  $x$  would be at most  $a$ , by the floor property, and would belong to the same block as  $b$ . This is impossible. Thus  $p_{i+}(x) = b$ .

At a nonzero limit  $\lambda$ , the earlier floor values form a nonempty admitted subclass of  $W$ . Take its least value  $b$ , attained at some  $i_0 < \lambda$ . Because the floors decrease, every subsequent floor before  $\lambda$  equals  $b$ . Nesting places  $b$  in every earlier slice as well, so  $b \in H_\lambda$ . Every point of  $H_\lambda$  at most  $x$  is at most  $p_{i_0}(x) = b$ . This proves existence and stabilization.

This is elementary induction: the greatest-predecessor formula defines all floors from the supplied history without selecting class maps. Nesting also proves the two composition identities, and monotonicity in  $x$  is immediate.  $\square$

**Lemma XVI.5.4** (Finitely many changes). *For each fixed  $x$ , only finitely many stages  $i \in I$  have  $p_{i+}(x) \neq p_i(x)$ . No floor value first appears at a limit stage.*

*Proof.* The limit assertion follows from Lemma XVI.5.3. If the class of successor changes were not finite, taking its least remaining member would uniquely define increasing stages  $i_0 < i_1 < \dots$  with strictly decreasing floors. Ordinary set-valued recursion along  $\omega$ , followed by Class Replacement, gives a set-coded descending sequence in  $W$ , a contradiction. These are unique minimum choices, so neither form of Choice is used.  $\square$

Define the ordinal digit

$$c_i(x) = \text{otp}(\{z \in H_i : p_{i+}(x) \leq_W z <_W p_i(x)\}, <_W).$$

This interval is a set because its endpoints lie in one set-interval block. The digit is nonzero exactly at a floor change. Consequently

$$\text{NF}_H(x) = \{(i, c_i(x)) : c_i(x) > 0\} \in P(\Gamma)$$

is a finite set graph. Its dependence on  $x$  is elementary. Finiteness here, like the theorem itself, is interpreted internally in a nonstandard model.

**Theorem XVI.5.5** (Finite normal form with initial image). *If  $H$  terminates on  $\Gamma + 1$ , then  $\text{NF}_H$  is a class order isomorphism of  $W$  onto an initial segment of  $P(\Gamma)$ .*

*Proof.* First establish a digit-insertion rule. Let  $b \in H_{i+}$ , and let  $z$  be the point of ordinal rank  $\rho$  in the  $H_i$  block beginning at  $b$ , when such a point exists. Then  $p_i(z) = z$  and  $p_{i+}(z) = b$ . At later stages, the floors of  $z$  and  $b$  agree by Lemma XVI.5.3. At every earlier stage both floors determining a digit equal  $z$ , since  $z \in H_i$ . Thus insertion adds the digit  $\rho$  at  $i$ , keeps the higher digits of  $b$ , and makes all lower digits zero.

An actual code reconstructs its point uniquely. Start from the final anchor  $m$  and read its finitely many nonzero digits in decreasing stage order, using the insertion rule. Each requested rank exists for an actual code. Lemma XVI.5.4 ensures there are no other floor changes, including at limits. The resulting point is therefore  $x$ . This proves injectivity.

To prove initiality, fix  $q < \text{NF}_H(x)$  and let  $i$  be the greatest exponent of disagreement. Decoding the common higher digits gives the anchor  $b = p_{i+}(x)$ . Write  $d = c_i(x)$  and  $c = q(i)$ , so  $c < d$ . The  $H_i$  block at  $b$  contains points  $a, a'$  of ranks  $c, c + 1$ , with

$$a <_W a' \leq_W p_i(x) \leq_W x.$$

Insert digit  $c$ , obtaining anchor  $a$ , and keep  $a'$  as a fixed upper bound.

Process the remaining nonzero digits of  $q$  in decreasing exponent order. For each lower exponent  $j < i$ , the current anchor and  $a'$  both belong to  $H_{j+}$ . Initially this follows from membership in  $H_i$ ; after an insertion at  $k > j$ , the new anchor lies in  $H_k \subseteq H_{j+}$ . They are distinct retained representatives. Therefore the  $H_j$  block beginning at the current anchor is nonfinal and has type Ord. Every requested ordinal digit exists inside it, strictly below  $a'$ . Insert that digit and continue.

After finitely many steps the resulting  $y$  satisfies  $\text{NF}_H(y) = q$  and  $y < a' \leq x$ . Thus every polynomial below an actual code occurs with a smaller preimage. Applied to two actual codes, this also gives exact order preservation, using injectivity and linearity. The image is initial, as required.  $\square$

The fixed upper bound in this proof is essential: it guarantees complete Ord blocks for all lower digits. Mere injectivity into a polynomial order would not yield strong comparability.

### XVI.5.3 Restrictions and prescribed schedules

**Lemma XVI.5.6** (Anchored convex restriction). *Let  $Y$  be a nonempty convex subclass of  $W$ , with  $a = \min_W Y$ . If  $H$  is a canonical history on  $W$ , then on the same schedule*

$$J_i = \{a\} \cup \{y \in H_i \cap Y : a <_W y\}$$

*is the canonical history of the induced order on  $Y$ . It terminates whenever  $H$  terminates.*

*Proof.* The initial clause and the limit intersections follow directly. For a successor stage fix  $x \in H_i \cap Y$  with  $a < x$ , and let  $u = p_i(a)$ . There are no  $H_i$  points in  $(u, a]$ . Convexity gives

$$\begin{aligned} [u, x]_W \cap H_i &= \{u\} \cup \{z \in H_i : a < z \leq x\}, \\ [a, x]_W \cap J_i &= \{a\} \cup \{z \in H_i : a < z \leq x\}. \end{aligned}$$

These intervals are sets simultaneously. A global witness below  $x$  showing that  $x$  is not a least representative is also a local witness if it is above  $a$ . If it is at or below  $a$ , restriction of its interval and insertion of  $a$  gives a local set interval. Conversely, a local witness above  $a$  is global too,

whereas the local witness  $a$  can be replaced by  $u$  using the displayed identities. Hence the retained representatives strictly above  $a$  coincide. The local minimum  $a$  is always retained, proving the successor clause. A final global singleton contributes no point above  $a$ , so the local final slice is  $\{a\}$ .  $\square$

Bare intersection with  $Y$  would sometimes discard its minimum; the anchor cannot be omitted. The earlier polynomial construction supplies, in GB, the explicit history

$$K_i = \{q \in P(\Gamma) : \text{supp } q \subseteq I_{\geq i}\}, \quad K_* = \{0\}.$$

Condensation deletes the least available exponent; the limit intersection retains exactly the exponents above every earlier threshold.

**Corollary XVI.5.7** (Exact fixed-schedule criterion). *For nonempty class well-orders  $W, \Gamma$ , a canonical terminating history of  $W$  on  $\Gamma + 1$  exists if and only if  $W$  is class-isomorphic to an initial segment of  $P(\Gamma)$ .*

*Proof.* The forward implication is [Theorem XVI.5.5](#). Conversely, restrict the explicit polynomial history to the supplied nonempty initial range and pull it back through the class isomorphism. [Lemma XVI.5.6](#) verifies the recursion clauses; the zero polynomial gives the final singleton.  $\square$

#### XVI.5.4 The equivalence and its exact scope

**Theorem XVI.5.8** (Canonical histories over GB). *Over GB, the following principles are equivalent:*

1. CWO: *of any two class well-orders, one is class-isomorphic to an initial segment of the other, allowing the whole order.*
2. CTH: *every nonempty  $W$  has a canonical history on  $W + 1$ .*
3. *Every nonempty  $W$  has a canonical terminating history on some class-well-order schedule  $\Gamma + 1$ .*
4. *Every nonempty  $W$  is class-isomorphic to an initial segment of  $P(W)$ .*

*Proof.* The implication  $(2) \Rightarrow (3)$  is [Lemma XVI.5.2](#).

For  $(3) \Rightarrow (1)$ , form the tagged sum  $T = R + S$  of two nonempty orders. Apply (3) once to obtain one history on a schedule  $\Gamma + 1$ . Anchored convex restriction gives histories for  $R$  and  $S$  on that same schedule. Their normal forms have initial ranges in the same order  $P(\Gamma)$ . Two initial subclasses of a linear order are comparable by inclusion. Compose the map onto the smaller range with the inverse map on the larger range to obtain the required class initial-segment isomorphism. Empty inputs are immediate. There is no simultaneous choice of histories for many orders.

For  $(1) \Rightarrow (4)$ , first observe that any class order embedding  $f : W \rightarrow W$  satisfies  $x \leq_W f(x)$ . Otherwise the least counterexample  $x$  has  $f(x) < x$  and  $f(f(x)) < f(x)$ , giving an earlier counterexample. It follows that  $W + 1$  cannot embed into  $W$ : if the last point mapped to  $a$ , the restricted embedding would give  $a \leq f(a) < f(*) = a$ .

Now put  $\Gamma = W + 1$ . The choice-free polynomial theorem makes  $P(\Gamma)$  a class well-order. The coefficient-one monomials  $e_t$  embed  $W + 1$  into it. Comparability with  $W$  must therefore give an initial embedding  $f : W \rightarrow P(\Gamma)$ ; the opposite direction would embed  $W + 1$  into  $W$ . Its range lies strictly below  $e_*$ , since otherwise initiality would put  $e_*$  and every  $e_x$  in the range, again embedding  $W + 1$  into  $W$  through  $f^{-1}$ . The polynomials below  $e_*$  are exactly  $P(W)$ , which proves (4).

Finally,  $(4) \Rightarrow (2)$  follows from [Corollary XVI.5.7](#) with  $\Gamma = W$ . Explicitly, pull the support-threshold polynomial history back through the supplied initial-segment isomorphism.  $\square$

**Proposition XVI.5.9** (Uniqueness with a fixed schedule). *Two canonical histories for the same input order and schedule agree at every stage. Suppose the sets, input order, and schedule remain fixed while the collection of available classes is enlarged, and both orders remain class well-orders in the larger realization. Then an already available history and its normal forms retain their values and agree with any newly available canonical history on that schedule.*

*Proof.* The class of disagreement stages is elementary in the two supplied histories. If nonempty, it has a least member. That member cannot be the first stage, whose slice is prescribed. At a successor the equal preceding slices have equal condensations, and at a limit the equal earlier slices have equal intersections. Each possibility contradicts disagreement. For the second claim, the set-interval tests and recursion clauses quantify only over the unchanged sets with the given classes as parameters. The old history still satisfies those clauses, and the assumed well-ordering of the schedule in the larger realization permits uniqueness to identify it with any new candidate. The ordinal interval ranks defining the normal forms are unchanged as well.  $\square$

Thus a stronger class theory can supply a previously absent history without changing an old one. This distinction concerns existence of one class witness; it does not provide a class-valued operation selecting histories for a totality of class well-orders. Over the choiceless base, preservation of an old relation's class-well-order property under enlargement of the class collection is not being assumed without a hypothesis.

The repository's four-way equivalence and the preceding normal-form machinery are the mathematical starting point [77]. Our strengthening consists of the GB polynomial theorem and the checked elimination of Choice from the remaining dependencies. It gives neither a proof of CWO in GB nor a proof that CWO yields arbitrary elementary transfinite recursion. Suitable ETR supplies the required histories; the reverse comparison remains separate [27].

There is also a necessary limitation concerning carriers. The repository reduces the history principle to well-orders of the entire surreal class by transporting arbitrary proper class carriers through a global bijection. That corollary retains its Global Choice hypothesis. The choice-free theorem above quantifies directly over the given class carriers and does not assume that every proper class is bijective with Ord or with the surreals.

*Note XVI.5.10* ([merge]; this section re-proves Part XIV over GB). Every statement of this section except [theorem XVI.5.8](#)'s base theory is a re-proof, with the same arguments, of source 29's results in Part XIV, which source 34 credits throughout: [definition XVI.5.1](#) is [definition 108.10](#); [lemma XVI.5.2](#) is source 20's [theorem 108.1](#) and source 29's [note 108.11](#); [lemma XVI.5.3](#) is [lemma 108.12](#); [lemma XVI.5.4](#) is [proposition 108.13](#); the digits  $c_i(x)$  are (S29.27); [theorem XVI.5.5](#) is [theorem 108.16](#); [lemma XVI.5.6](#) is [lemma 108.17](#); the explicit history  $K_i$  is (S29.26); [corollary XVI.5.7](#) is [corollary 108.18](#); [theorem XVI.5.8](#) is [theorem 108.19](#), there over GBC; and [proposition XVI.5.9](#) is source 29's paragraph "Uniqueness and changes of the class collection" after [corollary 108.20](#). Source 29's argument used global choice only through the well-foundedness of  $P(\Gamma)$  ([note 108.15](#)); source 34 checked that floors, finite changes, normal forms, restriction and the four implications use only uniquely specified minima, and replaced that one step by [theorem XVI.4.2](#). This report agrees with that dependency analysis: the proofs of [lemmas 108.12](#) and [108.17](#), [proposition 108.13](#), [theorem 108.16](#), and [corollary 108.18](#) as printed in Part XIV take least elements of admitted classes and collect uniquely specified  $\omega$ -sequences, and nothing else. Source 35 proves the same equivalence over GB independently ([note XVI.5.19](#)). Source 29's reduction to the surreal carrier ([corollary 108.20](#)) keeps global choice, as both sources say. The equivalence answers over GB the question of [note 108.4](#), of item (b) of [section 112](#) and of source 20's [research question 113.111](#); each now carries a dated note.

### XVI.5.5 Source 35: condensation, finite addresses, and comparison without Choice

This section strengthens a result recorded in the ProveIt manuscript [78]. That manuscript proves, over GBC, an equivalence between complete canonical condensation histories and strong comparison of class well-orders; its Part XIV explicitly leaves the corresponding question over GB without Global Choice open. We prove the equivalence over the choice-free base used here: the sets satisfy ZF, and the class axioms provide elementary comprehension and Class Replacement. Neither set Choice nor Global Choice occurs in the proof. The principal repair is the choice-free finite-support theorem, [Note XVI.4.4](#); the remaining argument is established below with its class-existence requirements explicit. The normal-form construction itself, and the equivalence over GBC, are credited to the repository.

Throughout, a class well-order means an order in which every nonempty admitted subclass has a least element. In particular, we do not replace this hypothesis by the absence of a descending  $\omega$ -sequence. An initial segment may be the whole order. Class carriers always consist of sets; a block or history slice can be a proper class, but never becomes an element of another class.

#### XVI.5.5.1 One condensation is elementary

Let  $W = (X, <_W)$  be nonempty. For a nonempty subclass  $A \subseteq X$ , with its induced order, define

$$x \sim_A y \iff [\min_W(x, y), \max_W(x, y)]_W \cap A \text{ is a set.}$$

The right side is elementary: it asserts that there exists a set whose members are exactly the displayed interval. Let  $D_W(A)$  consist of the least elements of the  $\sim_A$ -blocks.

*Note XVI.5.11* (Source 35, Lemma 4.1, “Set-interval blocks”). *The relation  $\sim_A$  is a convex equivalence relation. Its blocks have canonical ordinal rank maps, and each block is isomorphic either to a set ordinal or to Ord. A set-sized block, if present, is final. In particular, a block followed by another block has type  $\Omega$ .* This is source 29’s [note 108.9](#) for the induced order on  $A$ , with the same proof, and source 32’s and source 33’s [notes XVI.3.5](#) and [XVI.3.10](#); source 35 notes that the rank of a point is the order type of a set that already carries the supplied well-order, so no well-ordering of a set is chosen.

This gives the repository’s canonical division theorem. Let  $B_W$  be the ordered class of minima of the proper blocks of  $W$ , and let  $\rho_W$  be the ordinal type of the final set block, or zero if there is none. Then

$$W \cong \Omega \cdot B_W + \rho_W. \tag{S35.8}$$

Here the product is a  $B_W$ -indexed sum of copies of  $\Omega$ . The isomorphism sends a point in a proper block to its block minimum and its ordinal rank within that block; it sends the final set block to  $\rho_W$ . This is one elementary class map. Thus the word “canonical” does not conceal a choice of one isomorphism for each block. When  $W$  is a set,  $B_W$  is empty and  $\rho_W = \text{otp}(W)$ . For a proper carrier,  $B_W$  is nonempty. Formula (S35.8) and its proof are already in [78]; the quotient can be as complicated as an arbitrary class well-order, so this single division does not finish the analysis.

#### XVI.5.5.2 What a complete history asserts

Let  $\Gamma = (I, <_\Gamma)$  be a nonempty class well-order and append a tagged final point  $*$ . Each  $i \in I$  has an immediate successor  $i^+$  in  $\Gamma + 1$ . A nonzero limit stage has no immediate predecessor; its predecessor class need not be a set.

*Note XVI.5.12* (Source 35, Definition 4.2, “Canonical condensation history”). *A history for  $W$  on  $\Gamma + 1$  is a single class relation  $H \subseteq (I \cup \{*\}) \times X$  with  $H_{\min \Gamma} = X$ ,  $H_{i+} = D_W(H_i)$  for  $i \in I$ , and  $H_\lambda = \bigcap_{i <_{\Gamma+1} \lambda} H_i$  at nonzero limits (source 35’s displays (9)–(11)). It terminates if  $H_* = \{m\}$ ,  $m = \min_W X$ ; CTH says that every nonempty  $W$  has such a history on  $W + 1$ . This is [definition XVI.5.1](#) and [definition 108.10](#).*

The recursion clauses are elementary in the earlier history. Their solutions, however, are class-valued histories; elementary comprehension alone does not assert that a solution exists. Once  $H$  is supplied, elementary induction along its schedule proves that the slices decrease and all contain  $m$ . It also proves uniqueness for fixed  $W$  and schedule: a least stage at which two histories differ is incompatible with the corresponding recursion clause.

*Note XVI.5.13* (Source 35, Proposition 4.3, “Input-order termination”). *Every supplied history on  $W + 1$  terminates; more precisely  $H_x \subseteq \{m\} \cup \{y \in X : x \leq_W y\}$  for  $x \in X$ . This is [lemma XVI.5.2](#), source 20’s [theorem 108.1](#) and source 29’s [note 108.11](#), by the same induction along  $W$ .*

### XVI.5.5.3 Floors and the finiteness of every individual address

*Note XVI.5.14* (Source 35, Lemma 4.4, “Canonical floors”). *For every stage  $i$  of a supplied history and every  $x \in X$ , the maximum  $p_i(x) = \max_W(H_i \cap (-\infty, x]_W)$  exists; the graph of all these maps is elementary in  $H, W$ ; for  $i \leq j$ ,*

$$p_j(x) \leq_W p_i(x), \quad p_j(p_i(x)) = p_j(x), \quad p_i(p_j(x)) = p_j(x); \quad (\text{S35.12})$$

*and at each nonzero limit  $\lambda$  the earlier floors of a fixed point are eventually constant, with value  $p_\lambda(x)$ . This is [lemma XVI.5.3](#) and source 29’s [lemma 108.12](#) with (S29.24), by the same induction; source 35 stresses that no new class is defined at an induction step, the value class being defined by one formula from the single supplied  $H$ .*

*Note XVI.5.15* (Source 35, Lemma 4.5, “Finite changes”). *For a fixed  $x$ , the class  $\{i \in I : p_{i+}(x) \neq p_i(x)\}$  is finite. No new floor value first occurs at a limit stage. This is [lemma XVI.5.4](#) and [proposition 108.13](#): an infinite change class would yield, by a uniquely determined recursion collected by Class Replacement (“not an application of Dependent Choice”), increasing stages with strictly decreasing floors.*

The limit rule also has an intrinsic quotient interpretation. Put  $x E_i y$  if  $p_i(x) = p_i(y)$ . The projection identities and eventual stabilization give

$$E_\lambda = \bigcup_{i < \lambda} E_i$$

at every nonzero limit: if two limit floors agree, choose an earlier stage after the stabilization stage of each floor. Thus an identification of original points never first appears at a limit.

[merge] The remark above is source 29’s [corollary 108.14](#). The explicit history (S35.13) is source 34’s  $K_i$  after [lemma XVI.5.6](#) and source 29’s (S29.26); source 35’s paragraph after it is the fullest verification of its successor clause printed here.

### XVI.5.5.4 Polynomial histories and canonical finite normal forms

Write  $P(\Gamma)$  for the class of finite partial functions from  $I$  to nonzero set ordinals, compared at the greatest exponent where their coefficients differ. Missing coefficients are zero. By [Note XVI.4.4](#), this is a class well-order in the choice-free base. Its explicit history on  $\Gamma + 1$  is

$$K_i = \{q : \text{supp}(q) \subseteq \{j : i \leq_\Gamma j\}\}, \quad K_* = \{0\}. \quad (\text{S35.13})$$

Indeed, fixing all coefficients strictly above  $i$  gives one set-interval block of  $K_i$ : its  $i$ -coefficient varies through  $\text{Ord}$ . Bounded intervals within this fiber are sets. Between different higher parts, the interval contains arbitrarily large  $i$ -coefficients on the lower higher part and is proper. Removing the  $i$ -coefficient therefore selects exactly the block minima. At a limit, intersection of the support thresholds is the required threshold; at the final stage only the empty polynomial remains. The formula is uniform and elementary, so this particular history needs no recursion axiom.

Now let  $H$  be a supplied terminating history for  $W$  on  $\Gamma + 1$ . Define

$$c_i(x) = \text{otp}([p_{i+}(x), p_i(x))_W \cap H_i, <_W). \quad (\text{S35.14})$$

The interval is a set because its endpoints lie in the same  $\sim_{H_i}$ -block. Its rank is zero exactly when the two floors coincide. Consequently

$$\text{NF}_H(x) = \{(i, c_i(x)) : i \in I, c_i(x) > 0\}$$

is a finite polynomial. This is a set-valued elementary class map.

*Note XVI.5.16* (Source 35, Theorem 4.6, “Finite normal form from a supplied history”). *The map  $\text{NF}_H$  is an isomorphism from  $W$  onto an initial segment of  $P(\Gamma)$ .* This is [theorem XVI.5.5](#) and source 29’s [theorem 108.16](#), with the same proof: one insertion adds the digit  $\rho$  at stage  $i$  and zeros below it; reading the finitely many nonzero digits from the final floor  $m$  reconstructs  $x$ ; for  $q$  below an actual code, the points  $a <_W a'$  of ranks  $c$  and  $c + 1$  in the block at  $p_{i+}(x)$  satisfy

$$a <_W a' \leq_W p_i(x) \leq_W x \quad (\text{S35.15})$$

(source 29’s [\(S29.29\)](#)), and the fixed upper bound  $a'$  keeps every later block nonfinal, so every requested lower digit can be inserted below  $a'$ .

The upper bound  $a'$  in [\(S35.15\)](#) is essential. It ensures that all subsequently requested smaller digits can be inserted inside nonfinal blocks, even when the input order has a truncated last block. Consequently the theorem gives an initial-segment embedding, which is stronger than an embedding into an arbitrary suborder.

#### XVI.5.5.5 Restriction to a convex interval

*Note XVI.5.17* (Source 35, Lemma 4.7, “Anchored restriction”). *If  $Y$  is a nonempty convex subclass of  $W$  and  $a = \min_W Y$ , then*

$$J_i = \{a\} \cup \{y \in H_i \cap Y : a <_W y\} \quad (\text{S35.16})$$

*is the canonical history of  $Y$  on the same schedule, and it terminates whenever  $H$  does.* This is [lemma XVI.5.6](#) and [lemma 108.17](#), with the same two displayed intervals.

Intersecting with  $Y$  without restoring its minimum would generally fail. For an initial segment the anchor is the global minimum, and ordinary intersection suffices.

*Note XVI.5.18* (Source 35, Theorem 4.8, “Exact criterion for a fixed schedule”). *For nonempty class well-orders  $W$  and  $\Gamma$ , the following are equivalent in GB:  $W$  has a canonical terminating history on  $\Gamma + 1$ ;  $W$  is class-isomorphic to an initial segment of  $P(\Gamma)$ .* This is [corollary XVI.5.7](#) and [corollary 108.18](#), by the same restriction and pullback; every nonempty initial image contains 0.

### XVI.5.5.6 The equivalence over the choice-free base

Let CWO assert that any two class well-orders are comparable by a class isomorphism of one onto an initial segment of the other.

*Note XVI.5.19* (Source 35, Theorem 4.9, “Choice-free history–comparison equivalence”). *Over GB with ZF sets and no form of Choice assumed, the following are equivalent: (1) CWO; (2) CTH: every nonempty  $W$  has a history on  $W + 1$ ; (3) every nonempty  $W$  has a terminating history on some class-well-order schedule  $\Gamma + 1$ ; (4) every nonempty  $W$  is class-isomorphic to an initial segment of  $P(W)$ .* This is source 34’s [theorem XVI.5.8](#), proved independently with the same four implications: (2) $\Rightarrow$ (3) by termination; (3) $\Rightarrow$ (1) from one history of the tagged sum  $R + S$  and its two anchored restrictions; (1) $\Rightarrow$ (4) by comparing  $W$  with  $P(W + 1)$ , which contains  $W + 1$  as the monomials  $e_i$ ; (4) $\Rightarrow$ (2) by the explicit relation  $H_i = \{x \in X : \text{supp}(f(x)) \subseteq \{j : i \leq_W j\}\}$ ,  $H_* = f^{-1}[\{0\}]$ . Source 29’s [theorem 108.19](#) is the same theorem over GBC. Source 35’s choice-free input is its [note XVI.4.4](#).

This proves the characterization over GB requested in the repository’s open-item list. It does not determine whether CWO follows from GB, and it does not establish  $\text{CWO} \Rightarrow \text{ETR}$ . Elementary transfinite recursion supplies the displayed history equations, so the proof also gives

$$\text{GB} + \text{ETR} \vdash \text{CTH} \wedge \text{CWO}.$$

The converse from comparison to unrestricted elementary transfinite recursion remains a separate question.

The axiom distinction matters for scope. The theorem applies to every *supplied* class well-order on a class of set labels. Transporting all proper carriers to a single preferred carrier, such as the whole surreal class, can require Global Choice and is not part of this strengthening. Similarly, the conclusion supplies an individual history for each individual input; it does not produce a same-level class whose members are all class histories.

Finally, finite addresses do not impose a finite or ordinal bound on the length of an order. Their exponents belong to the supplied class schedule and can themselves have proper classes of predecessors. What the theorem controls is the finite amount of changing information attached to each individual point. The existence of a complete uniform history, and hence of these addresses for every input order, has exactly the comparison content expressed in [Note XVI.5.19](#).

### XVI.5.6 Source 32: condensation: general termination and sharp examples

The repository asks whether iterating set-interval condensation eventually collapses every raw class well-order, while distinguishing its explicit polynomial examples from arbitrary recursion [79]. There are really two issues: existence of an admitted hierarchy and termination of a hierarchy once available. The second has a general answer.

[merge] The question source 32 quotes is the one of source 23’s status file; this report had answered it before source 32 was written ([remark XVI.1.1](#)).

#### XVI.5.6.1 An elementary condensation operator

Let  $E$  be a convex equivalence relation on  $W$ . Write  $r_E(x)$  for the least point in the  $E$ -class of  $x$ , and let  $Q_E$  be the class of these least representatives in their inherited order. Define

$$x \mathcal{C}_W(E) y \iff [r_E(x), r_E(y)]_{Q_E} \text{ is a set.} \quad (\text{S32.7})$$

This is again a convex equivalence relation, by [note XVI.3.5](#) applied to  $Q_E$  and then pulled back to  $W$ . It is coarser than  $E$ . All of [\(S32.7\)](#) is elementary in  $W, E$ : least representatives and set-sized intervals are expressed by quantifying only over sets.

For a supplied class well-order of stages, a *condensation hierarchy* begins with equality, applies  $\mathcal{C}_W$  at successors, and takes unions of its previous equivalence relations at nonzero limits. Unions are along an increasing chain, so they are convex equivalence relations. Stage domains and relations must be coded by one admitted class; an external assertion that each individual stage exists is not enough.

### XVI.5.6.2 Termination by the order's own length

*Note XVI.5.20* (Source 32, Theorem 6.1, “Conditional general termination”). *Let  $W$  be a nonempty class well-order, and append a new greatest stage  $\infty$  to form  $W+1$ . Suppose an admitted condensation hierarchy  $(E_t)_{t \in W+1}$  on  $W$  exists, using equality at the least stage,  $\mathcal{C}_W$  at successors, and unions at nonzero limits. Then  $E_\infty$  is universal. In particular,  $\text{GBC} + \text{ETR}_{W+1}$  supplies a hierarchy that collapses  $W$  by its own order length.* This is source 20's [theorem 108.1](#), source 29's [note 108.11](#) and [lemma XVI.5.2](#), for hierarchies of equivalence relations; such hierarchies are the nested histories of those statements ([remark XVI.5.24](#)). Source 32's proof follows; its invariant [\(S32.8\)](#) is the retention bound [\(S20.1\)](#) read through that correspondence.

*Source 32's proof.* Let  $w_0$  be the least point of  $W$ . We prove by class well-order induction on the stages  $t \in W+1$  that

$$x \in W \text{ and } x <_W t \implies x E_t w_0, \quad (\text{S32.8})$$

where all points of  $W$  precede  $\infty$ . At the first stage the assertion is vacuous.

Suppose  $t$  is the immediate successor of  $s$ . If  $s = w_0$ , the assertion needed is just reflexivity. Otherwise, the induction hypothesis says that all points below  $s$  lie in the one  $E_s$ -block containing  $w_0$ . The quotient interval from that block to the block containing  $s$  has at most two points: a point below  $s$  already belongs to the first block, and there are no other points before  $s$  to create intermediate blocks. A two-point or one-point interval is a set. Applying  $\mathcal{C}_W$  therefore merges  $s$  and all its predecessors with  $w_0$ , proving [\(S32.8\)](#) at  $t$ .

If  $t$  is a nonzero limit, take  $x < t$ . There is a stage  $s$  with  $x < s < t$ , since otherwise  $x$  would be the immediate predecessor of  $t$ . The induction hypothesis gives  $x E_s w_0$ , and the union rule gives  $x E_t w_0$ . This also handles  $t = \infty$  when  $W$  has no greatest point. If  $W$  has a greatest point, the successor argument handles  $\infty$ . Thus every point is equivalent to  $w_0$  at the final stage.

For existence under ETR, code the history by a class of triples  $(t, x, y)$ . The first-stage, successor, and limit clauses above form an elementary recursion rule with parameters  $W$  and its stage order. Formula [\(S32.7\)](#) is elementary, so  $\text{ETR}_{W+1}$  gives the required class. The induction establishing that its sections are increasing convex equivalence relations uses the operator properties already proved.  $\square$

**Status.** The termination implication itself is a theorem of GBC about any admitted hierarchy satisfying the stated clauses. ETR is a sufficient existence hypothesis. This is not an argument that bare GBC admits every such hierarchy, nor that this particular recursion operator has the full strength of ETR.

The invariant [\(S32.8\)](#) avoids a potentially misleading strategy: it does not try to assign a decreasing external ordinal size to the successive quotients. A quotient may be isomorphic to the previous quotient for a very long time while the quotient *maps* continue to identify new points.

### XVI.5.6.3 An explicit family attaining arbitrarily long bounds

Here we re-establish the polynomial mechanism already present in the repository, so that the sharpness argument is self-contained. Fix an admitted class well-order  $\Gamma$  and put

$$P(\Gamma) = \Omega^{[\Gamma]}.$$

For a stage  $c \in \Gamma + 1$ , define directly

$$p E_c q \iff p(d) = q(d) \text{ for every } d \in \Gamma \text{ with } c \leq d. \quad (\text{S32.9})$$

At the added last stage there are no such  $d$ , so the relation is universal. The formula defines the entire hierarchy at once, without ETR.

*Note XVI.5.21* (Source 32, Theorem 6.2, “Exact polynomial condensation length”). *The relations (S32.9) form a condensation hierarchy on  $P(\Gamma)$ . For nonempty  $\Gamma$ , no stage belonging to  $\Gamma$  is universal, while the added final stage is universal. Thus its first collapse occurs at the stage of length  $\Gamma$ .* This is source 23’s [note 108.8](#) (Part XIV), source 15’s [theorem 53.4](#) and the explicit history  $K_i$  of [lemma XVI.5.6](#)’s sequel, and source 33’s [note XVI.5.25](#); the proof is the same: the least representative of an  $E_c$ -class clears the coefficients below  $c$ ; at a successor two representatives agreeing above  $s$  span a set interval, while different higher parts leave a proper class of coefficients at  $s$  between them; at a limit a finite set of differing exponents is bounded below an earlier stage; and the monomial at  $c$  separates zero from the next stage.

**Corollary XVI.5.22** (Isomorphic quotients can hide real progress). *For  $P(\Omega) = \Omega^{[\Omega]}$ , the quotient by  $E_\alpha$  is isomorphic to  $P(\Omega)$  for every set ordinal  $\alpha$ , but the quotient at the class-limit stage  $\Omega$  is a singleton. In particular, no set-ordinal bound on condensation lengths can work for all explicit class well-orders.*

*Proof.* At stage  $\alpha$ , the retained exponent tail is  $[\alpha, \text{Ord})$ , which is isomorphic to  $\text{Ord}$  by the ordinary ordinal-tail correspondence. Transporting finite supports gives the asserted quotient isomorphism. Nevertheless the equivalence relations strictly increase: the monomial at coordinate  $\alpha$  survives  $E_\alpha$  and is identified with zero at  $E_{\alpha+1}$ . Formula (S32.9) is universal only at the final class-limit stage. For each proposed set bound, this same example survives beyond it.  $\square$

[merge] [Corollary XVI.5.22](#) is the self-similarity of source 18’s [proposition 52.15](#) (Part IX) at every set stage, for  $P(\Omega)$  instead of  $P(\omega)$ , and the remark after source 20’s [theorem 108.1](#) that repeated quotient types do not stop a history; source 33’s [example XVI.5.26](#) gives the case  $\Gamma = \omega$ .

This is a particularly important warning for a formalization: equality of quotient order types is not equality of equivalence relations, and it is not a reason to stop an iteration. The bonding maps contain indispensable information.

## XVI.5.7 Source 33: polynomial condensation and finite digits

### XVI.5.7.1 Ordinal-coefficient polynomials

For a class well-order  $\Gamma$ , let

$$P(\Gamma) = \Omega^{[\Gamma]}$$

be the finite-support order from [section XVI.4.5](#). Its elements may be written formally as

$$p = \Omega^{\gamma_0} a_0 + \Omega^{\gamma_1} a_1 + \cdots + \Omega^{\gamma_{m-1}} a_{m-1}, \quad \gamma_0 >_\Gamma \cdots >_\Gamma \gamma_{m-1}, \quad 0 < a_i \in \text{Ord}. \quad (\text{S33.5.1})$$

This is a notation for a finite list of exponent–coefficient pairs. It does not presuppose that a point  $\gamma_i$  of  $\Gamma$  is a set ordinal. Repeated terms are combined only according to the chosen coding convention; in the canonical presentation each exponent occurs once.

Write  $\Gamma^+ = \Gamma + 1$  and denote its new greatest point by  $\infty$ . For  $b \in \Gamma^+$ , define

$$p E_b q \iff p(\gamma) = q(\gamma) \text{ for every } \gamma \in \Gamma \text{ with } \gamma \geq b. \quad (\text{S33.5.2})$$

At  $b = \infty$  the condition is empty. At the least stage it is equality. The family  $E_b$  is a single elementary class relation in  $b, p, q$ .

**Definition XVI.5.23** (Exact condensation tower). Let  $W$  be a nonempty class well-order. An *exact condensation tower* indexed by  $\Gamma^+$  is a uniform family of convex equivalence relations  $F_b$  on  $W$  satisfying:

- (i)  $F_b$  is equality at the least stage;
- (ii) at a successor stage  $a^+$ , two points are  $F_{a^+}$ -equivalent exactly when the interval between their  $F_a$ -classes in  $W/F_a$  is a set;
- (iii) at a nonzero limit stage  $b$ ,  $F_b = \bigcup_{a < b} F_a$ .

Quotients are always represented by the minima of their classes. The tower is *exhausting* if  $F_\infty$  is universal.

For any  $a \in \Gamma$ , its immediate successor exists in  $\Gamma^+$ : either there is a next point of  $\Gamma$ , or the next point is  $\infty$ . A nonzero limit means a point with no immediate predecessor. These descriptions require no external ordinal numbering of the stages.

*Remark XVI.5.24* ([merge]; towers of equivalence relations are nested histories). Let  $W = (X, <_W)$  be nonempty with least point  $m$ , let  $\Gamma$  be nonempty, and let  $(F_b)_{b \in \Gamma^+}$  be an exact condensation tower in the sense of [definition XVI.5.23](#). Source 32's hierarchies ([note XVI.5.20](#)) are the same objects: its operator ([S32.7](#)) is clause (ii). Put

$$H_b = \{x \in X : x = \min_W[x]_{F_b}\},$$

the class of least points of the  $F_b$ -classes, elementary in the tower. Then  $H$  is a canonical history of  $W$  on  $\Gamma + 1$  ([definition XVI.5.1](#)), its floors are  $p_b(x) = \min_W[x]_{F_b}$ , and the tower is exhausting exactly when  $H$  terminates. Conversely every canonical history  $H$  arises in this way from exactly one exact tower, namely  $x F_b y \iff p_b(x) = p_b(y)$ , which is source 35's equivalence  $E_b$  after [note XVI.5.15](#).

*Proof.* Each  $F_b$ -class is convex, so its least point  $r$  is the greatest point of  $H_b$  below any of its members  $x$ : a point  $z$  of  $H_b$  with  $r <_W z \leq_W x$  would lie in the class of  $x$  by convexity and so would not be a least point. Hence  $p_b(x) = \min_W[x]_{F_b}$ . At the least stage  $F$  is equality and  $H = X$ . At a successor  $a^+$ , clause (ii) says that  $x$  and  $y$  are  $F_{a^+}$ -equivalent exactly when the  $F_a$ -classes between theirs form a set; these classes are represented by their least points, which are exactly the points of  $H_a$  between  $p_a(x)$  and  $p_a(y)$ , so the condition is  $p_a(x) \sim_{H_a} p_a(y)$  for the relation  $\sim_A$  that defines  $D_W$  before [definition XVI.5.1](#). Every  $F_{a^+}$ -class is therefore the union of the  $F_a$ -classes whose least points form one  $\sim_{H_a}$ -block, and its least point is the least point of that block:  $H_{a^+} = D_W(H_a)$ . At a nonzero limit  $\lambda$ ,  $F_\lambda = \bigcup_{a < \lambda} F_a$ , so  $x$  is least in its  $F_\lambda$ -class exactly when no  $y <_W x$  is  $F_a$ -equivalent to  $x$  for some  $a < \lambda$ , that is, exactly when  $x \in H_a$  for every  $a < \lambda$ :  $H_\lambda = \bigcap_{a < \lambda} H_a$ .  $F_\infty$  is universal exactly when its one class has least point  $m$  and no other, that is  $H_\infty = \{m\}$ . Conversely, for a history  $H$  the relations  $p_b(x) = p_b(y)$  are convex by the monotonicity of floors, satisfy (i) and (ii) by the computation just made, and satisfy (iii) by the stabilization of floors at limits ([lemma XVI.5.3](#); source 29's [corollary 108.14](#)). The two passages are inverse because  $p_b(x) = \min_W[x]_{F_b}$ .  $\square$

Consequently source 33's [note XVI.5.32](#) and source 32's [note XVI.5.20](#) are source 20's [theorem 108.1](#), and source 33's digit map is a normal-form map ([remark XVI.5.29](#)).

[merge] [corrected after independent check, 4 October 2026] The hypothesis that  $\Gamma$  is nonempty was missing; [definition XVI.5.1](#) requires it. Source 33's [definition XVI.5.23](#) does not: for  $\Gamma = \emptyset$  its tower is the single relation  $F_\infty$ , equality, which is exhausting exactly when  $W$  has one point, while no history is defined.

*Note XVI.5.25* (Source 33, Theorem 5.2, “Exact polynomial condensation”). *The family (S33.5.2) is an exhausting exact condensation tower for  $P(\Gamma)$ . For every stage  $b$ ,*

$$P(\Gamma)/E_b \cong P(\Gamma_{\geq b}), \quad (\text{S33.5.3})$$

*with the quotient represented by truncating all exponents below  $b$ . No stage  $b < \infty$  is universal. All these assertions hold in GBC.* This is source 32's [note XVI.5.21](#) and source 23's [note 108.8](#), whose clause (ii) is the same quotient formula; source 33's proof is the same truncation argument.

**Example XVI.5.26** (Stationary quotient types, nonstationary identifications). For  $\Gamma = \omega$ , every finite-stage quotient  $P(\omega)/E_n$  is isomorphic to  $P(\omega)$ , since the tail  $[n, \omega)$  has type  $\omega$ . Nevertheless  $E_n$  is nonuniversal for every finite  $n$  and  $E_\omega$  is universal. Replacing a coherent tower by a list of quotient *types* therefore loses essential information.

[merge] [Example XVI.5.26](#) is the case  $\Gamma = \omega$  of source 32's [corollary XVI.5.22](#) and source 18's [proposition 52.15](#).

The general phenomenon of prescribed long condensation is related to the repository's existing work. The contribution of [note XVI.5.25](#) here is the explicit arithmetic presentation, uniform formula, and exact quotient calculation used in the next theorem; priority for the broad realization principle is not claimed.

### XVI.5.7.2 A finite-digit theorem for arbitrary supplied towers

For an exhausting tower  $(F_b)$  on  $W$  and  $a \in \Gamma$ , the  $F_a$ -classes inside the  $F_{a+}$ -class of  $x$  form one set-interval block of  $W/F_a$ . That block is set-like by [note XVI.3.10](#). Consequently the position of the  $F_a$ -class of  $x$  within it is a set ordinal. Denote this ordinal by

$$r_a(x) = \text{otp}\{C : C \text{ is an } F_a\text{-class in } [x]_{F_{a+}}, C < [x]_{F_a}\}. \quad (\text{S33.5.4})$$

In (S33.5.4), the notation  $C$  is shorthand for its least representative, so the displayed collection is genuinely a set of sets.

**Theorem XVI.5.27** (Finite-digit embedding). *Suppose  $W$  is nonempty and has a supplied uniform exhausting exact condensation tower  $(F_b)_{b \in \Gamma^+}$ . Then*

$$\text{supp}_W(x) = \{a \in \Gamma : r_a(x) \neq 0\}$$

*is finite for every  $x \in W$ , and the map*

$$\Phi(x) = \{(a, r_a(x)) : r_a(x) \neq 0\} \quad \text{is an order embedding } W \longrightarrow P(\Gamma). \quad (\text{S33.5.5})$$

*The theorem is provable in GBC from the supplied tower; it does not assert that GBC constructs every such tower.*

*Proof. Step 1: every digit is an ordinal.* The set-likeness argument preceding the theorem proves that each predecessor collection in (S33.5.4) is a set well-order. Its ordinary ordinal collapse is unique, so all digits are specified by one elementary formula with the tower as a parameter.

*Step 2: nonzero digits occur at only finitely many stages.* Fix  $x$ . Start with  $\sigma = \infty$  and with  $z$  the least point of  $[x]_{F_\sigma} = W$ . More generally maintain that  $z$  is the least point of  $[x]_{F_\sigma}$ . If  $x = z$ , every digit at a stage below  $\sigma$  is zero:  $x$  occupies the first  $F_a$ -class in its  $F_{a+}$ -class for each such  $a$ .

Otherwise, let  $\tau \leq \sigma$  be the least stage at which  $x$  and  $z$  are equivalent. It is not the first stage, since  $x \neq z$ . It is not a limit, since the limit rule would give equivalence at an earlier stage. Therefore  $\tau = a^+$  for some  $a \in \Gamma$ . At stage  $a$ , the two points lie in different  $F_a$ -classes within one  $F_{a+}$ -class. Since  $z < x$ , we have  $r_a(x) > 0$ .

For  $a < b < \sigma$ , the points  $z, x$  are already  $F_b$ -equivalent, and  $z$  is still least in the larger  $F_{b+}$ -class containing them. Hence  $r_b(x) = 0$ . Replace  $\sigma$  by  $a$  and  $z$  by the least point of  $[x]_{F_a}$ . Repeat the argument inside that class.

If the process did not terminate, the successive selected exponents would form a strictly descending  $\omega$ -sequence in  $\Gamma$ . The next selected exponent and the new minimum are uniquely specified by elementary formulas. As in [note XVI.2.12](#), ordinary set recursion and class replacement would collect this into a forbidden set sequence. The process therefore terminates after finitely many steps. The selected exponents are precisely all stages with nonzero digit. Thus (S33.5.5) is a finite set code.

*Step 3: comparison is preserved.* Let  $x < y$  and take the least stage at which  $x, y$  become equivalent. Again it has the form  $a^+$ . At all stages  $b > a$  their digits agree, because their  $F_b$ -classes are the same. At  $a$ , their distinct  $F_a$ -classes lie in one set-like block, and the class of  $x$  precedes the class of  $y$ . Therefore

$$r_a(x) < r_a(y).$$

The greatest differing digit is exactly  $a$ , which is precisely the rule for  $\Phi(x) < \Phi(y)$  in  $P(\Gamma)$ . In particular, the map is injective.  $\square$

*Remark XVI.5.28* (What the theorem does not claim). The conclusion is an order embedding. No claim is made here that this specific digit map always has initial image. Converting arbitrary suborders to initial segments is a separate comparison issue. Under a theory with class well-order comparability, an initial embedding of  $W$  into  $P(\Gamma)$  can be obtained, but that assertion is not used in the proof above.

*Remark XVI.5.29* ([merge]; the digit map always has initial image). [Remark XVI.5.28](#) makes no claim that  $\Phi$  has initial image, and source 33's research question [research question 113.263](#) asks for which supplied towers it is initial. It always is; the remark and the first part of the question are stale, and stay on record with this proof. Let  $(F_b)_{b \in \Gamma^+}$  be a supplied uniform exhausting exact tower on  $W$ . If  $\Gamma$  is empty, exhaustion of equality forces the nonempty  $W$  to be a singleton; then  $P(\Gamma) = 1$  and  $\Phi$  is the unique isomorphism, hence initial. Assume henceforth that  $\Gamma$  is nonempty, and let  $H$  be the terminating history of [remark XVI.5.24](#), with floors  $p_b(x) = \min_W [x]_{F_b}$ . Fix  $a \in \Gamma$  and  $x \in W$ . The  $F_a$ -classes  $C$  contained in  $[x]_{F_{a+}}$  with  $C < [x]_{F_a}$  are represented by their least points; these lie in  $H_a$ , are at least  $\min_W [x]_{F_{a+}} = p_{a+}(x)$  and are below  $\min_W [x]_{F_a} = p_a(x)$ ; conversely, a point  $z \in H_a$  with  $p_{a+}(x) \leq_W z <_W p_a(x)$  lies in  $[x]_{F_{a+}}$  by convexity and is the least point of an  $F_a$ -class below that of  $x$ . Hence

$$r_a(x) = \text{otp}(\{z \in H_a : p_{a+}(x) \leq_W z <_W p_a(x)\}, <_W) = c_a(x),$$

the digit of source 34's normal form ([theorem XVI.5.5](#); source 29's (S29.27)), and  $\Phi = \text{NF}_H$ . By [theorem XVI.5.5](#) (over GB; source 35's [note XVI.5.16](#); source 29's [theorem 108.16](#) over GBC),  $\Phi$  is an

isomorphism of  $W$  onto an initial segment of  $P(\Gamma)$ . So  $\Phi$  is initial for every supplied tower, without any comparison principle; initiality is the capped reconstruction in the proof of [theorem XVI.5.5](#), which [theorem XVI.5.27](#)'s proof does not attempt. The last sentence of the question, whether a different canonical compression map has a weaker axiom bound, has two readings. As a question about the base theory for  $\Phi$ , it is answered by the same identification:  $\Phi$  needs only GB and the supplied tower. As a question about existence for every  $W$ , any map with initial image costs exactly CWO over GB ([corollary XVI.5.7](#) and [theorem XVI.5.8](#)), while mere embeddings  $x \mapsto e_x$  into  $P(W)$  are free.

[merge] [corrected after independent check, 4 October 2026] The text of 4 October 2026 said that this part of the question “is answered by the same identification:  $\Phi$  needs only GB and the supplied tower”; that holds only for the first reading, and the two readings are now separated. A further bounded review found that the earlier proof immediately invoked a terminating history for every supplied tower. For  $W = 1$  and  $\Gamma = 0$  the exhausting tower exists but the printed canonical-history definition requires nonempty  $\Gamma$ ; the singleton case above repairs that invocation without restricting the initiality conclusion. The old domain claim is retained here with this counterexample.

### XVI.5.7.3 Recursion gives a converse

The principle  $\text{ETR}_\Lambda$  says that every elementary class recursion along the specified class well-order  $\Lambda$  has a solution. It is more than a notational license to write a recursively defined family.

**Proposition XVI.5.30** (Conditional converse). *Assume  $\text{GBC} + \text{ETR}_{\Gamma^+}$ . If a nonempty class well-order  $W$  embeds into  $P(\Gamma)$ , then its exact condensation tower indexed by  $\Gamma^+$  exists and is exhausting. Consequently, in this theory,*

$$W \hookrightarrow P(\Gamma) \iff W \text{ has an exhausting exact } \Gamma^+ \text{-tower.}$$

*Proof.* The successor operation in [definition XVI.5.23](#), represented using block minima, is elementary in the previous equivalence relation. The limit operation uses an existential set quantifier over earlier stage labels. Thus the stated recursion principle produces the exact tower  $(F_b)$  of  $W$ . Transport  $W$  to the image of its embedding in  $P(\Gamma)$ .

We prove by class well-order induction that, for points of  $W$ ,

$$E_b \subseteq F_b.$$

The first stage is immediate. At a successor, two points in a common  $E_{a^+}$ -class meet only a set of ambient  $E_a$ -classes between them. Within the interval of  $W$ , an occupied  $E_a$ -class lies inside a single  $F_a$ -class by induction. Select the least point of its intersection with that interval, then the least representative of the resulting  $F_a$ -class. Class replacement on the set of ambient classes shows that the intervening  $F_a$ -classes form a set. Hence the two points are  $F_{a^+}$ -equivalent.

At a limit the inclusion follows from the union rules. Since  $E_\infty$  is universal, so is  $F_\infty$ . The reverse implication is [theorem XVI.5.27](#).  $\square$

*Remark XVI.5.31* ([merge]; under  $\text{ETR}_{\Gamma+1}$  an embedding into  $P(\Gamma)$  becomes initial). In  $\text{GBC} + \text{ETR}_{\Gamma^+}$ , suppose a class well-order  $W$  embeds into  $P(\Gamma)$ . If  $W$  is empty, its unique embedding is initial. If  $W$  is nonempty and  $\Gamma$  is empty, then  $P(\Gamma) = 1$  forces  $W$  to be a singleton, again giving an initial embedding. For nonempty  $W$  and  $\Gamma$ , combine [proposition XVI.5.30](#) with [remark XVI.5.29](#): its exact tower exists and is exhausting, so its normal-form map has initial image. Thus in that theory, for every  $W$  and  $\Gamma$ ,  $W \hookrightarrow P(\Gamma) \Leftrightarrow W \preceq_{\text{init}} P(\Gamma)$ , and, for nonempty  $W$  and  $\Gamma$ , by [corollary XVI.5.7](#)

both say that  $W$  has a terminating history on  $\Gamma + 1$ . Source 33 states only the embedding form; the upgrade is this write's, by the two cited proofs.

[merge] [corrected after independent check, 4 October 2026] The hypothesis that  $W$  and  $\Gamma$  are nonempty, which [corollary XVI.5.7](#) requires, was missing from the last clause. For  $W = 1$  and  $\Gamma = 0$  the initial embedding exists but the stated canonical history is undefined, as in [remark XVI.5.24](#). The source's [proposition XVI.5.30](#) and this remark also said that the exact tower exists for “a class well-order  $W$ ”, without the nonemptiness required by [definition XVI.5.23](#). For  $W = 0$  and  $\Gamma = 1$  the embedding premise holds but that tower lies outside its definition. The proposition now states its nonempty domain, and the separate empty cases above prove the broader embedding/initial-embedding equivalence. These counterexamples retain both earlier omissions; no tower convention is silently extended.

*Note XVI.5.32* (Source 33, Proposition 5.7, “Exhaustion under a sufficient recursion principle”). *If  $W$  is a nonempty class well-order and  $\text{ETR}_{W+1}$  holds, then the exact condensation tower of  $W$  indexed by  $W + 1$  is exhausting.* This is source 20's [theorem 108.1](#) with its existence clause, and source 32's [note XVI.5.20](#), through [remark XVI.5.24](#). Source 33's proof inducts on stages  $x \in W + 1$ , showing that all points strictly below  $x$  lie in one  $F_x$ -class: at  $x = y^+$  the point  $y$  lies in that class or the next, and one condensation step merges the prefix through  $y$ ; at a limit any two points of the prefix lie below an earlier stage. It calls this “a sufficient axiom bound, not an optimality theorem”. The existence of exhausting towers for all nonempty class well-orders is CTH by [remark XVI.5.24](#), hence equivalent to CWO ([theorem XVI.5.8](#)). The earlier wording “all class well-orders” included  $W = 0$ , which lies outside [definition XVI.5.23](#); that domain counterexample is retained here, and the nonempty qualification is explicit.

This is a sufficient axiom bound, not an optimality theorem. The explicit polynomial towers of [note XVI.5.25](#) require no such axiom because their entire family is given by the single truncation formula ([S33.5.2](#)).

## XVI.6 Hereditary normal forms and a first fixed point

Finite-support exponentiation admits an explicit fixed-point construction that goes beyond every finite tower with base  $\text{Ord}$ . This section works in GB. We write  $\Omega$  as a typographical symbol for the class order  $\text{Ord}$ , not as a new set ordinal. The construction uses the familiar hereditary normal-form pattern from ordinal analysis: for example, hereditary base- $\omega_1$  normal forms below  $\varepsilon_{\omega_1+1}$  already appear in Weiermann's discussion [85]. Finite supports and preservation of initial segments also belong to the established framework of normal dilators [86]. Our purpose is to give the proper-class construction, its foundational justification, and its universal property directly. We do not claim to have invented hereditary ordinal notation.

[merge] The hereditary system is new to this report; the four sources construct it independently. Source 35's  $\mathcal{E}$  ([note XVI.6.11](#)) is this  $\text{E}$ , with the same terms and comparison, proved well-ordered over GBC ([note XVI.6.13](#)); source 32's  $\mathcal{H}(A)$ , printed  $\text{E}(A)$ , is the general base of [corollary XVI.6.10](#), over GBC ([note XVI.6.24](#)); source 33 reaches the same fixed point as the direct limit  $\mathbb{T}$  of the finite towers ([theorem XVI.6.26](#)). In this section  $\text{E}^{\leq n}$  is source 34's  $E_n$ , the terms of height at most  $n$ , renamed because  $E_i$  is a floor equivalence in Section XVI.5.

### XVI.6.1 A class of finite codes

**Definition XVI.6.1** (Hereditary base- $\Omega$  terms). The raw expressions are finite rooted ordered trees with ordinal coefficients. We write the empty tree as 0, and a nonempty tree as

$$t = [(t_0, a_0), \dots, (t_{k-1}, a_{k-1})], \quad k > 0,$$

where the  $t_i$  are its exponent subtrees and the  $a_i$  are nonzero set ordinals. Compare two raw expressions recursively by lexicographically comparing their lists of exponent-coefficient pairs: compare exponents first and coefficients second; after an identical prefix, the shorter list is smaller. A term is *valid* when all its exponent subterms are valid and

$$t_0 > t_1 > \dots > t_{k-1}.$$

Let  $\mathbf{E}$  be the class of valid terms, with this order. Its intended display notation is

$$t = \Omega^{t_0} a_0 + \dots + \Omega^{t_{k-1}} a_{k-1}.$$

Every expression is a set. The recursive comparison terminates because each recursive call concerns smaller finite trees. Validity, comparison, and the finite set of subterms therefore have uniform first-order definitions, using finite computation witnesses if desired. In particular, the definition does not invoke a recursion of length  $\omega$  whose values are classes. This distinction matters: arbitrary class-valued recursion can require additional axioms even when its indexing order is small.

For an infinite initial cardinal  $\kappa$ , let  $\mathbf{E}[\kappa]$  consist of the terms all of whose coefficients are below  $\kappa$ . It is a set of finite codes. Define an ordinal interpretation on this set by

$$v_\kappa(0) = 0, \quad v_\kappa(t) = \kappa^{v_\kappa(t_0)} a_0 + \dots + \kappa^{v_\kappa(t_{k-1})} a_{k-1}. \quad (\text{S34.5})$$

This is ordinary evaluation of a finite tree in set ordinal arithmetic.

**Lemma XVI.6.2** (Bounded-coefficient comparison). *For  $s, t \in \mathbf{E}[\kappa]$ ,*

$$s < t \iff v_\kappa(s) < v_\kappa(t).$$

*Proof.* Induct on the total size of the two trees. By the induction hypothesis, the interpreted exponent lists remain strictly decreasing, and comparison of their exponents agrees with comparison of the subterms. All coefficients lie below  $\kappa$ . The usual comparison theorem for finite-support base- $\kappa$  representations therefore compares the two ordinal values at exactly the first exponent-coefficient difference of their lists. If one list ends after an identical prefix, its remaining value is zero and is smaller than the nonempty remaining sum of the other list. These are exactly the defining cases of term comparison.  $\square$

**Theorem XVI.6.3** (Well-foundedness in GB). *The definable relation on  $\mathbf{E}$  is a class well-order.*

*Proof.* Strict linearity follows from the comparison lemma: the finitely many coefficients in any two or three terms have a common cardinal bound, so irreflexivity, trichotomy, and transitivity transfer from ordinal comparison. Now let  $S$  be any nonempty set of terms. The coefficients appearing anywhere in  $S$  form a set of ordinals. Choose an infinite initial cardinal  $\kappa$  above all of them; arbitrarily large well-orderable initial cardinals exist in ZF. The comparison lemma embeds  $S$  into the ordinals, so  $S$  has a least term. Every nonempty set subset therefore has a minimum. [Lemma XVI.2.2](#) implies that every nonempty admitted subclass has a minimum as well. This last step requires neither set Choice nor Global Choice.  $\square$

This proof uses a different ordinal interpretation for different bounded collections of terms. It never attempts an ordinal-valued order embedding of the whole proper class  $\mathbf{E}$ .

**Example XVI.6.4** (Reading and comparing terms). Consider

$$s = \Omega^{\Omega+3}7 + \Omega^{\Omega+1}\omega^2 + 19, \quad t = \Omega^{\Omega+3}7 + \Omega^{\Omega+1}(\omega^2 + 1).$$

These are finite codes with ordinary ordinal coefficient labels. The leading exponent and coefficient agree. At the next common exponent,  $\omega^2 < \omega^2 + 1$ , so  $s < t$ ; the final coefficient 19 cannot change the outcome. Under any sufficiently large cardinal interpretation, the same comparison is an ordinary ordinal calculation. No object called the ordinal  $\Omega + 3$  is required inside the original universe: its occurrence is itself an exponent subtree.

The class and its order are parameter-free definable, although individual terms carry arbitrary ordinal data. A fixed finite syntax with constants from a set supplies only a set of terms. Allowing all set ordinal coefficients is what makes this notation system a proper class. This is compatible with ordinary definability: every particular term is constructed from a finite tuple of ordinal parameters and a finite tree shape. It does not entail a truth predicate deciding which ordinals are definable without parameters. Thus the presentation keeps separate the definability of an entire class order, the parameters describing one of its elements, and the availability of a short written name for a coefficient.

## XVI.6.2 Height, initial segments, and finite towers

Define the syntactic height by

$$h(0) = 0, \quad h(t) = 1 + \max_{i < k} h(t_i) \quad (t \neq 0),$$

and put  $\mathbf{E}^{\leq n} = \{t \in \mathbf{E} : h(t) \leq n\}$ . Thus  $\mathbf{E}^{\leq 0} = \{0\}$ , while  $\mathbf{E}^{\leq 1}$  consists of zero and the constants  $\Omega^0 a$ , and is canonically isomorphic to  $\text{Ord}$ . Write 1 for the constant with coefficient 1, and define the finite sequence of constructions

$$\tau_0 = 1, \quad \tau_{n+1} = \Omega^{\tau_n}. \quad (\text{S34.6})$$

Here the latter expression is the singleton root list  $[(\tau_n, 1)]$ . Each  $\tau_n$  is a finite term; the resulting  $\omega$ -sequence is set-coded.

**Theorem XVI.6.5** (Exact height cuts). *For every  $n < \omega$ ,*

$$\mathbf{E}^{\leq n} = \mathbf{E}_{< \tau_n}, \quad \mathbf{E}^{\leq n+1} \cong \text{Ord}^{[\mathbf{E}^{\leq n}]}$$

*Consequently the height stages are proper initial segments with order types*

$$1, \quad \Omega, \quad \Omega^{[\Omega]}, \quad \Omega^{[\Omega^{[\Omega]}]}, \quad \dots,$$

*and  $\mathbf{E} = \bigcup_{n < \omega} \mathbf{E}^{\leq n}$  has cofinality  $\omega$ .*

*Proof.* Only zero lies below the least positive term 1, proving the initial-cut claim for  $n = 0$ . Removing the root identifies  $\mathbf{E}^{\leq n+1}$  with finite graphs whose exponent support lies in  $\mathbf{E}^{\leq n}$ , with arbitrary nonzero ordinal coefficients. This proves the displayed isomorphism. Suppose  $\mathbf{E}^{\leq n} = \mathbf{E}_{< \tau_n}$ . A term lies below the monomial  $\Omega^{\tau_n}$  exactly when all its exponent support lies below  $\tau_n$ : a greater

exponent makes it larger, while an equal greatest exponent requires coefficient at least 1 and also makes it at least the monomial. Thus  $E^{\leq n+1} = E^{< \tau_{n+1}}$ .

The term  $\tau_n$  has height  $n+1$ , so it belongs to  $E^{\leq n+1}$  and not to  $E^{\leq n}$ . The cuts are therefore proper and the sequence  $(\tau_n)$  is strictly increasing. Every finite tree has finite height, so the cuts exhaust  $E$  and this sequence is cofinal. There is no largest term; a finite subset cannot be cofinal. Hence the least possible cofinality is exactly  $\omega$ .  $\square$

A proper class well-order can have set cofinality because it need not be setlike. Here the predecessor class of the term  $\Omega$  already contains a copy of every set ordinal. The theorem also shows that every exponent subterm of a nonzero term is smaller than the whole term: its height lies below that of the term, and the height levels are initial.

### XVI.6.3 The fixed-point isomorphism and leastness

**Theorem XVI.6.6** (A definable fixed point). *There is a canonical definable class isomorphism*

$$\text{Ord}^{[E]} \cong E.$$

*Proof.* Sort the finite support of a graph in decreasing  $E$ -order and make its exponent-coefficient pairs the children of a new root. This produces a valid term. Conversely, remove the root of a term to recover the finite graph. The constructions are inverse, and both orders compare the greatest exponent at which a coefficient differs.  $\square$

Leastness has a precise formulation which requires neither a collection of all class order types nor a general comparability theorem.

**Theorem XVI.6.7** (Least initial pre-fixed point). *Let  $X$  be a class well-order, and suppose that*

$$j : \text{Ord}^{[X]} \longrightarrow X$$

*is an initial order embedding. There is a unique finite-term evaluation  $e : E \longrightarrow X$  satisfying*

$$e(0) = j(\emptyset), \quad e([(t_i, a_i)]_{i < k}) = j(\{(e(t_i), a_i) : i < k\}). \quad (\text{S34.7})$$

*This map is an initial order embedding. In particular,  $E$  embeds initially into every class well-order equipped with an isomorphism  $\text{Ord}^{[X]} \cong X$ .*

*Proof.* Define  $e(t) = x$  by the existence of a finite assignment of elements of  $X$  to all subterms of  $t$ , satisfying (S34.7) at every node and assigning  $x$  to the root. Finite-tree induction proves existence and uniqueness, simultaneously proving preservation and reflection of comparison. Indeed, already evaluated exponent subterms have the same strict order as before, so the graph at the next root is well-defined; finite-support comparison followed by the order embedding  $j$  gives exactly the desired comparison. Elementary comprehension supplies the class graph of  $e$ . All witnesses in this definition are finite sets.

It remains to prove initiality. Put  $I_n = e(E^{\leq n})$ . Since  $j$  is initial and the empty graph is least,  $I_0 = \{j(\emptyset)\}$  is an initial segment of  $X$ . If  $I_n$  is initial in  $X$ , the finite graphs supported on  $I_n$  form an initial segment of  $\text{Ord}^{[X]}$ . The evaluation equation identifies their image under  $j$  with  $I_{n+1}$ . Hence  $I_{n+1}$  is initial. Their increasing union  $e(E)$  is therefore initial as well. Uniqueness follows from finite-tree induction on the evaluation equation.  $\square$

The argument defines one evaluation class by finite witnesses and then studies its restrictions. It does not recursively assemble an  $\omega$ -sequence of classes. In this concrete sense,  $\mathbf{E}$  is the least fixed point of the base-Ord power constructor, already in  $\mathbf{GB}$ . The assertion neither supplies  $\mathbf{ETR}$  along  $\mathbf{E}$  nor makes  $\mathbf{E}$  a largest definable class well-order.

**Corollary XVI.6.8** (An explicit long condensation history). *The order  $\mathbf{E}$  has an elementary canonical history on  $\mathbf{E} + 1$ . Its first singleton slice occurs at the appended final stage.*

*Proof.* Transport the explicit history of  $P(\mathbf{E})$  through the root isomorphism. At a stage  $t \in \mathbf{E}$ , the retained terms are precisely those whose root exponents are all at least  $t$ , together with zero. This is the polynomial history used in Section XVI.5. The monomial  $\Omega^t$  is a nonzero retained point, so that slice is not a singleton. The final slice is  $\{0\}$ .  $\square$

The universal property also makes the meaning of “least” independent of our chosen tree coding. A different presentation with the same fixed-point property and the same initial universal property receives an initial embedding from  $\mathbf{E}$  and supplies one in the reverse direction. Their composites are initial self-embeddings of class well-orders and hence are identities: a least point of disagreement would contradict initiality. The presentations are therefore uniquely isomorphic. This is a statement about specified class maps, not a quotient whose members would themselves be proper classes.

There is also a precise distinction between reaching the fixed-point order and naming it as one of its elements. Every term lies below some  $\tau_n$ , while the sequence of these terms is cofinal in  $\mathbf{E}$ . Consequently no term denotes an initial segment of type  $\mathbf{E}$  itself. The fixed-point isomorphism concerns the whole class presentation. To continue beyond it one may use a new class-order construction, such as  $\mathbf{E} + 1$  or the general-base construction below; the finite terms already defined do not silently acquire an additional terminal element.

#### XVI.6.4 Exact calibration in larger universes

**Theorem XVI.6.9** (Bounded-coefficient order type). *For an infinite initial cardinal  $\kappa$ , the map  $v_\kappa$  is an isomorphism of  $\mathbf{E}[\kappa]$  onto the least fixed point of ordinary ordinal exponentiation  $\xi \mapsto \kappa^\xi$ . This is the least epsilon number strictly greater than  $\kappa$ . In particular,*

$$\text{otp}(\mathbf{E}[\omega]) = \varepsilon_0, \quad \text{otp}(\mathbf{E}[\kappa]) = \varepsilon_{\kappa+1} \quad \text{if } \kappa \text{ is uncountable.}$$

*Proof.* The coefficient-bounded height stages have ordinal types  $c_0 = 1$  and  $c_{n+1} = \kappa^{c_n}$ , by root removal and ordinary finite-support exponentiation. They exhaust  $\mathbf{E}[\kappa]$ , so its ordinal type is  $\lambda = \sup_{n < \omega} c_n$ . Continuity gives  $\kappa^\lambda = \lambda$ . Any fixed point bounds all  $c_n$ , by induction, and therefore bounds  $\lambda$ .

If  $\kappa^\xi = \xi$ , then  $\xi \leq \omega^\xi \leq \kappa^\xi = \xi$ , so  $\xi$  is an epsilon number. Also  $\xi > \kappa$ : for  $2 \leq \xi \leq \kappa$  one has  $\kappa^\xi \geq \kappa^2 > \kappa$ , while  $\xi = 0, 1$  are not fixed. Conversely, let  $\varepsilon > \kappa$  be an epsilon number. Choose  $0 < \delta < \varepsilon$  with  $\kappa \leq \omega^\delta$ . Since  $\delta\varepsilon = \varepsilon$ ,

$$\varepsilon = \omega^\varepsilon \leq \kappa^\varepsilon \leq (\omega^\delta)^\varepsilon = \omega^{\delta\varepsilon} = \varepsilon.$$

For completeness,  $\delta\varepsilon = \varepsilon$  follows by bounding  $\delta$  by  $\omega^\eta$  for some  $\eta < \varepsilon$  and using  $\eta + \varepsilon = \varepsilon$ .

Finally, every uncountable initial cardinal satisfies  $\varepsilon_\kappa = \kappa$ . Indeed, for  $\alpha < \kappa$  the usual construction of the epsilon enumeration gives  $|\varepsilon_\alpha| \leq \max(\aleph_0, |\alpha|) < \kappa$ ; continuity, together with  $\varepsilon_\alpha \geq \alpha$ , now gives  $\sup_{\alpha < \kappa} \varepsilon_\alpha = \kappa$ . The next epsilon number is consequently  $\varepsilon_{\kappa+1}$ .  $\square$

The bounded-coefficient sets must not be confused with the height cuts. For example, the constant term  $\kappa$  is excluded from  $E[\kappa]$ , whereas the larger term  $\Omega$  is included. Thus  $E[\kappa]$  is not initial in the full  $E$ . In a full class model  $(V_\kappa, \mathcal{P}(V_\kappa))$  with  $\kappa$  inaccessible, all the finite codes in question belong to  $V_\kappa$ . Its internally defined  $E$  therefore has external order type exactly  $\varepsilon_{\kappa+1}$ . This supplies an exact external measurement without turning that ordinal into a set of the smaller universe.

[merge] Source 34's general-base system  $H(A)$  is printed  $E(A)$ ;  $E = E(\Omega)$  up to the identification of  $\Omega$  with its nonzero coefficients.

**Corollary XVI.6.10** (Other class bases). *For every class well-order  $A$  with at least two elements, the analogous hereditary finite normal forms  $E(A)$  form a class well-order in GB. They satisfy  $A^{[E(A)]} \cong E(A)$  and the same least initial pre-fixed-point property. Their height stages are the finite base- $A$  towers and are cofinal with order type  $\omega$ .*

*Proof.* Use nonzero elements of  $A$  as coefficients. In any nonempty set  $S$  of terms, all coefficients, together with the least element of  $A$ , form a set. Collapse their induced well-order to an ordinal, choose an infinite initial cardinal above that ordinal, and interpret all terms of  $S$  at that cardinal with the collapsed coefficients. This preserves comparison and supplies a least element of  $S$ . Finite triples establish linearity, and Lemma XVI.2.2 gives class well-foundedness in GB. Root removal, the least nonzero coefficient, and finite evaluation prove the remaining assertions exactly as above.  $\square$

## XVI.6.5 Source 35: hereditary notation and fixed-point completion

The polynomial operator admits a systematic extension beyond every fixed finite tower of powers. Its first fixed point has finite descriptions, and its existence does not require elementary transfinite recursion. The more delicate question is whether an *arbitrary supplied* class well-order can be placed inside such a fixed point. We prove an exact criterion for that extension, and thereby obtain another characterization of the repository's condensation-history principle.

Class notation for epsilon-like orders above Ord is established proof-theoretic practice. Jeon's note explicitly recalls Rathjen's class order  $E_0 = \varepsilon_{\text{Ord}+1}$  and its role in induction principles [88, Proposition 1.5]; the cited source is [89]. The finite hereditary construction below belongs to that tradition. We use our own notation  $E$  so that its precise meaning is fixed by a class-order construction, without presupposing a universe of generalized ordinal objects. The local extension criterion in Theorem XVI.6.18 is an additional result developed here; its priority outside the sources examined has not been independently established.

### XVI.6.5.1 Finite hereditary $\Omega$ -terms

*Note XVI.6.11* (Source 35, Definition 5.1, "Normalized hereditary terms"). *An  $\Omega$ -term is a finite tree: the empty list is the term 0, and a nonzero term is a list  $t = ((t_0, \alpha_0), \dots, (t_{r-1}, \alpha_{r-1}))$  with  $t_0 > \dots > t_{r-1}$  and  $0 < \alpha_i \in \text{Ord}$ , whose exponent entries are themselves terms, displayed as  $\Omega^{t_0} \alpha_0 + \dots + \Omega^{t_{r-1}} \alpha_{r-1}$ . Lists are compared lexicographically from the first pair, comparing exponents first and coefficients second; a proper common-prefix extension is larger, and exponent comparisons use the same rule recursively.  $E$  is the class of normalized terms. This is source 34's definition XVI.6.1, with the same order. Source 35 writes  $\mathcal{E}$ , printed  $E$  (section 1.3.4).*

The definition concerns finite trees labelled by set ordinals. It does not place a proper class inside another class. Recursive comparisons involve smaller finite trees, so normalization and comparison can be expressed by the existence of a finite set-coded computation trace. Consequently both predicates are elementary definitions in GB. In a nonstandard model, "finite" has that model's internal meaning, as throughout this article.

Write  $c(0) = 0$  and  $c(\alpha) = ((0, \alpha))$  for  $\alpha > 0$ . These are the constant terms. To avoid confusing syntax with an actual proper-class element, write

$$u = ((c(1), 1)), \quad M(t) = ((t, 1)).$$

Thus  $u$  is the term displayed as  $\Omega$ , while  $M(t)$  is displayed as  $\Omega^t$ . The symbol  $\Omega$  in the display is a constructor symbol;  $u$  itself is an ordinary set code.

**Lemma XVI.6.12** (Bounded specialization). *Let  $S$  be any set of terms, closed under taking exponent subterms. There is an additively indecomposable set ordinal  $\Lambda > 1$  such that the evaluation*

$$v_\Lambda(0) = 0, \quad v_\Lambda(t) = \sum_{i < r} \Lambda^{v_\Lambda(t_i)} \alpha_i$$

*is strictly order preserving on  $S$ .*

*Proof.* Choose  $\Lambda$  strictly above every coefficient occurring in  $S$ ; a sufficiently large power of  $\omega$  suffices. The displayed evaluation is ordinary set recursion on finite trees. Simultaneous induction on the sizes of two trees proves preservation of comparison. For the induction step, exponent comparisons have already been preserved. If  $\gamma < \delta$  and  $a < \Lambda$ , then

$$\Lambda^\gamma a < \Lambda^{\gamma+1} \leq \Lambda^\delta.$$

For  $\delta > 0$ , the ordinal  $\Lambda^\delta$  is additively indecomposable, so a finite tail of lower-exponent summands remains below it. At exponent zero there is no lower tail. Therefore the largest exponent of disagreement, followed by its coefficient, decides both the syntactic and the evaluated comparison. This is exactly the comparison rule in [Note XVI.6.11](#).  $\square$

*Note XVI.6.13* (Source 35, Theorem 5.3, “The first explicit polynomial fixed point”). *In GBC,  $\mathbf{E}$  is a proper class well-order, and assembling a polynomial into one new root gives an elementary class isomorphism  $\rho : P(\mathbf{E}) \rightarrow \mathbf{E}$ . This is source 34’s [theorem XVI.6.3](#), which needs only GB, and [theorem XVI.6.6](#). Source 35’s well-ordering proof applies [lemma XVI.6.12](#) to the subterms of a set-coded descending sequence, which global choice produces from a subclass without least element (first minimizing set-theoretic rank, then using the global choice function); source 34 applies its [lemma XVI.6.2](#) to an arbitrary nonempty set of terms and concludes by [lemma XVI.2.2](#). The root map is the same.*

*Note XVI.6.14* (Source 35, Proposition 5.4, “Exact tower cuts and cofinality”). *Put  $b_0 = u$  and  $b_{n+1} = M(b_n)$ . Then  $\mathbf{E}_{<b_0} \cong \text{Ord}$ ,  $\mathbf{E}_{<b_{n+1}} \cong P(\mathbf{E}_{<b_n})$  and  $\mathbf{E}_{<b_n} \cong P^n(\text{Ord})$ . The sequence  $(b_n)_{n < \omega}$  is strictly increasing and cofinal in  $\mathbf{E}$ . In particular,  $\mathbf{E}$  has cofinality  $\omega$ . This is source 34’s [theorem XVI.6.5](#) with the index shifted:  $b_n = \tau_{n+1}$  and  $\mathbf{E}_{<b_n} = \mathbf{E}^{\leq n+1}$ ; the proof is the same (the cut below  $M(b)$  consists of the terms whose root exponents lie below  $b$ ). Source 35 adds that the sequence is obtained by set-valued recursion on  $\omega$ , so its range is a set.*

The apparent tension between a proper-class carrier and a countable cofinal set is useful. It is the *set-like* proper well-order  $\text{Ord}$  that has no set cofinal subset. An order with proper-class initial segments can have set cofinality. Here each  $b_n$  is a set code whose predecessors form the indicated, generally proper, class.

*Note XVI.6.15* (Source 35, Theorem 5.5, “Leastness with an explicit witness”). *Suppose  $F$  is a class well-order and  $\varphi : P(F) \cong F$  is a supplied class isomorphism. There is a unique class map  $v : \mathbf{E} \rightarrow F$  with  $v(0) = \varphi(\emptyset)$  and  $v(t) = \varphi(\{(v(t_i), \alpha_i) : i < r\})$ ; it is an isomorphism onto an initial segment of  $F$ . This is the case of source 34’s [theorem XVI.6.7](#) in which the supplied initial*

embedding  $j : \text{Ord}^{[F]} \rightarrow F$  is an isomorphism; source 34's hypothesis, an initial pre-fixed point, is weaker. The evaluation is the same finite-trace definition. For initiality source 34 inducts on the height levels  $I_n = e(\mathbf{E}^{\leq n})$ , source 35 by structural induction on  $t$ ; its proof is printed as a second route.

*Source 35's proof.* Evaluate each finite tree from its leaves upward. This defines one elementary class map by finite traces, with  $\varphi$  as a parameter. Simultaneous induction on two trees shows that distinct exponent subterms have distinct images, so the displayed finite graph is a polynomial, and that comparison is preserved. Uniqueness follows from the same finite recursion.

We prove initiality by structural induction on  $t$ . There is nothing below  $v(0)$ . For nonzero  $t$ , let  $s$  be its largest exponent subterm, and take  $y <_F v(t)$ . Every exponent  $a$  in  $q = \varphi^{-1}(y)$  satisfies  $a \leq_F v(s)$ , since  $q < \varphi^{-1}(v(t))$  in polynomial order. If  $a < v(s)$ , the inductive assertion for  $s$  supplies its preimage under  $v$ ; equality has preimage  $s$ . Decode these finitely many exponents and retain their ordinal coefficients. They form a normalized term  $t'$  with  $v(t') = y$ . Thus everything below an image point belongs to the image. No comparison principle for arbitrary class well-orders was used.  $\square$

This theorem gives a precise sense in which  $\mathbf{E}$  is the first fixed point of  $A \mapsto P(A)$ . The existence of the isomorphism is part of the fixed-point assertion. An external equality of order types in an enclosing universe would not supply the class parameter needed by the proof in an arbitrary class model.

The use of bounded specialization also has a precise limitation. Bounding every coefficient by a set ordinal produces a set of finite trees, but generally does not produce an initial subclass of the full term order. A new, larger constant coefficient still denotes a term below  $u$ . Specialization is therefore a device for ruling out a particular set-coded descending sequence. The actual initial subclasses used to measure the tower are the exponent cuts in [Note XVI.6.14](#), not arbitrary coefficient cutoffs.

**An enclosing-universe check.** In the full model  $(V_\kappa, \mathcal{P}(V_\kappa))$  at a strongly inaccessible  $\kappa$ , the internal coefficients range externally over the ordinals below  $\kappa$ . Evaluate terms at the ordinary ordinal base  $\kappa$ . The evaluation identifies  $\mathbf{E}$  with the least positive solution of  $\kappa^\lambda = \lambda$ . Indeed, the successive tower cuts have types  $\kappa, \kappa^\kappa, \kappa^{\kappa^\kappa}, \dots$ , and ordinary base- $\kappa$  normal forms show that their union contains every ordinal below the supremum of this tower. The supremum is the first fixed point by continuity and strict increase of ordinal exponentiation.

This is also the least ordinary epsilon number strictly above  $\kappa$ . If  $\lambda = \kappa^\lambda$ , then  $\omega^\lambda \leq \lambda \leq \omega^\lambda$ , so  $\lambda$  is an epsilon number; the fixed point is larger than  $\kappa$ . Conversely, the first epsilon number  $\epsilon > \kappa$  satisfies

$$\kappa^\epsilon = (\omega^\kappa)^\epsilon = \omega^{\kappa \cdot \epsilon} = \omega^\epsilon = \epsilon.$$

Here  $\omega^\kappa = \kappa$  and  $\kappa \cdot \epsilon = \epsilon$ . Since an uncountable initial ordinal  $\kappa$  also satisfies  $\varepsilon_\kappa = \kappa$ , this ambient type is  $\varepsilon_{\kappa+1}$ . The calculation explains the familiar epsilon notation while retaining the necessary distinction: internally  $\mathbf{E}$  is a proper class order, whereas externally the displayed epsilon number is a set ordinal.

[merge] The enclosing-universe check is a second proof of source 34's [theorem XVI.6.9](#) for uncountable inaccessible  $\kappa$ , and source 33 states the tower  $t_{n+1} = \kappa^{t_n}$  in its Section 9.2 (Section XVI.8).

### XVI.6.5.2 Completion from an initial polynomial embedding

The next construction permits an arbitrary seed order, provided its initial embedding into its polynomial order is supplied. This hypothesis isolates exactly the potentially missing comparison

information.

*Note XVI.6.16* (Source 35, Lemma 5.6, “Finite-support preservation”). *If  $f : A \rightarrow B$  is an initial embedding of class well-orders, mapping each exponent through  $f$  gives an initial embedding  $P(f) : P(A) \rightarrow P(B)$ . This operation preserves identities and composition, and preserves properness of initial embeddings.* This is source 35’s own lemma XVI.4.5 for the base  $\Omega$ , with functoriality added, and source 34’s rule after (S34.3); the proof transports finite supports, and an exponent  $b$  omitted by  $f$  gives the omitted monomial at  $b$ .

**Theorem XVI.6.17** (Explicit fixed-point completion). *In GBC, suppose that  $j : A \rightarrow P(A)$  is an initial embedding of class well-orders. There is a class well-order  $C(A, j)$ , an initial embedding  $\iota : A \rightarrow C(A, j)$ , and a class isomorphism*

$$\Phi : P(C(A, j)) \longrightarrow C(A, j),$$

*all elementary in the supplied parameters. If  $j$  is proper,  $\iota$  is proper and  $C(A, j)$  has a definable increasing cofinal  $\omega$ -sequence. Moreover,  $C(A, j)$  initially embeds into every polynomial fixed point into which  $A$  initially embeds.*

*Proof.* For notation, write

$$A_n = P^n(A), \quad j_n = P^n(j) : A_n \longrightarrow A_{n+1}.$$

These symbols do not assume an arbitrary class recursion. A member of  $A_n$  is a finite nested polynomial code, with at most  $n$  polynomial levels and leaves labelled in  $A$ . Empty polynomials can terminate a branch earlier. Tags distinguish leaves from polynomial nodes. Membership and comparison are verified on a finite tree. The map  $j_n$  replaces every bottom-level  $A$ -label  $a$  by the finite polynomial  $j(a)$  and retains the outer nodes. This too is checked by a finite trace. Thus one elementary formula defines all stages and all maps uniformly in  $n$ .

Each  $A_n$  is a class well-order and each  $j_n$  is initial. Uniform finite induction is legitimate here: in GBC, well-foundedness can be expressed as the absence of a set-coded descending  $\omega$ -sequence, an elementary assertion about the uniformly defined stages. Alternatively, a proposed descending sequence at one stage uses only a set of bottom labels and coefficients; their set well-order types and ordinary finite polynomial constructions give a direct contradiction. Initiality follows from Note XVI.6.16.

For  $n \leq m$ , let  $j_{n,m}$  be the finite composite from  $A_n$  to  $A_m$ , with  $j_{n,n}$  the identity. On tagged pairs  $(n, a)$ , put

$$(n, a) \sim (m, b) \iff j_{n,k}(a) = j_{m,k}(b), \quad k = \max(n, m).$$

Each equivalence class has a unique representative at its least stage. Use those representatives as the carrier of  $C(A, j)$ . Concretely, all pairs at stage zero are retained; a pair  $(n, a)$ ,  $n > 0$ , is retained exactly when  $a$  is not in the range of  $j_{n-1}$ . This is a class of set codes, not a class whose members are equivalence classes. Order representatives by comparison of their images in a common finite stage. Injectivity and compatibility of the connecting maps prove that equality and order are well defined.

Let  $\iota_n : A_n \rightarrow C(A, j)$  send a point to its least-stage representative. The maps are initial embeddings. Indeed, a point below  $\iota_n(a)$  can be compared with it in a common later stage; initiality of  $j_{n,k}$  supplies a unique preimage in  $A_n$ . Every point belongs to some  $\iota_n[A_n]$ . Given a nonempty subclass of the colimit, choose one of its points and a stage containing that point. Its intersection

with that stage has a least element. Initiality shows that no point outside the stage can be smaller. Thus the colimit is a class well-order.

To construct  $\Phi$ , take a polynomial  $p$  on the colimit. Its finite support is contained in one  $\iota_n[A_n]$ : take the maximum of the finitely many least-stage numbers of its exponents. Decode the support into  $A_n$ , retaining the coefficients, to obtain  $p_n \in P(A_n) = A_{n+1}$ , and put

$$\Phi(p) = \iota_{n+1}(p_n).$$

For the empty support choose  $n = 0$ . The result is independent of the chosen stage because  $j_{n+1,m+1} = P(j_{n,m})$ . Choosing a common stage for two supports proves that  $\Phi$  preserves order strictly. It is onto: a point represented at a positive stage already is a polynomial on the preceding stage; a point at stage zero can first be moved to stage one using  $j$ . This proves the fixed-point assertion.

If  $j$  is proper, so is every  $j_n$ . Let  $d_n$  be the least point of  $A_{n+1}$  omitted by  $j_n$ . The points  $\iota_{n+1}(d_n)$  increase strictly, and the  $n$ th one lies above the whole image of  $A_n$ . They are therefore cofinal. Their definition is uniform and set valued, so Class Replacement supplies the corresponding set sequence.

Finally suppose  $h : A \rightarrow F$  is initial and  $\varphi : P(F) \cong F$ . Finite evaluation gives initial maps

$$h_0 = h, \quad h_{n+1} = \varphi \circ P(h_n) : A_{n+1} \rightarrow F.$$

Two initial embeddings from one class well-order into another must agree: at a least disagreement, the smaller image would lie below the other and hence would be the latter map's image of an earlier point, contradicting injectivity and earlier agreement. Applying this uniqueness to  $h_{n+1} \circ j_n$  and  $h_n$  proves compatibility. The maps therefore induce an initial embedding of the colimit into  $F$ . All evaluations and identifications above are finite set computations relative to the supplied classes; no  $\text{ETR}_\omega$  instance has been invoked.  $\square$

For  $A = \text{Ord}$ , take  $j$  to send an ordinal coefficient to the constant polynomial at the least exponent. This is a proper initial embedding. Its completion is exactly the hereditary system above: a finite stage has finitely nested polynomial roots, and identifying constant expansions gives the normalized hereditary trees. The first point missing from the zeroth-stage image is  $b_0 = u$ ; the first point missing from the next-stage image is  $b_1 = \Omega^u$ ; the subsequent missing points are  $b_2, b_3, \dots$ . Thus the general colimit construction and the explicitly indexed tower cuts give the same order and the same cofinal sequence.

### XVI.6.5.3 The exact local criterion

**Theorem XVI.6.18** (Local fixed-point extension criterion). *For any class well-order  $W$ , the following are equivalent over GBC:*

1. *there is a class initial embedding  $W \rightarrow P(W)$ ;*
2. *there are a class well-order  $F$ , a class initial embedding  $W \rightarrow F$ , and a class isomorphism  $P(F) \cong F$ .*

*For nonempty  $W$ , these are also equivalent to the existence of its canonical terminating condensation history on the schedule  $W + 1$ .*

*Proof.* The forward implication is [Theorem XVI.6.17](#). For the converse, identify  $W$  with its initial image  $A \subseteq F$  and write  $\varphi : P(F) \cong F$ . The monomial map

$$g(b) = \varphi(\{(b, 1)\})$$

is an order embedding of  $F$  into itself. Every such embedding is inflationary. Otherwise its least counterexample  $b$  would satisfy  $g(g(b)) < g(b) < b$ , making  $g(b)$  an earlier counterexample.

Take  $a \in A$  and  $q = \varphi^{-1}(a)$ . If  $b \in \text{supp}(q)$ , then the coefficient-one monomial at  $b$  is at most  $q$ . Hence

$$b \leq_F g(b) \leq_F a.$$

Initiality gives  $b \in A$ . Thus  $\varphi^{-1}$  maps  $A$  into  $P(A)$ . Its range there is initial: a polynomial below  $\varphi^{-1}(a)$  has image under  $\varphi$  below  $a$ , which belongs to  $A$ . Transport back through the original embedding to obtain  $W \rightarrow P(W)$ . The last equivalence is exactly the repository's fixed-schedule normal-form criterion proved in the preceding section.  $\square$

**Corollary XVI.6.19** (A fixed-point characterization of comparability). *Let FPE assert that every class well-order initially embeds in a class well-order  $F$  with a supplied isomorphism  $P(F) \cong F$ . Then*

$$\text{GBC} \vdash \text{FPE} \longleftrightarrow \text{CWO} \longleftrightarrow \text{CTH}.$$

*Requiring the initial extension in FPE to be proper gives the same global principle.*

*Proof.* Apply [Theorem XVI.6.18](#) to each input and use the repository equivalence between CWO, CTH, and the assertion that every  $W$  initially embeds in  $P(W)$ . For a proper extension, apply that assertion to the tagged order  $W + 1$  before taking its completion. The converse is immediate.  $\square$

This conclusion calibrates *extending every input*, even though one explicit fixed point already exists in GBC. It also avoids an invalid inference from a countable display of class-valued stages to a need for  $\text{ETR}_\omega$ . The special operator used here is finitary and has uniform finite codes; arbitrary elementary class recursions need not have that property. No equivalence with full ETR follows from this argument.

There is no hidden choice of a class witness for every member of a proper collection. The local construction takes one order and one embedding as supplied parameters and returns one explicitly defined completion. The global principle quantifies over inputs and asserts existence separately for each one. It does not assert a single class whose entries are all those completions, nor does it provide a uniform satisfaction predicate for arbitrary formulas defining orders. This distinction is essential when translating the result into a theory whose classes are precisely the definable classes of a fixed set-theoretic model.

#### XVI.6.5.4 A next fixed point, with no maximal endpoint

**Corollary XVI.6.20** (Successor fixed-point extension). *Given  $B$  and a class isomorphism  $\varphi : P(B) \cong B$ , GBC constructs a polynomial fixed point strictly extending  $B$  initially. It is least among polynomial fixed points properly extending  $B$ , in the sense of supplied initial embeddings.*

*Proof.* Let  $A = B + 1$ , with appended point  $*$ . Define an initial embedding  $j : A \rightarrow P(A)$  by

$$j(b) = \varphi^{-1}(b) \quad (b \in B), \quad j(*) = \{(*, 1)\}.$$

The first part fills exactly  $P(B)$ , and the second point is the first polynomial after that initial subclass. Thus  $j$  is initial and proper. Its completion contains  $B + 1$  initially and is a fixed point, by [Theorem XVI.6.17](#). Any fixed point properly extending  $B$  contains an initial copy of  $B + 1$ , by adjoining its least point outside the image of  $B$ . The universal property of the completion therefore proves leastness.  $\square$

Consequently the first hereditary fixed point is not a final boundary. It has a next fixed point, and every supplied fixed point has another one beyond it. Each externally specified finite repetition is available from these explicit constructions. Organizing all such extensions along a prescribed arbitrary class index is a further uniformity problem; it is not supplied merely by writing an indexed epsilon or Veblen symbol. A rigorous notation system must specify its set codes, its comparison rule, the admitted embeddings, and the existence principle used to assemble any genuinely transfinite family.

[merge] Theorems XVI.6.17 and XVI.6.18 and corollaries XVI.6.19 and XVI.6.20 are proved here only by source 35; none of sources 32–34 and nothing earlier in this report constructs a fixed-point completion. Source 35 keeps them over GBC and asks whether they hold over GB (its question 10.6, research question 113.270); they do (theorem XVI.6.21). The “repository equivalence” used in the proof of corollary XVI.6.19 is theorem 108.19 over GBC, and theorem XVI.5.8 over GB.

**Theorem XVI.6.21** ([merge]; completion without choice). *The following hold over GB, with ZF sets and no form of set choice or global choice.*

- (1) Source 35’s bounded-specialization principle, lemma XVI.4.8.
- (2)  $E$  is a class well-order and root formation is an isomorphism  $P(E) \cong E$  (note XVI.6.13).
- (3) The fixed-point completion theorem XVI.6.17: for every initial embedding  $j : A \rightarrow P(A)$  of class well-orders there are  $C(A, j)$ ,  $\iota$  and  $\Phi$  with all the properties stated there.
- (4) The local criterion theorem XVI.6.18; the characterization corollary XVI.6.19 in the form  $GB \vdash FPE \leftrightarrow CWO \leftrightarrow CTH$ , with its proper-extension variant; and the successor fixed point corollary XVI.6.20.

*Proof.* Apart from citing the GBC form of the history–comparison equivalence in the proof of corollary XVI.6.19 (replaced in (4) by theorem XVI.5.8), source 35’s proofs use global choice only to infer that a linear order is a class well-order from the absence of descending set sequences. Over GB use instead source 34’s lemma XVI.2.2: a class linear order is a class well-order exactly when every nonempty set subset has a least element. That condition quantifies only over sets, so it is elementary in the order.

(1) Let  $S$  be a nonempty set of terms of the class  $T$  of lemma XVI.4.8. The labels occurring in  $S$  form a set of ordinals, by Replacement, and so have a strict upper bound. By hypothesis there is a larger  $\kappa$  for which all terms with labels below  $\kappa$ , in particular all members of  $S$ , have a strictly order-preserving interpretation into a set ordinal. The member of  $S$  with the least interpretation is least in  $S$ , since  $S$  is linearly ordered. Thus every nonempty set subset of  $T$  has a least element, and lemma XVI.2.2 applies.

(2) Source 35’s  $\mathcal{E}$  and source 34’s  $E$  are the same class with the same order (note XVI.6.11); this is theorems XVI.6.3 and XVI.6.6.

(3) In the proof of theorem XVI.6.17 the stages  $A_n = P^n(A)$  and the maps  $j_n = P^n(j)$  are defined by one elementary formula uniformly in  $n \in \omega$ , with  $A$  and  $j$  as class parameters, through finite nested codes, and  $A_{n+1}$  is literally  $P(A_n)$  under this coding. Let  $\varphi(n)$  say:  $<_{A_n}$  is a strict linear order on  $A_n$ , every nonempty set subset of  $A_n$  has a  $<_{A_n}$ -least element, and  $j_n$  is an order embedding of  $A_n$  onto an initial subclass of  $A_{n+1}$ . Every quantifier of  $\varphi$  ranges over sets, so  $\varphi$  is elementary, and  $\{n \in \omega : \neg\varphi(n)\}$  is a set; if it were nonempty it would have a least element. Hence internal induction on  $n$  is available for  $\varphi$ .  $\varphi(0)$  holds because  $A$  is a class well-order,  $P(A)$  is linearly ordered and  $j$  is initial. Suppose  $\varphi(n)$ . By lemma XVI.2.2,  $A_n$  is a class well-order; then  $A_{n+1} = P(A_n)$  is a class well-order by theorem XVI.4.2, so it is linear and its nonempty set subsets have least elements;  $A_{n+2} = P(A_{n+1})$  is linear by the finite lexicographic comparison; and  $j_{n+1} = P(j_n)$  is initial by note XVI.6.16, whose proof only transports finite supports. So  $\varphi(n+1)$

holds, and  $\varphi(n)$  holds for every  $n \in \omega$ . By [lemma XVI.2.2](#) once more, applied with  $n$  as a parameter, each  $A_n$  is a class well-order. This replaces the paragraph of source 35’s proof that invokes global choice (“Uniform finite induction is legitimate here: in GBC, . . .”); its alternative route through a proposed descending sequence also needs choice to produce the sequence.

The rest of source 35’s proof makes no choice. The carrier of  $C(A, j)$  consists of least-stage representatives, defined by an elementary formula, and its order compares images in a common finite stage. A nonempty subclass of the colimit has a point in some  $\iota_n[A_n]$ ; the intersection of the subclass with that stage has a least element because  $A_n$  is a class well-order, and initiality makes it least overall. The isomorphism  $\Phi$  decodes finite supports. If  $j$  is proper,  $d_n$  is the least element of the nonempty class  $A_{n+1} \setminus j_n[A_n]$ , uniquely specified, and Class Replacement collects  $(d_n)_{n < \omega}$ . For the universal property, the maps  $h_n$  are defined by finite evaluation uniformly in  $n$ ; “ $h_n$  is an initial embedding of  $A_n$  into  $F$ ” is elementary, and induction on  $n$  proves it by [note XVI.6.16](#) and the isomorphism  $\varphi : P(F) \cong F$ ;  $h_{n+1} \circ j_n = h_n$  because two initial embeddings between class well-orders agree ([lemma XVI.2.5](#), whose least-disagreement proof is choice-free).

(4) In [theorem XVI.6.18](#) the forward implication is (3). The converse uses that the monomial map  $g$  is an order embedding of a class well-order into itself, hence inflationary ([lemma XVI.2.5](#)), and initiality; the final equivalence is [note XVI.5.18](#) with  $\Gamma = W$ , which holds over GB. For [corollary XVI.6.19](#), apply the local criterion to each input and replace the GBC equivalence [theorem 108.19](#) by its GB form [theorem XVI.5.8](#); for the proper variant, apply it to  $W + 1$ . [Corollary XVI.6.20](#) uses only (3) and the universal property.  $\square$

[merge] This answers source 35’s question 10.6 ([research question 113.270](#)) positively. The point source 35 raises there, the “internal uniformity of the iterated stages”, is exactly the induction on  $\varphi$ : [lemma XVI.2.2](#) makes “ $A_n$  is a class well-order” equivalent to an elementary property of  $n$ , so the induction is internal to the model and needs no metatheoretic iteration and no class-valued recursion. Source 35’s leastness ([note XVI.6.15](#)), tower cuts ([note XVI.6.14](#)) and bounded specialization at an indecomposable base ([lemma XVI.6.12](#)) use no choice as printed. The proof is this write’s; no source states it. It had not been reviewed when written; an independent adversarial check of 4 October 2026 ([section XVI.12](#)) found it valid, with no mathematical gap, after the two editorial corrections recorded next.

**Review remark H4 (retained dependency correction).** [merge] [corrected after independent check, 4 October 2026] In (1) the class of terms of [lemma XVI.4.8](#), printed  $T$  there, was misprinted  $T_m$  twice. The first sentence of the proof said that source 35’s proofs use global choice only for that inference; its proof of [corollary XVI.6.19](#) also cites the GBC equivalence [theorem 108.19](#), which item (4) already replaces by [theorem XVI.5.8](#), so the argument was complete and only the sentence is reworded. The check also notes that in (3) the finite-trace definitions of membership and order in  $A_n$  agree with  $P$  applied to  $A_{n-1}$ ; that agreement holds by construction and can be proved by the same induction, folded into  $\varphi(n)$ .

## XVI.6.6 Source 35: a systematic notation discipline

The purpose of a notation is to make a specified family of orders usable. A notation should identify its carrier, its comparison rule, the axioms proving well-ordering, and the meaning of its equality. There is no need to pretend that every class order has one canonical set-valued name. The preceding results instead suggest several compatible levels of notation.

### XVI.6.6.1 Order constructors and labelled normal forms

At the first level, a term is an instruction for constructing a presentation. Constants name the empty order, the singleton order, set ordinals,  $\Omega$ , and explicitly supplied class well-orders. Binary constructors form  $A + B$ ,  $A \cdot B$ , and the finite-support power  $A^{[B]}$ . A family constructor  $\sum_{i \in I} W_i$  is permitted only when its input is one uniform class relation. An initial direct limit constructor includes its actual connecting maps as data. Consequently every constructor has a finite, well-typed specification.

At the second level, once an exponent order  $\Gamma$  is fixed, a polynomial code is

$$q = ((i_0, \alpha_0), \dots, (i_{r-1}, \alpha_{r-1})), \quad i_0 >_\Gamma \dots >_\Gamma i_{r-1}, \quad 0 < \alpha_j \in \text{Ord}.$$

The code is a set. Its displayed notation may be written

$$\sum_{j < r} \Omega^{\langle i_j \rangle_\Gamma} \alpha_j,$$

where  $\langle i \rangle_\Gamma$  means the initial segment  $\Gamma_{<i}$ , not an unexplained ordinal assigned to  $i$ . This superscript convention is optional when  $\Gamma$  is the ordinary ordinal class, but indispensable for an arbitrary class exponent order.

*Note XVI.6.22* (Source 35, Proposition 6.1, “Meaning of a polynomial as a cut”). *For the preceding code  $q \in P(\Gamma)$ , its strict initial segment has the explicit order decomposition  $P(\Gamma)_{<q} \cong \sum_{j < r} P(\Gamma_{<i_j}) \cdot \alpha_j$ . Thus the displayed polynomial is an actual finite sum of class well-orders. The assertion holds in GB.* This is source 34’s (S34.4), by the same partition of the predecessors of  $q$  by the greatest exponent at which they fall below it.

This proposition separates two objects that a compact notation often conflates:  $q$  is one set code, whereas the order denoted by the cut below  $q$  can be a proper class. For example, the code with coefficient 1 at exponent 1 and zero elsewhere is a set, but its predecessor order in  $P(\text{Ord})$  is  $\Omega$ . A notation system for orders beyond  $\text{Ord}$  is therefore possible without any individual notation being a proper-class object.

### XVI.6.6.2 Worked comparisons and arithmetic

Finite polynomials with ordinal exponents provide the following strict comparisons, all witnessed inside the same polynomial order:

$$\Omega + 1 < \Omega \cdot 2 < \Omega \cdot \omega < \Omega^2 < \Omega^2 + \Omega \cdot \omega < \Omega^3.$$

Here and in worked displays within one notation order,  $<$  abbreviates the proper initial-segment comparison of the represented cuts. Compare the greatest exponent of disagreement; if it agrees, compare its ordinal coefficient. No search through all lower exponents is needed.

For instance,

$$q = \Omega^3 \cdot 2 + \Omega \cdot \omega + 7, \quad r = \Omega^3 \cdot 2 + \Omega \cdot (\omega + 1)$$

satisfy  $q < r$ . Their exponent-3 coefficients agree. At exponent 1, the coefficient  $\omega$  is smaller than  $\omega + 1$ , so the finite tail 7 does not affect the comparison.

Ordinal addition is visibly noncommutative. The identities

$$(\Omega^2 + \Omega \cdot 3 + 7) + (\Omega \cdot 4 + 5) = \Omega^2 + \Omega \cdot 7 + 5$$

and

$$(\Omega \cdot 4 + 5) + (\Omega^2 + \Omega \cdot 3 + 7) = \Omega^2 + \Omega \cdot 3 + 7$$

hold as presentation isomorphisms. In the first calculation the later  $\Omega$ -block absorbs the earlier finite tail. In the second it absorbs the entire earlier summand. More generally, when adding a nonzero right-hand polynomial, retain the left-hand exponents greater than its leading exponent, add the two coefficients at that exponent in the *ordinal* sense, and retain the right-hand lower tail. Each coefficient sum is a set ordinal, so there is no carry into the class base  $\Omega$ .

For products, the direction of the factors must remain explicit:

$$(\Omega + 1) \cdot \omega = \Omega \cdot \omega, \quad \omega \cdot (\Omega + 1) = \Omega + \omega.$$

The first has  $\omega$  successive proper blocks. In the second, the initial  $\omega \cdot \Omega$  is set-like and hence has type  $\Omega$ , followed by one copy of  $\omega$ . The equality

$$\Omega^{[\Omega+1]} \cong \Omega^{[\Omega]} \cdot \Omega$$

comes directly from splitting the final exponent coordinate. It does not depend on a recursive definition taking a supremum over a proper collection of class objects.

The absorption laws for a set base are particularly instructive:

$$2^{[\Omega]} \cong \omega^{[\Omega]} \cong \Omega, \quad \Omega^{[\Omega]} \not\cong \Omega.$$

The first presentations have set-sized predecessors and proper carriers. In the last one, the predecessor class below the monomial at exponent 1 is already proper, so the order is not set-like. This is a structural proof of the difference, rather than a symbolic rule about an imagined largest ordinal.

### XVI.6.6.3 Hereditary terms and the first exponential closure

In the hereditary system of the preceding section, the exponents themselves are terms. Comparison descends through finitely many subtrees until it reaches ordinal coefficients. The following is a typical legal term:

$$\Omega^{\Omega^2 + \Omega \cdot 3 + 5} \cdot \omega + \Omega^{\Omega + 7} \cdot 4 + 9.$$

Its meaning is a cut in the class of hereditary terms. The term's finite tree is a set even though its first exponent already denotes a proper-class order.

Let  $\mathbf{E}$  be the complete hereditary term order. The finite tower markers give a strictly increasing cofinal sequence in  $\mathbf{E}$ ; every single term lies below some such marker. Hence  $\mathbf{E}$  is longer than every finite tower stage and has a specified isomorphism  $P(\mathbf{E}) \cong \mathbf{E}$ . The notation  $\mathbf{E}$  names the whole order, while a term  $t$  names one of its proper initial cuts. This avoids representing the entire fixed point by one of its own elements.

There are two useful ways of continuing. One may introduce a new named constant for the order  $\mathbf{E}$  and construct its successor, products, and powers. Or one may apply the fixed-point completion construction to  $\mathbf{E} + 1$ , obtaining a larger exponential fixed point. Repeating a fixed, explicitly specified finite construction is legitimate. Claiming a universal class-valued recursion through all class well-orders requires a further principle and is not built into this syntax.

### XVI.6.6.4 What is effective, and what is only definable

There are four distinct levels of computational content.

1. A *mathematical class presentation* permits arbitrary set ordinal coefficients. These coefficients have exact mathematical order, but they are not all finite strings.

2. A *relative comparison procedure* compares hereditary terms using a supplied comparison procedure for their coefficient notations. Finite structural recursion then suffices.
3. An *effective notation language* restricts coefficients to a chosen recursively presented ordinal system. It has countably many expressions and names only the corresponding selected cuts.
4. A *proof-carrying presentation* stores, with each new constructor, a proof of well-order preservation or an initial embedding certificate. This is the appropriate interface for a formal mathematics library.

The small executable artifact accompanying this article implements the finite-tree comparison idea with nonnegative integer coefficients. It also checks the finite-support split and flatten maps against ordinary finite ordered sets. Its task is to make the conventions reproducible; it is not a decision procedure for arbitrary definable class well-orders or a formal proof of the theorems above.

[merge] The executable artifact mentioned above is shipped as `code/35-completion-finite_notation_checks.py`, with its recorded output `data/35-completion-finite_notation_results.json` ([appendix A.13](#)).

### XVI.6.6.5 An interface for extensible notations

A useful formal specification associates four items with each presentation: a predicate for legal codes, a comparison relation, a stated well-order theorem, and a semantics relating codes to initial cuts. A constructor additionally records how it acts on class maps. For example, the exponent-order constructor  $P$  acts on an initial embedding by replacing each exponent label by its image. This preservation law is what makes the completion theorem possible.

A notation package should therefore expose more than a pretty printer. It should expose the explicit initial embedding of one stage into the next, the inverse on its image, and the map that interprets a finite code. Such witnesses permit comparisons and direct limits in weak class theory even where unrestricted class well-order comparability is unavailable. The definability theorem in the next section shows why this disciplined extensibility is preferable to promising one complete language for all class orders.

### XVI.6.7 Source 32: finite terms beyond every finite exponential tower

The finite-support construction can itself be iterated inside finite syntax. This gives an exponential fixed-point presentation without performing a class-valued recursion of unbounded length.

*Note XVI.6.23* (Source 32, Definition 4.1, “Hereditary digit terms”). *Fix a class well-order  $A$  with least points  $0_A < 1_A$ . A hereditary  $A$ -term is either 0, or a finite list  $t = [(t_0, a_0), \dots, (t_{m-1}, a_{m-1})]$  where the  $t_i$  are hereditary terms in strictly decreasing order and  $a_i \in A \setminus \{0_A\}$ . Compare nonzero terms by their leading exponents, then their leading coefficients, and then their remaining lists; an exhausted list is smaller than a nonexhausted one. The term 0 is least.* Source 32 writes  $\mathcal{H}(A)$  for this presentation, printed  $\mathbf{E}(A)$ ; it is source 34’s general base of [corollary XVI.6.10](#), and for  $A = \Omega$  it is  $\mathbf{E}$  up to identifying coefficients.

This definition is a finite-tree definition, not a recursive specification along a proper-class well-order. Membership and comparison are computed by recursion on the finite heights of the input trees (or the maximum of the heights of two trees). The requirement that the exponent list decrease is checked using comparisons of strictly smaller trees. Terms are finite sets of labels and finite-tree structure.

*Note XVI.6.24* (Source 32, Theorem 4.2, “A hereditary fixed-point presentation”). In GBC,  $E(A)$  is a class well-order and there is an explicit isomorphism

$$E(A) \cong A^{[E(A)]}. \quad (\text{S32.4})$$

The constant terms form a proper initial copy of  $A$ . There is a set-coded increasing  $\omega$ -sequence cofinal in  $E(A)$ . This is source 34’s [corollary XVI.6.10](#) (over GB), with the cofinality of [theorem XVI.6.5](#). Source 32’s proof is source 34’s: evaluate the terms occurring in a set of terms at the ordinal type  $a \geq 2$  of their coefficient labels,  $\text{val}(t) = \sum_{i < m} a^{\text{val}(t_i)} \rho(a_i)$ , which preserves and reflects comparison by [lemma XVI.4.9](#); a descending sequence would give a descending sequence of ordinals, and [lemma XVI.2.8](#) concludes in GBC. The constants are the segment below  $[(1, 1_A)]$  with  $1 = [(0, 1_A)]$ , and the cofinal sequence is  $v_0 = 1$ ,  $v_{n+1} = [(v_n, 1_A)]$ , source 34’s  $\tau_n$ .

For  $A = \Omega$ , these terms provide an explicit proper-class order above all finite towers based at  $\Omega$ , with an isomorphism to its own  $\Omega$ -power. More precisely, the segment below  $v_n$  has the corresponding finite-tower presentation: root decomposition identifies the segment below  $v_{n+1}$  with  $A^{(E(A))^{<v_n}}$ , starting with the one-point segment below  $v_0 = 1$ .

This is a useful answer to “how far can one stretch?” but it is not an endpoint. Adjoining a last point produces a strictly larger order by [note XVI.2.10](#). One can also repeat finite-term constructions over the new base. The significance is that these examples are already definable by finite syntax in GBC; their existence is not evidence that GBC supports arbitrary recursion along them.

## XVI.6.8 Source 33: coherent towers of powers and a fixed point

### XVI.6.8.1 An explicit tower, not an arbitrary class recursion

Define presentations

$$T_0 = \Omega, \quad T_{n+1} = \Omega^{[T_n]} \quad (n < \omega).$$

These can be coded uniformly by finite rooted trees: leaves carry ordinal labels, a node carries a finite descending list of exponent subtrees and nonzero ordinal coefficients, and a level label specifies the required nesting depth. Validity and comparison are obtained by finite bottom-up evaluation on the code tree. In particular, a set records the entire finite evaluation at every node. No truth predicate for the whole universe is required.

This description supplies one elementary definition of the family of carriers and orders. First-order induction on  $n$ , using [note XVI.4.12](#), verifies that every stage is a class well-order. This is different from asserting that *every* arbitrary class-valued recursion of length  $\omega$  has a solution.

Embed  $T_0$  into  $T_1$  by sending  $\alpha$  to the constant polynomial with coefficient  $\alpha$  at the least exponent, with zero sent to the empty polynomial. Call this  $i_0$ . Inductively, let  $i_{n+1}$  replace every exponent by its image under  $i_n$ , leaving coefficients unchanged. These maps also have uniform finite-tree definitions.

**Lemma XVI.6.25.** *Every  $i_n : T_n \rightarrow T_{n+1}$  is a proper initial embedding.*

*Proof.* The constants form a proper initial segment of  $T_1$ . More generally, if  $j : A \rightarrow B$  has initial image, the induced exponent map  $\Omega^{[A]} \rightarrow \Omega^{[B]}$  has initial image: any polynomial below an image polynomial cannot have a nonzero coefficient at an exponent outside the initial image. If  $j$  is proper, a monomial at the least omitted exponent is not in that image. Apply induction.  $\square$

### XVI.6.8.2 The direct limit

Take the disjoint union of all pairs  $(n, t)$  with  $t \in T_n$ . Identify  $(n, t)$  and  $(m, s)$  when their images agree at a common later finite stage. Each equivalence class has a unique representative at its least level. Use these least-level representatives as a class carrier  $\mathbb{T}$ . Comparison is computed by lifting two representatives to the larger of their levels. Thus both equality and order on  $\mathbb{T}$  are elementary from the finite-tree coding.

**Theorem XVI.6.26** (A definable fixed point beyond finite towers). *The direct limit  $\mathbb{T}$  is a class well-order, every  $T_n$  is a proper initial suborder of  $\mathbb{T}$ , and there is a definable order isomorphism*

$$\Omega^{[\mathbb{T}]} \cong \mathbb{T}.$$

*This construction is available in GBC.*

*Proof.* The coherent initial embeddings make each  $T_n$  an initial suborder of the limit. For a nonempty subclass  $S \subseteq \mathbb{T}$ , choose  $x \in S$  and a stage  $T_n$  containing it. The intersection of  $S$  with that stage has a least point. Every point of  $\mathbb{T}$  below  $x$  already belongs to that same initial stage, so this least point is least in  $S$ . Thus  $\mathbb{T}$  is well-ordered. Properness follows from [lemma XVI.6.25](#).

An element of  $\Omega^{[\mathbb{T}]}$  uses only finitely many exponent points of  $\mathbb{T}$ . All those points lie in a common finite stage  $T_n$ . Interpret the same polynomial as a point of  $T_{n+1}$ , hence of  $\mathbb{T}$ . A different sufficiently large choice of stage gives the same limit point, by the definition of  $i_{n+1}$ .

This map is order preserving because any two finite supports can be put into one stage. It is onto because every point of a stage  $T_{n+1}$  already is a polynomial over  $T_n$ , and every point of  $T_0$  is represented among the constants of  $T_1$ . It is therefore the required isomorphism.  $\square$

The fixed point is not a ceiling:  $\mathbb{T} + 1$  again strictly exceeds  $\mathbb{T}$  under embeddability. Further explicit notation systems can be built, but their uniform definition and well-foundedness must be checked rather than inferred from suggestive ordinal symbols. The diagonal theorem below rules out one uniform system containing every definable possibility in its own language.

[merge] Source 33's direct limit, which it writes  $E$ , is printed  $\mathbb{T}$ :  $E$  is a floor equivalence in Section XVI.5 and  $E$  is the hereditary order.  $\mathbb{T}$  is  $E$  up to a canonical isomorphism: source 33's embedding  $i_0$  of  $T_0 = \Omega$  into  $T_1$  is source 35's seed embedding  $j$  for  $A = \text{Ord}$ , its maps  $i_{n+1}$  are  $P(i_n)$ , so  $\mathbb{T}$  is source 35's completion  $C(\text{Ord}, j)$ , which source 35 identifies with the hereditary system (the paragraph after [theorem XVI.6.17](#)). Directly: by [theorem XVI.6.7](#), applied to the isomorphism  $\Omega^{[\mathbb{T}]} \cong \mathbb{T}$  of [theorem XVI.6.26](#),  $E$  embeds initially into  $\mathbb{T}$ ; by the universal property in [theorem XVI.6.17](#), applied to root formation  $P(E) \cong E$  and the initial copy of  $\text{Ord}$  formed by the constant terms,  $\mathbb{T}$  embeds initially into  $E$ ; both composites are initial self-embeddings of class well-orders, hence identities ([lemma XVI.2.5](#)), so both maps are isomorphisms. Source 33 constructs  $\mathbb{T}$  in GBC; the construction works in GB by [theorem XVI.6.21](#) (3). The finite tower  $T_n$  is source 34's  $E^{\leq n+1} = E_{<\tau_{n+1}}$  ([theorem XVI.6.5](#)).

## XVI.7 Uniform catalogs and truth jumps

The preceding notation systems describe substantial families of orders. A different question is whether one uniform notation system can encompass every available class well-order. There is a direct obstruction, which also leads to an explicit construction showing how an added truth predicate increases the definable order spectrum. The results in this section are proved as structural consequences; no claim of historical priority is intended.

Write  $C \hookrightarrow D$  when there is a class order embedding of  $C$  into  $D$ . This notation requires neither a cofinal image nor an initial image. In particular, we will not substitute the general class comparison principle for an embedding argument.

### XVI.7.1 A diagonal sum for uniform families

**Definition XVI.7.1** (Uniform class family). A uniform family  $(C_i)_{i \in I}$  consists of class relations  $D(i, x)$  and  $R(i, x, y)$ : the domain of  $C_i$  is  $\{x : D(i, x)\}$ , and its strict order is the corresponding slice of  $R$ . Thus the family is represented by classes of *set tuples*. An external list of formulas is not, by itself, such a uniformly interpreted family.

**Theorem XVI.7.2** (Uniform-family diagonal). *Work in GB, and let  $(I, <_I)$  be an available class well-order. If  $(C_i)_{i \in I}$  is a uniform family of class well-orders, then*

$$\Delta = \sum_{i \in I} (C_i + 1)$$

*is a class well-order. For every  $i \in I$ , the order  $C_i + 1$  embeds as a convex block of  $\Delta$ , while*

$$\Delta \not\hookrightarrow C_i.$$

*If  $I$  is proper, then  $\Delta$  is proper.*

*Proof.* Use tagged set codes  $\langle i, 0, x \rangle$  for  $x \in C_i$  and  $\langle i, 1 \rangle$  for the last point of its block. Order these codes first by  $<_I$  and then by the order of  $C_i + 1$ . Elementary comprehension supplies both the domain and the relation.

Let  $S$  be a nonempty subclass of this order. The class of indices of blocks meeting  $S$  has a least member  $i$ . The intersection of  $S$  with that block has a least member, since  $C_i + 1$  is a class well-order. That member is least in  $S$ , proving well-foundedness.

The inclusion of the  $i$ th block is explicit. If an embedding  $f : \Delta \rightarrow C_i$  existed, its restriction to that block would embed  $C_i + 1$  into  $C_i$ , contrary to the successor obstruction [lemma XVI.3.2](#). This contradiction excludes *every* available class embedding, including one using additional class parameters. Finally,  $i \mapsto \langle i, 1 \rangle$  injects  $I$  into  $\Delta$ ; if the latter were a set, class replacement applied to the inverse would make  $I$  a set.  $\square$

**Corollary XVI.7.3** (No uniform cofinal catalog). *In GBC, no uniform class-indexed family of class well-orders is cofinal for order embedding among all class well-orders. In particular, no such family represents every class well-order up to class isomorphism.*

*Proof.* Restrict a global well-order to the index class and apply [Theorem XVI.7.2](#). Its diagonal sum embeds into no catalog member.  $\square$

This remains an obstruction when the proposed catalog is redundant or ineffective. What matters is uniform interpretation as actual class relations. If the family and its index order are definable from fixed parameters, the diagonal sum is definable from the same parameters. Consequently such a family cannot even be cofinal among all well-orders definable from those parameters. This does not prohibit partial notation systems, bounded fragments, or interpretation using stronger parameters. It identifies why simply enumerating formulas does not produce a universal notation system: their intended interpretations have not thereby been collected into one class relation.

### XVI.7.2 A well-order supplied by one truth predicate

Fix a set-like global well-order  $G$  of  $V$  and a class parameter  $A$ ; finitely many class predicates can be combined into  $A$  by tags. We do not assume that  $G$  is definable from  $A$ . Let  $T$  be a full elementary satisfaction class for

$$(V, \in, A, G).$$

Here “full” means that  $T$  evaluates all first-order formula codes with finite set-valued assignments and satisfies the compositional Tarskian clauses. It is an additional assumed class, not something being defined in the language whose truth it expresses. The established connection between truth predicates and elementary transfinite recursion provides the foundational context [22].

The key to a uniform catalog at this stronger level is that class well-foundedness has a first-order test in GBC. Namely, a class relation is well-founded exactly when there is no set-coded descending  $\omega$ -sequence. In the converse direction, if a nonempty class has no minimal member,  $G$  selects a predecessor of each of its points; ordinary set-valued recursion on  $\omega$  yields a descending sequence. This is not class-valued ETR. The sharper GB + DC version is proved in [22, Section 4].

Index pairs of domain and relation formulas, together with a packed set parameter, by

$$i = (e, f, p), \quad \varphi_e(x, p; A, G), \quad \psi_f(x, y, p; A, G).$$

Restrict to valid syntactic codes of these arities, and order the resulting proper index class  $I$  by  $G$ . Packing finite tuples into  $p$  includes every presentation with finitely many set parameters.

From  $e, f$  one effectively obtains the code of a first-order formula  $\text{WO}_{e,f}(p; A, G)$ . It asserts that  $\psi_f$  is a strict linear order on the  $\varphi_e$ -domain, and that no set function  $s$  on  $\omega$  has all its values in that domain with

$$\psi_f(s(n+1), s(n), p; A, G) \quad \text{for every } n \in \omega.$$

Consequently

$$\text{Valid}(i) \iff T(\ulcorner \text{WO}_{e,f} \urcorner, p)$$

is a uniform elementary condition using  $T$ . Define  $W_i$  by interpreting  $\varphi_e, \psi_f$  through  $T$  when  $i$  is valid, and by taking the empty order otherwise. Explicitly, its domain is given by

$$x \in W_i \iff \text{Valid}(i) \wedge T(e, x, p),$$

with  $x <_{W_i} y$  defined by  $x, y \in W_i$  and  $T(f, x, y, p)$ . By the compositional clauses and the preceding test, every fiber is a class well-order. Invalid formulas cannot introduce an ill-founded summand.

**Theorem XVI.7.4** (Relative truth jump). *Under the preceding GBC assumptions, let*

$$J(T; A, G) = \sum_{i \in I}^G (W_i + 1).$$

*This is a proper class well-order definable from  $T, A, G$ . For every class well-order  $C$  whose domain and order are first-order definable from  $A, G$  and finitely many set parameters,*

$$C + 1 \hookrightarrow J(T; A, G), \quad J(T; A, G) \nrightarrow C.$$

*The first embedding identifies  $C + 1$  with a convex block. In particular,  $J(T; A, G)$  is not class-isomorphic to any such  $C$ .*

*Proof.* The satisfaction class uniformly interprets the fiber family, so [Theorem XVI.7.2](#) applies. A presentation of  $C$  occurs at the index formed by its formula codes and packed parameters. Its fiber is exactly  $C$ , which gives the asserted block and rules out every reverse embedding. Each index contributes its last point, ensuring properness.  $\square$

This gives a precise sense in which truth increases the order spectrum: one newly definable order dominates every earlier definable presentation and cannot embed back into any of them. It cannot itself have an  $A, G$ -definable presentation with set parameters, since that presentation would be one of the fibers to which the theorem applies. The obstruction concerns order types, not only the definability of a particular isomorphism.

In bare GBC these conclusions concern order embeddings. If the ambient theory additionally proves comparison, for example in  $\text{GBC} + \text{ETR}$ , then each  $C$  is isomorphic to a proper initial segment of  $J(T; A, G)$ : comparison in the other direction is excluded by the reverse-embedding obstruction. The argument needs no class choice or second-order comprehension to gather the fibers. Their simultaneous interpretation comes from the supplied  $T$ .

### XVI.7.3 Iteration and the scope of the notation

Let  $\Gamma$  be a class well-order, include its domain and relation among the base predicates  $A$ , and suppose a  $\Gamma$ -iterated truth predicate  $U$  is available. Its slice  $U_\gamma$  is a truth predicate for

$$(V, \in, A, G, U_{<\gamma}).$$

The earlier aggregate is represented by set pairs  $\langle \delta, z \rangle$ ; it is not a class whose elements are classes. The construction above is uniform, so it defines a uniform family

$$J_\gamma = J(U_\gamma; A \oplus U_{<\gamma}, G),$$

where  $\oplus$  denotes the tagged join of predicates. Here the fixed syntactic translation between separate predicates and their tagged join is understood when applying  $U_\gamma$ .

**Corollary XVI.7.5** (Growth along iterated truth). *For  $\delta <_\Gamma \gamma$ ,*

$$J_\delta + 1 \hookrightarrow J_\gamma, \quad J_\gamma \not\hookrightarrow J_\delta.$$

*Proof.* From  $U_{<\gamma}$  and the set parameter  $\delta$ , one recovers the slice  $U_\delta$  and the restriction  $U_{<\delta}$ . Thus the fixed formulas constructing  $J_\delta$  can be expressed using  $A, G, U_{<\gamma}$  and parameter  $\delta$ . Apply [Theorem XVI.7.4](#) at stage  $\gamma$ .  $\square$

This conditional statement handles successor and limit stages alike. It assumes the whole truth iteration as one class; it does not infer that iteration from the separate existence of its slices. Arbitrary available class well-order lengths of iterated truth belong to the established ETR framework [22], while extensions obtained by adjoining truth predicates are studied in class-theoretic potentialism [84].

The symbols  $J_\gamma$  therefore provide systematic relative notation for a strictly increasing family in the stated embedding sense. They do not denote canonical absolute class ordinals: the ordering of formula codes and parameters through  $G$  affects the sum. Their robust content is the domination property and the definability environment in which they appear. Determining whether weaker hypotheses suffice for such dominating orders, or whether an appropriate domination principle recovers truth, remains a separate question; no converse follows from the construction.

**Corollary XVI.7.6** (Bounded-fragment jumps). *For each fixed natural number  $n$ , GBC admits an  $A, G$ -definable class well-order  $K_n$  dominating every class well-order whose domain and relation have  $\Sigma_n$  or  $\Pi_n$  definitions in the Lévy hierarchy of  $\mathcal{L}(\in, A, G)$ , with arbitrary finite tuples of set parameters. Each such  $C$  satisfies*

$$C + 1 \hookrightarrow K_n, \quad K_n \nrightarrow C.$$

*There is no single  $A, G$ -set-parameter-definable uniform family of class well-orders having these domination properties simultaneously for all  $n$ .*

*Proof.* For a fixed  $n$ , partial satisfaction for syntactically normalized  $\Sigma_n$  and  $\Pi_n$  formulas is elementary definable. Bounded matrices can be evaluated in a transitive set containing their assignments, with the predicates restricted to that set; the fixed number of unbounded quantifier blocks is then interpreted directly.

Use this partial evaluator to interpret the candidate domains and relations. Apply the first-order linearity and descending-sequence test to those interpreted relations, replacing invalid fibers by the empty order. Their uniform diagonal sum gives  $K_n$  by [Theorem XVI.7.2](#); a full truth predicate is unnecessary for this fixed fragment.

If all the resulting domination properties belonged to one definable uniform family, that family would be cofinal among all  $A, G$ -set-parameter definable class well-orders: every fixed defining formula has some finite Lévy complexity. Its definable diagonal sum would contradict that cofinality by [Theorem XVI.7.2](#).  $\square$

Thus separate constructions for every fixed complexity bound must be distinguished from an internally uniform sequence of those constructions. No assertion of separation at each pair of adjacent complexity levels is being made.

[merge] This report's earlier diagonal theorems work at the level of relations: no uniform class of codes lists every class well-order of **No** (source 15's [theorem 57.4](#); source 08's [note 19.41](#); [theorems 19.37](#) and [19.38](#)), because a diagonal enumeration differs from each row on one pair. [Theorem XVI.7.2](#) works at the level of order types: the diagonal sum embeds into no row at all. It is proved independently by all four sources ([note XVI.7.8](#), [note XVI.7.14](#), [note XVI.7.17](#)); [corollary XVI.7.3](#) is [corollary XVI.7.9](#) and [notes XVI.7.16](#) and [XVI.7.18](#). [Corollary XVI.7.6](#) is the bounded-complexity diagonal of source 33's [theorem XVI.7.20](#), printed in full below because source 33's corollaries use its parameter-free form, and of source 35's [note XVI.7.13](#); source 35's [theorem XVI.7.11](#) is the pure-language form on Ord.

#### XVI.7.4 Source 35: definability, uniform bounds, and complexity separation

An explicit notation can describe a very long class well-order without describing all such orders. The distinction becomes sharp when the interpretation of the notations is itself one class relation. We prove that every uniformly interpreted family has a strict upper bound, even for the comparatively weak relation of suborder embeddability. Combining this observation with partial satisfaction gives a separation theorem for the complexity of presentations of class order types.

The separation below is a consequence of elementary coding and well-foundedness; no claim of historical priority is made. Its role here is to strengthen the repository's obstruction to exhaustive lists of labelled orders. That earlier obstruction can omit another presentation of an already represented type. The obstruction below escapes every represented type, and even every type embedding into one of the represented orders.

### XVI.7.4.1 A uniform family is always bounded

Throughout this section an embedding is an order-preserving injection whose graph is an available class. The notation  $A \hookrightarrow B$  permits an arbitrary suborder as image. It does not assert the stronger initial-segment relation  $A \preceq_{\text{init}} B$ .

*Note XVI.7.7* (Source 35, Lemma 7.1, “An appended point cannot be absorbed”). *In GB, if  $W$  is a class well-order, then  $\neg(W+1 \hookrightarrow W)$ .* This is the second assertion of source 34’s lemma XVI.3.2 and of source 35’s own lemma XVI.2.5. The proof differs: instead of the least point moved downward, it iterates the restricted map from the image of the appended point and obtains a descending set sequence. It is printed as a second route.

*Source 35’s proof.* Suppose that  $f : W+1 \rightarrow W$  is an embedding, and let  $*$  denote the tagged appended point. Identify the original copy of  $W$  with  $W$  only for purposes of this proof, and put  $g(x) = f(x)$  on that copy. Set  $a_0 = f(*)$ . Since every original point precedes  $*$ , we have  $g(a_0) <_W a_0$ . Define  $a_{k+1} = g(a_k)$  for  $k < \omega$ . Order preservation gives  $a_{k+2} <_W a_{k+1}$  whenever  $a_{k+1} <_W a_k$ . Ordinary set-valued recursion and Class Replacement produce this sequence as a set. Its range has no  $W$ -least element, contradicting well-foundedness. The tags ensure that no set outside the original carrier has been tacitly assumed to exist.  $\square$

*Note XVI.7.8* (Source 35, Theorem 7.2, “Strict bound for a uniform family”). *Work in GB. Let  $I$  carry a supplied class well-order  $\triangleleft$ , and let  $(W_i)_{i \in I}$  be a uniform family of class well-orders. There is a class well-order  $U$ , elementary definable from these data, such that for every  $i \in I$ ,  $W_i \hookrightarrow U$  and  $\neg(U \hookrightarrow W_i)$ .* *In GBC, the conclusion applies to a family indexed by any class of sets, since Global Choice supplies the required order of  $I$ .* This is source 34’s theorem XVI.7.2 with  $U = \sum_{i \in (I, \triangleleft)} (W_i + 1)$  (source 34’s  $\Delta$ ), and its last clause is corollary XVI.7.3’s proof; the proof is the same: least occupied row, then least point in the row, and a row inclusion composed with  $U \hookrightarrow W_i$  would embed  $W_i + 1$  into  $W_i$  (note XVI.7.7).

**Corollary XVI.7.9** (No cofinal uniform notation system). *In GBC, no uniformly class-coded family of class well-orders is cofinal among all class well-orders under suborder embeddability. In particular, no such family represents every class well-order type. If strong comparability CWO is additionally assumed, the bound in Note XVI.7.8 is also a strict upper bound under initial-segment comparison.*

*Proof.* Apply the theorem to the proposed family. Its output  $U$  embeds into none of its members, which contradicts cofinality. Under CWO, comparison of  $W_i$  and  $U$  must give an initial-segment embedding  $W_i \preceq_{\text{init}} U$ : the reverse alternative would in particular give  $U \hookrightarrow W_i$ . Equality of types is excluded by the same argument.  $\square$

[merge] The first two sentences of corollary XVI.7.9 are source 34’s corollary XVI.7.3; the clause under CWO is source 34’s remark after theorem XVI.7.4 for its truth jump. Lemma XVI.7.10 is the ordinal-carrier case of the equivalence of lemma XVI.2.8, proved without choice by least-ordinal selection; source 34’s lemma XVI.2.2 gives, over GB, the set-subset form for every linear carrier.

The hypothesis concerns a semantic interpreter, not just a collection of strings. A syntax class  $T$  together with one class relation decoding the carrier and comparison relation of every term in  $T$  is covered by the corollary. Enlarging the alphabet, allowing ordinal parameters, or admitting terms of set size does not remove the obstruction if the result still has such an interpreter. The construction even gives an explicit next order: sum the successors of all currently interpreted orders. A proposed system cannot both interpret that entire sum and remain exhaustive.

This does not prohibit useful notation systems for large fragments, nor a metatheoretic scheme assigning a different defining formula to each notation. The latter need not supply a single internal

evaluation class. It also does not turn arbitrary suborder embeddings into initial-segment embeddings in GB; the final assertion of the corollary deliberately exposes that extra premise.

#### XVI.7.4.2 A definable test for well-foundedness on ordinal carriers

The fixed-complexity argument needs to select the well-orders among uniformly evaluated relations. This selection does not require a class quantifier.

**Lemma XVI.7.10** (Ordinal-carrier well-foundedness). *In GB, a strict linear class order  $R$  on Ord is a class well-order if and only if there is no set function  $f : \omega \rightarrow \text{Ord}$  satisfying*

$$f(k+1) R f(k) \quad (k < \omega).$$

*Consequently this property is elementary in the class parameter  $R$ .*

*Proof.* A descending sequence has a nonempty range without an  $R$ -least member. Conversely, suppose that an available nonempty subclass  $B \subseteq \text{Ord}$  has no  $R$ -least member. Choose its least member in the usual ordinal order as  $f(0)$ . Given  $f(k)$ , take the usual-ordinal-least member of

$$\{\beta \in B : \beta R f(k)\}$$

as  $f(k+1)$ . This class is nonempty by hypothesis, and the choice is unique. Set-valued recursion along  $\omega$ , followed by Class Replacement, gives the prohibited set function. No choice of a class witness is involved.  $\square$

For arbitrary class carriers, the corresponding equivalence is established in the standard class-recursion literature over GB + DC, and hence over GBC [22, discussion preceding Definition 6]. The ordinal carrier permits the direct least-ordinal selection above. In a nonstandard or externally ill-founded model, this is an internal criterion: it refers to the model's own set functions and available classes. External well-foundedness must be stated separately.

#### XVI.7.4.3 Strict separation at every fixed definability level

Fix a standard finite  $n \geq 1$ . A  $\Sigma_n$  presentation on Ord means a strict order relation given by a formula of the set-theoretic Lévy hierarchy, allowing a finite tuple of ordinal parameters. We use prenex representatives; over the present set theory the customary versions of the hierarchy give the same class of definable relations.

For this fixed  $n$  there is a first-order partial satisfaction formula  $\text{Sat}_{\Sigma_n}$  that evaluates all such formula codes. Its construction is a metatheoretic finite induction, not a uniform truth definition for arbitrary  $n$ . The distinction is explicit in the standard development: bounded truth is  $\Delta_1$ -definable, and the fixed  $\Sigma_n$  truth predicate is  $\Sigma_n$ -definable for  $n \geq 1$  [87, Lemma 2.13 and Definitions 2.14–2.15].

**Theorem XVI.7.11** (Fixed-complexity separation of class order types). *For every fixed standard  $n \geq 1$ , there is a parameter-free first-order definition of a class well-order  $U_n$  on Ord with the following properties, provably in GB. If  $R$  is a class well-order on Ord admitting a  $\Sigma_n$  definition with ordinal parameters, then*

$$R \hookrightarrow U_n, \quad \neg(U_n \hookrightarrow R).$$

*In particular,  $U_n$  has no  $\Sigma_n$  ordinal-parameter presentation up to available class isomorphism. Restricted to definable classes and definable maps, these statements are also theorems of ZFC understood as a scheme.*

*Proof.* A potential presentation is coded by  $c = (e, \vec{\alpha})$ , where  $e$  is a code for a  $\Sigma_n$  formula with the appropriate free variables and  $\vec{\alpha}$  is a finite tuple of ordinals. Define

$$\xi R_c \eta \iff \text{Sat}_{\Sigma_n}(e, \langle \xi, \eta, \vec{\alpha} \rangle).$$

Let  $I_n$  consist of exactly those codes for which  $R_c$  is a strict linear order on Ord and has no descending set function of length  $\omega$ . This is an elementary class definition: the displayed satisfaction formula has already been fixed, and [Lemma XVI.7.10](#) expresses the remaining condition using only set quantifiers. Every section indexed by  $I_n$  is therefore a class well-order.

The codes can be treated as nonempty finite tuples of ordinals. There is a parameter-free set-like well-order of all such tuples: compare their maximum coordinates first, their finite lengths second, and then use the lexicographic order at a fixed length. Every nonempty subclass has a least maximum, a least length at that maximum, and finally a least tuple in the indicated finite lexicographic order. The predecessors of a given tuple form a set, since their entries are bounded by its maximum coordinate and they belong to the set of finite sequences from that bound. Restrict this order to  $I_n$ .

[Note XVI.7.8](#) now constructs

$$S_n = \sum_{c \in I_n} (R_c + 1).$$

Every input  $R$  in the theorem is one of its sections, by correctness of the fixed partial satisfaction predicate. Thus  $R \hookrightarrow S_n$ , whereas an embedding  $S_n \hookrightarrow R$  would contradict [Note XVI.7.7](#).

It remains to put the carrier on Ord without adding a definable global choice assumption. The tagged carrier of  $S_n$  is itself parameter-free definably coded by finite ordinal tuples. Use the set-like tuple order just described on this carrier, and assign to each point the ordinal order type of its predecessor set. The assignment is definable and is an isomorphism with an initial subclass of Ord. The carrier is proper:  $I_n$  includes a code for the usual ordinal order, whose row already has a proper class of points. Hence the image cannot be a set ordinal, since Class Replacement applied to the inverse map would then make the carrier a set. The image is all of Ord.

Transport  $S_n$  across this canonical bijection and call the result  $U_n$ . All definitions used only the fixed natural number  $n$ , which can be built into the defining formula; there are no set parameters. Transport preserves the embedding conclusions. Finally, if a  $\Sigma_n$  ordinal-parameter presentation were isomorphic to  $U_n$ , that isomorphism would in particular embed  $U_n$  into an input order, a contradiction.  $\square$

The theorem separates order types, rather than merely the complexity of different names for one relation. Its negative conclusion allows any admitted embedding, even one defined using additional parameters or available as a nondefinable class. It does not claim separation of two consecutive syntactic levels: no optimal upper complexity for the output formula has been asserted. The same construction can be made for any fixed syntactic fragment having a definable partial evaluator, provided that its codes and permitted parameters have a supplied well-order.

**Corollary XVI.7.12** (The separation family has no uniform ordinal-parameter evaluator). *There is no first-order formula  $H(n, \xi, \eta, \vec{\gamma})$ , with one fixed finite tuple of ordinal parameters  $\vec{\gamma}$ , whose sections  $H_n$ , for every standard  $n \geq 1$ , are class well-orders on Ord satisfying the negative conclusion of [Theorem XVI.7.11](#) at level  $n$ .*

*Proof.* The fixed formula  $H$  is equivalent to a  $\Sigma_m$  formula for some standard finite  $m \geq 1$ . Its  $m$ -th section, with the additional ordinal parameter  $m$ , is itself a  $\Sigma_m$  ordinal-parameter presentation. The stipulated negative property for that section would therefore prohibit its identity embedding into itself.  $\square$

This is why the assertion *for each fixed  $n$*  cannot be silently rewritten as the existence of one definable sequence of the resulting class relations. The corollary has the stated ordinal-parameter scope. It does not, by this argument alone, exclude a uniform definition using an arbitrary non-ordinal- definable set parameter or a new truth predicate.

*Note XVI.7.13* (Source 35, Proposition 7.7, “Version with arbitrary set parameters”). *Fix an available global well-order  $G$  of the universe. In the language  $\{\in, G\}$ , and for each fixed standard  $n \geq 1$ , there is a  $G$ -definable class well-order strictly bounding all  $\Sigma_n(\in, G)$ -definable class well-orders with arbitrary set parameters, under suborder embeddability. The carrier and relation of an input presentation may both be defined by such formulas. No single formula in this language, even with additional fixed set parameters, uniformly provides such bounding orders for every standard  $n$ . This is source 33’s [theorem XVI.7.20](#) with its [corollary XVI.7.22](#), and source 34’s [corollary XVI.7.6](#) for  $A$  empty; source 35’s proof evaluates the two formulas by the fixed partial satisfaction predicate, filters by the GBC well-foundedness test, orders the codes by a set-like global well-order definable from  $G$ , applies [note XVI.7.8](#), and obtains the nonuniformity as in [corollary XVI.7.12](#), all fixed set parameters of a proposed uniform formula being among those allowed in its own offending section.*

Naming  $G$  is substantive. Global Choice as a class axiom does not assert that a global well-order is definable in the pure membership language. The proposition consequently gives a relative definability theorem, whereas [Theorem XVI.7.11](#) on ordinal carriers gives the unconditional pure-language version.

### XVI.7.5 Source 32: no uniformly definable family reaches the end

There is no largest class well-order, since  $W + 1$  always defeats  $W$ . A stronger statement excludes one uniformly coded family from being cofinal among all admitted class well-orders, even for the weaker arbitrary-embedding relation.

*Note XVI.7.14* (Source 32, Theorem 7.1, “Uniform diagonal domination”). *Let  $I$  be a nonempty class well-order and  $(W_i)_{i \in I}$  a uniformly coded family of class well-orders. Define*

$$D = \sum_{i \in I} (W_i + 1). \quad (\text{S32.10})$$

*Then  $D$  is a class well-order, every  $W_i$  embeds into  $D$ , and  $D$  embeds into none of the  $W_i$ . The theorem is provable in GBC without class-order comparability or ETR. This is source 34’s [theorem XVI.7.2](#), with the same proof by [proposition XVI.3.4](#) and [note XVI.2.10](#); source 34 shows it in GB. Source 32’s diagonal  $D$  is source 34’s  $\Delta$ ; it is not the condensation operator  $D_W$ .*

Notice what the theorem does *not* assert: the copy of  $W_i$  used in the sum need not be initial. No initial comparison is required for the contradiction. In an external setting where these presentations are ordinary well-orders, the usual ordinal comparison converts the conclusion into the strict inequality of order types.

**Corollary XVI.7.15** (A fixed finite syntax has a definable bound). *Fix finitely many first-order formula pairs for a domain and an order relation, with arbitrary set parameters and fixed admitted class parameters. There is one class well-order, definable from the same class parameters and a fixed global well-order, that does not embed into any valid well-order presentation defined by those formulas.*

*Proof.* Encode each finite tuple of set parameters by one set. A finite disjunction of the given formulas provides a uniform family indexed by a finite formula tag and the parameter code. By [lemma XVI.2.8](#), being a valid well-order is an elementary predicate on each fiber. Replace invalid

fibers by the empty order. Global Choice well-orders the index class, and [note XVI.7.14](#) supplies the desired bound. All definitions involve only the given finitely many formulas, so no truth predicate for arbitrary formulas is being used.  $\square$

[merge] [Corollary XVI.7.15](#) is the finite-list case of source 34’s [corollary XVI.7.6](#); source 32 uses it in [theorem XVI.8.9](#).

*Note XVI.7.16* (Source 32, Corollary 7.3, “No universal admitted list”). *There is no admitted uniform class-coded family that contains, up to admitted isomorphism, every admitted class well-order. More strongly, no such family is cofinal for the relation  $\hookrightarrow$  among all admitted class well-orders.* This is source 34’s [corollary XVI.7.3](#), by restricting a global well-order to the index class; an empty family is plainly not cofinal.

An external list of formulas does not contradict this result. It is easy externally to enumerate finite strings that might define classes. The missing internal object is a uniform satisfaction relation evaluating all those formulas. Confusing an external enumeration of syntax with an admitted family of semantic evaluations is precisely the mistake that the next two sections exploit constructively.

## XVI.7.6 Source 33: a diagonal theorem for uniform families

### XVI.7.6.1 Strict domination without a comparison theorem

*Note XVI.7.17* (Source 33, Theorem 7.1, “Uniform-family diagonal”). *Let  $(W_i)_{i \in I}$  be a uniform family of class well-orders, where  $I$  is a nonempty class well-order. Define*

$$D = \sum_{i \in I} (W_i + 1). \quad (\text{S33.7.1})$$

*Then  $D$  is a class well-order and, for every  $i \in I$ ,*

$$W_i \hookrightarrow D, \quad D \not\hookrightarrow W_i. \quad (\text{S33.7.2})$$

*The construction and proof are available in GBC.* This is source 34’s [theorem XVI.7.2](#) and source 32’s [note XVI.7.14](#), with the same proof ([notes XVI.2.16](#) and [XVI.3.9](#)).

The theorem is stronger than a statement that a family has no maximum. It produces one order that strictly dominates *every member at once*, without choosing isomorphisms between members or comparing their lengths. It also works when some fibers are empty.

*Note XVI.7.18* (Source 33, Corollary 7.2, “No uniform catalogue”). *There is no class-coded family, indexed by sets, that contains up to isomorphism every available class well-order. More strongly, no such family is cofinal under embeddability among all available class well-orders.* This is source 34’s [corollary XVI.7.3](#) and source 32’s [note XVI.7.16](#).

This is an appropriate class-order version of the obstruction behind Burali–Forti, but its proof does not illegally collect all classes as objects. It quantifies over an already supplied uniform family and constructs one new relation from it.

### XVI.7.6.2 What remains possible

A language can have a set of finite expressions and a definable evaluator for a useful fragment: sums, products, finite powers, or the coherent tower of [section XVI.6.8](#). The obstruction says that such an evaluator cannot be cofinal among *all* well-orders definable in the same language if its evaluation is

itself definable there. One must increase complexity, add a truth predicate, weaken the coverage claim, or move to a stronger semantic setting.

In a theory with initial comparability, (S33.7.2) can be read as strict inequality of the usual external ordinal-like lengths. In the base theory it is deliberately stated using ordinary embeddings, where the proof is unconditional.

### XVI.7.7 Source 33: definability levels and parameter-free cofinality

[merge] Theorem XVI.7.20 is source 34's corollary XVI.7.6 in the language  $\{\in, G\}$ , with the diagonal order shown free of set parameters; source 35's note XVI.7.13 is the same statement, and its theorem XVI.7.11 removes  $G$  for orders on Ord with ordinal parameters. Lemma XVI.7.19 is the partial evaluator of source 34's proof of corollary XVI.7.6 and of source 35's paragraph before theorem XVI.7.11. Corollary XVI.7.21 is the external cofinality behind source 34's theorem XVI.8.3, reached by a different route (note XVI.8.16).

#### XVI.7.7.1 Fix the language before asking what is definable

Fix a named set-like global well-order  $G$  and the first-order language

$$\mathcal{L}_G = \{\in, G\}.$$

A presentation is *G-definable with set parameters* if its domain and relation are defined by two formulas of this language with a finite tuple of set parameters. It is *set-parameter-free* if no such tuple is needed. The named class  $G$  is still allowed.

Allowing an arbitrary new class parameter for each presentation would make this distinction meaningless: every relation is definable from itself. Likewise, allowing a truth predicate changes the language and must be recorded explicitly.

Choose an ordinary effective coding of formulas and finite parameter tuples. For each fixed standard natural number  $n$ , let  $\Sigma_n(G)$  denote a standard bounded level of the first-order hierarchy. It is harmless to pad formulas with unused quantifiers, so every particular first-order formula belongs to  $\Sigma_n(G)$  for some sufficiently large finite  $n$ . We require both the domain formula and the relation formula of a  $\Sigma_n(G)$  presentation to lie at that level.

**Lemma XVI.7.19** (Partial evaluation at a fixed level). *For each fixed standard finite  $n$ , there is an elementary formula  $\text{Sat}_n(e, \vec{a}; G)$  that correctly evaluates  $\Sigma_n(G)$  formulas coded by  $e$  at assignments  $\vec{a}$ . Its construction is a metatheoretic schema in  $n$ , not an assertion that all the predicates  $\text{Sat}_n$  form one  $G$ -definable class uniformly in  $n$ .*

*Proof.* Bounded formulas can be evaluated inside a set containing the transitive closures of the parameter values. Restrict the named class predicate  $G$  to the relevant set of pairs; elementary class separation supplies this restriction as a set. Ordinary satisfaction for that set structure evaluates the bounded formula.

For a fixed number of unbounded quantifier blocks, place those blocks in front of the bounded evaluation formula and handle their finite tuples of variables by set coding. This gives a finite first-order formula for the chosen level. The passage from level  $n$  to the next is a construction of formulas outside the object theory; it does not supply truth for all formulas in one predicate.  $\square$

#### XVI.7.7.2 The bounded-complexity diagonal

**Theorem XVI.7.20** (Bounded definability cannot bound class-order length). *For each fixed standard finite  $n$ , there is a class well-order  $D_n$  with a set-parameter-free definition in  $\mathcal{L}_G$  such that:*

- (a) every class well-order having a  $\Sigma_n(G)$  presentation with arbitrary set parameters embeds into  $D_n$ ;
- (b)  $D_n$  embeds into no class well-order having such a presentation;
- (c) in particular,  $D_n$  has no isomorphic  $\Sigma_n(G)$  presentation, even one using set parameters.

The quantification over  $n$  is a schema. Each instance is provable in GBC. Nonembedding in (b) holds for all embeddings available in the ambient class model, not merely for definable embeddings of bounded complexity.

*Proof.* Coding all candidate parameters. Let the index class be all sets in the order  $G$ . A valid index is a code

$$i = (e_D, e_R, \vec{p})$$

for a pair of  $\Sigma_n(G)$  formulas and a finite set-parameter tuple. Invalid codes will designate the empty order. Using the fixed evaluator from lemma XVI.7.19, define the candidate domain and relation jointly in  $i, x, y$ .

*Selecting only well-orders.* For a valid index, test whether the candidate relation, restricted to its domain, is a linear order and has no descending set function of domain  $\omega$ . This is a first-order property of  $i$  in the language with  $G$ : replace each occurrence of the candidate domain and relation by its  $\text{Sat}_n$  definition. By note XVI.2.12, the test is equivalent to being a class well-order in the ambient model. If the test fails, replace the candidate by the empty order.

Thus we have one  $G$ -definable uniform family  $(W_i)_{i \in V}$  of genuine class well-orders, containing every  $\Sigma_n(G)$  presentation with any set parameters. No truth predicate beyond the chosen partial level was used. The well-orderhood test can increase formula complexity; it is not claimed to remain  $\Sigma_n(G)$ .

*Diagonalization.* Put

$$D_n = \sum_{i \in (V, G)} (W_i + 1).$$

The index  $n$  has been fixed externally and is represented by a numeral in the resulting formula. All set parameters of all candidates are now variables ranging through the index class. Consequently this presentation of  $D_n$  has no set parameters.

Apply note XVI.7.17. It gives (a) and (b). If (c) failed, choose an index  $i$  coding an isomorphic  $\Sigma_n(G)$  presentation. That isomorphism would itself be an embedding of  $D_n$  into  $W_i$ , contradicting (b).  $\square$

**Corollary XVI.7.21** (Parameter-free presentations are externally cofinal). *Every  $G$ -definable class well-order with set parameters embeds into a set-parameter-free  $G$ -definable class well-order. Externally, the countable family of presentations*

$$D_0, D_1, D_2, \dots$$

*is cofinal under embeddability among all  $G$ -definable class well-orders with set parameters.*

*Proof.* The two formulas defining a given presentation have some fixed finite complexity bound  $n$ . Apply theorem XVI.7.20(a).  $\square$

This is a cofinality statement, not pointwise elimination of parameters. It does not say that every parameter-definable order has an isomorphic parameter-free presentation. The replacement order can be substantially longer, as the diagonal construction intentionally ensures.

**Corollary XVI.7.22** (No definable uniform cofinal family). *There is no  $G$ -definable uniform family of class well-orders, indexed by a  $G$ -definable class of sets and allowing a fixed finite tuple of set parameters in its definition, which is cofinal among all  $G$ -definable class well-orders with set parameters.*

*Proof.* Order the indices by the restriction of  $G$ . The diagonal of that family is again  $G$ -definable with the same fixed parameters. Cofinality would place its order type below a member under embeddability, contradicting [note XVI.7.17](#).  $\square$

In particular, the external list of formulas defining the  $D_n$  is not a uniform  $G$ -definable evaluation of all their order relations. The schema and the missing uniform evaluator coexist without contradiction. This is one place where the analogy with truth hierarchies is exact in its logical shape: every fixed level is available, while their complete uniform assembly requires a change of resources.

### XVI.7.7.3 Removing the named global order in special universes

**Corollary XVI.7.23.** *Suppose the universe has a parameter-free first-order definable set-like global well-order. Then every set-parameter-definable class well-order embeds into a parameter-free first-order definable class well-order. There is an external countable cofinal family of the latter presentations.*

*Proof.* Use the definable global order as  $G$  in [corollary XVI.7.21](#), then replace occurrences of  $G$  in each resulting formula by its fixed parameter-free definition. The substitution may increase finite complexity but introduces no parameters.  $\square$

The constructible universe provides the standard intended example through its canonical global ordering. Without a definable global well-order, this proof does not remove the named class parameter. It is important not to replace “relative to  $G$ ” by an unconditional parameter-free claim about every model of ZFC.

### XVI.7.7.4 A precise account of what has been resolved

The preceding theorems answer three concrete structural questions: *Can one fixed definability level be cofinal?* No. *Do arbitrary set parameters increase the external supremum beyond parameter-free presentations, once  $G$  is fixed?* No. *Can the resulting countable cofinal construction itself be uniformly evaluated in the same language?* No.

These are proved statements with explicit hypotheses. They are not claimed to settle a historically recognized open problem. Establishing whether the same arguments or consequences occur in the existing literature requires a broader bibliographic and expert review than the targeted search recorded here.

## XVI.8 External spectra and the effect of definability

The question “how far beyond Ord?” acquires a precise numerical answer after a model and its available classes have been fixed. The answer belongs to the external metatheory: a proper class of a set model is itself an ordinary set externally. Its genuinely well-founded orderings therefore have ordinary external ordinal ordertypes. This viewpoint does not turn an internal proper class into an internal set. It compares two different levels of discourse.

Throughout this section the metatheory is ZFC. A *transitive  $\beta$ -model*  $(M, \mathcal{X})$  is a transitive model of class theory which is correct about the well-foundedness of its class relations. Transitivity

alone does not imply this correctness: an external descending sequence through a class relation need not be a set of  $M$ . The distinction is standard in the model theory of second-order set theories [35]. Our spectra below count genuinely externally well-founded orders. The  $\beta$ -hypothesis will allow an internal definability test to select exactly those orders.

### XVI.8.1 The full spectrum over an inaccessible universe

**Theorem XVI.8.1** (Full spectrum). *Let  $\kappa$  be an inaccessible cardinal in the external universe. In the full class model*

$$\mathfrak{V}_\kappa = (V_\kappa, \mathcal{P}(V_\kappa)),$$

*the external ordertypes of class well-orders are exactly the ordinals  $\alpha < \kappa^+$ . Those whose domains are internally proper classes have exactly the ordertypes*

$$\kappa \leq \alpha < \kappa^+.$$

*Here  $\text{Ord}^{\mathfrak{V}_\kappa}$  has external ordertype  $\kappa$ .*

*Proof.* Inaccessibility gives  $|V_\kappa| = \kappa$ . Every class domain is an external subset of  $V_\kappa$ , so any well-order on it has cardinality at most  $\kappa$  and hence ordertype below  $\kappa^+$ . Conversely, every  $\alpha < \kappa^+$  has cardinality at most  $\kappa$ , so an injection into  $V_\kappa$  transports its ordering to a subclass of  $V_\kappa$ . Every such relation is available in the full class collection. Finite tuple coding stays inside  $V_\kappa$ , so binary relations can be represented by unary class predicates.

Every element of  $V_\kappa$  has cardinality below  $\kappa$ . Conversely, an external subset  $D \subseteq V_\kappa$  of cardinality below  $\kappa$  has bounded element ranks by regularity; consequently  $D \in V_\kappa$ . Thus a subclass is internally proper precisely when its external cardinality is  $\kappa$ . The second assertion follows.  $\square$

The use of inaccessibility also makes the full class model a legitimate model of the usual strong class axioms: arbitrary class comprehension is available, and regularity ensures that the image of an internal set under a class function remains an internal set. It is a  $\beta$ -model. Indeed, an external countable sequence of elements of  $V_\kappa$  has bounded ranks and belongs to  $V_\kappa$ . The same argument shows  $\beta$ -correctness for any GBC realization over this  $V_\kappa$ .

**Theorem XVI.8.1** supplies an exact ceiling, but only relative to this particular model and the full external class collection. The ceiling  $\kappa^+$  is not itself represented by one of its class well-orders. It is neither an internal successor cardinal of a set  $\text{Ord}$  nor a largest class ordertype. Restricting the available definitions gives a much smaller external ceiling.

### XVI.8.2 Parameter spectra are intervals; parameter-free spectra need not be

Fix a transitive set model  $M$  with a finite language  $L$  expanding membership by named class predicates. Assume these predicates occur in a GBC realization, so first-order definitions and their set restrictions are legitimate available classes. Put  $\lambda = |M|$ , externally. Let  $\mathcal{S}_{\text{par}}^L$  be the external ordertypes of well-orders on subclasses of  $M$  whose domains and relations are first-order  $L$ -definable using finite tuples of set parameters from  $M$ . Write  $\mathcal{S}_0^L$  for the parameter-free version. A named predicate is part of the language; “parameter-free” here excludes additional set parameters, not the named predicates themselves.

**Proposition XVI.8.2** (The parameter spectrum). *There is a limit ordinal  $\Theta_L < \lambda^+$  such that*

$$\mathcal{S}_{\text{par}}^L = [0, \Theta_L).$$

*The set  $\mathcal{S}_0^L$  is countable, is closed under successors, and has no greatest member. Its supremum has cofinality  $\omega$ . In general  $\mathcal{S}_0^L$  need not be an ordinal interval.*

*Proof.* There are countably many formulas and only  $\lambda$  finite parameter tuples, so  $|\mathcal{S}_{\text{par}}^L| \leq \lambda$ . If an order has external ordertype  $\alpha$  and  $\beta < \alpha$ , let  $x \in M$  be its element at position  $\beta$ . The initial segment below  $x$  is definable with  $x$  as one more set parameter and has ordertype  $\beta$ . Therefore the parameter spectrum is downward closed.

Tagged addition of one last element turns any definable presentation of  $\alpha$  into a definable presentation of  $\alpha + 1$ , using the same parameters. Thus this downward closed set has no largest member. It is an ordinal interval  $[0, \Theta_L)$  for a limit  $\Theta_L$ , and its cardinality bound implies  $\Theta_L < \lambda^+$ .

There are only countably many parameter-free definitions. Successor addition is still parameter-free, so their ordertypes have no largest member. Their supremum consequently has cofinality exactly  $\omega$ . The initial-segment argument does not establish downward closure here, because the cutoff point need not be parameter-free definable.  $\square$

In fact, for a parameter-free definable *set* well-order, its unique ordinal collapse is parameter-free definable. Thus, over  $V_\kappa$  for uncountable inaccessible  $\kappa$ , the countable parameter-free spectrum omits many ordinals below  $\kappa$ , whereas the definable class  $\text{Ord}$  itself supplies the external type  $\kappa$ . This gives a concrete reason the parameter-free spectrum is not downward closed in that setting.

For  $M = V_\kappa$ , the parameter spectrum contains  $\kappa$  and its successor, and [Proposition XVI.8.2](#) gives the strict bounds

$$\kappa < \Theta_L < \kappa^+.$$

These are external statements about definitions over the fixed structure. They do not require the isomorphism between two presentations of the same external type to be definable over that structure. The external initial-segment theorem therefore does not settle the internal class well-order comparability problem.

### XVI.8.3 Parameter elimination by a definable sum

We now prove a more informative relation between the two spectra. It uses explicit class sums to remove set parameters from an upper bound on a given definable ordertype. We present it as a synthesis theorem with a full proof, without a claim of historical priority. Naming the predicates is essential. The broader study of expansions by truth predicates and additional classes provides the appropriate surrounding context [\[84\]](#).

**Theorem XVI.8.3** (Parameter-free cofinality, relative to a global order). *Let  $(M, \mathcal{X})$  be a transitive  $\beta$ -model of GBC. Fix finitely many class predicates  $\vec{A} \in \mathcal{X}$  and a global well-order  $G \in \mathcal{X}$ . In the finite language  $L = \{\in, \vec{A}, G\}$ , the parameter-free spectrum is cofinal in the set-parameter spectrum. Consequently,*

$$\sup \mathcal{S}_0^L = \Theta_L, \quad \text{cf}(\Theta_L) = \omega.$$

*If  $G$  is parameter-free definable from the other named predicates, it need not be added as a separate symbol.*

*Proof.* Fix one pair of ordinary finite  $L$ -formulas  $\delta(x, \vec{p})$  and  $\rho(x, y, \vec{p})$ , with a fixed finite number of parameter positions. For every tuple  $\vec{q}$  of the corresponding length from  $M$ , let  $D_{\vec{q}}$  and  $R_{\vec{q}}$  be the domain and relation obtained by substituting  $\vec{q}$ . Let  $I_{\delta, \rho}$  be the class of those tuples for which  $M$  judges  $R_{\vec{q}}$  to be a class well-order on  $D_{\vec{q}}$ .

This filtering condition is first-order and uses no set parameters. Substitute the two fixed formulas into the requirements for a linear order and into the assertion that no descending *set* sequence of length  $\omega$  exists. There is no variable formula code to evaluate, so no satisfaction predicate is needed. Elementary comprehension supplies  $I_{\delta, \rho}$ , and the restriction of  $G$  well-orders its tuple codes.

Form the lexicographic sum

$$U_{\delta,\rho} = \sum_{\vec{q} \in (I_{\delta,\rho}, G)} (D_{\vec{q}}, R_{\vec{q}}).$$

Its elements are set pairs  $(\vec{q}, x)$  with  $\vec{q} \in I_{\delta,\rho}$  and  $x \in D_{\vec{q}}$ . Distinct blocks are compared by  $G$ , and elements of one block by  $R_{\vec{q}}$ . The domain and ordering are  $L$ -definable without set parameters, with the fixed formulas substituted into their definitions. Internally this is a class well-order: a nonempty subclass has a least occupied index and then a least element in that block. It is therefore externally well-founded by  $\beta$ -correctness. The same correctness ensures that the filter admitted no externally ill-founded candidates.

Every genuinely well-founded instance of this formula pair, with any particular parameter tuple  $\vec{p}$ , passes the internal test and occurs as a block of  $U_{\delta,\rho}$ . Its external ordertype is therefore at most  $\text{otp}(U_{\delta,\rho})$ . This proves that every member of  $\mathcal{S}_{\text{par}}^L$  is bounded by a member of  $\mathcal{S}_0^L$ .

Externally there are countably many ordinary finite formula pairs. Enumerating them gives a countable cofinal family of the separately defined orders  $U_{\delta,\rho}$ . The two spectra have the same supremum, and successor closure excludes a largest member. Hence  $\text{cf}(\Theta_L) = \omega$ .  $\square$

The hypotheses are deliberately explicit. The realization  $\text{Def}(M; \vec{A}, G)$ , allowing set parameters, inherits class replacement and satisfies GBC. It is also a  $\beta$ -model: both realizations have the same sets, and in each the well-foundedness of a common class relation is equivalent to the absence of a descending  $M$ -set  $\omega$ -sequence. They therefore agree about well-foundedness, and the larger realization is  $\beta$ -correct. No assumption that every possible external class is available is needed. Conversely, mere transitivity would not justify the filter: a candidate with an external descending sequence missing from  $M$  could be admitted. Naming  $G$  does not assert a parameter-free definable global well-order in the original pure membership language.

**Corollary XVI.8.4.** *For an inaccessible  $\kappa$  and fixed named predicates  $\vec{A}, G$  in the full class model over  $V_\kappa$ , with  $G$  a global well-order,*

$$\kappa < \Theta_L < \kappa^+, \quad \text{cf}(\Theta_L) = \omega.$$

*Parameter-free  $L$ -definitions are cofinal in this interval of parameter-definable types, although they realize only countably many of its members.*

#### XVI.8.4 Why the cofinal family does not create a largest notation

Choose an external enumeration of the finite formula pairs, and denote the resulting orders by  $U_n$ . For each standard  $n$  its definition is a finite formula, but the proof supplies no single  $L$ -formula that evaluates all these definitions uniformly. Such a uniform,  $L$ -definable cofinal family is impossible: its  $\omega$ -indexed lexicographic sum followed by one new last point would again be  $L$ -definable and would have ordertype larger than every member of the supposedly cofinal family.

A stronger class collection may contain a uniform code for the family. For example, the full collection  $\mathcal{P}(V_\kappa)$  does. There is no contradiction: using that additional class as a predicate enlarges the language of permitted definitions. The obstruction concerns a uniform code definable in the *same fixed language*. One could instead organize the construction using separate bounded-complexity satisfaction predicates. They likewise do not assemble into a definable full truth predicate for that language; the fixed-formula proof shows that this additional machinery is unnecessary here.

Thus external countable cofinality is compatible with the impossibility of internally listing a cofinal family by one definition. A research question suggested by these results is to classify the ordinals  $\Theta_L$  obtainable from a fixed  $V_\kappa$  as the named class predicates vary, subject to amenability

and the desired recursion axioms. Another is to determine which restricted notation calculi are cofinal in particular definability spectra. The present theorems give necessary bounds and an explicit external construction; they do not identify one absolute endpoint beyond Ord.

[merge] [Theorem XVI.8.1](#) is source 12’s full-class model [theorem 21.1](#) (iv) (Part V; extended to every limit height by source 31, [theorem XV.9.3](#)), proved again by sources 35, 32 and 33 (notes [XVI.8.5](#), [XVI.8.8](#) and [XVI.8.15](#)). The definable ceilings of the four sources are one invariant. Over  $V_\kappa$  with  $\kappa$  inaccessible, source 32’s  $\delta_A$  is  $\Theta_L$  for  $L = \{\in, G, A\}$  ([theorem XVI.8.9](#): its spectrum is the interval  $[0, \delta_A)$ ), source 33’s  $\delta_G$  and  $\delta_G^0$  are  $\Theta_L$  and  $\sup \mathcal{S}_0^L$  for  $L = \{\in, G\}$  ([note XVI.8.16](#)), and source 35’s  $\delta_{\text{set}}$  is  $\Theta_L$  for the pure language  $L = \{\in\}$ , by [proposition XVI.8.2](#) applied in the full model ([theorem XVI.8.6](#)). [Theorem XVI.8.3](#) is the most general form, for any transitive  $\beta$ -model of GBC with a named global well-order; sources 32 and 33 prove the case  $V_\kappa$ , and source 32 adds  $\kappa^{\delta_A} = \delta_A$ , source 33 the closure under ordinal arithmetic. Together they answer in part source 31’s research question 113.239 (section 113.29).

### XVI.8.5 Source 35: external lengths: the full-model spectrum and definability-sensitive cutoffs

The constructions above are meaningful internally, without assigning a set ordinal to a proper class order. An ambient set universe can nevertheless measure their lengths when the entire class model is a set there. Keeping these two viewpoints separate gives a precise answer to “how far beyond Ord?” and prevents an external cardinal bound from becoming an internal largest notation.

#### XVI.8.5.1 The exact full-model spectrum

Work in an ambient universe satisfying ZFC, and let  $\kappa$  be strongly inaccessible. Consider the two-sorted structure

$$\mathcal{M}_\kappa = (V_\kappa, \mathcal{P}(V_\kappa)).$$

Its sets are the elements of  $V_\kappa$ ; its classes are *all ambient subsets* of  $V_\kappa$ , with the appropriate tagged copies if the two sorts are formally disjoint. This notation does not assert that  $\mathcal{P}(V_\kappa)$  is a set or a class *inside*  $\mathcal{M}_\kappa$ . Relations and functions use the usual set codes for ordered pairs.

This structure satisfies KM with Global Choice. Full comprehension holds because every subset of the first-order universe is available. For Class Replacement, if  $a \in V_\kappa$  and a class function has domain  $a$ , its image has cardinality less than  $\kappa$ . Regularity bounds the ranks of its elements below  $\kappa$ , so the image belongs to  $V_\kappa$ . A bijection between  $\kappa$  and  $V_\kappa$  in the ambient universe provides Global Choice. Here the identity  $|V_\kappa| = \kappa$  uses strong inaccessibility.

*Note XVI.8.5* (Source 35, Theorem 9.1, “Full external spectrum”). *The external order types of class well-orders in  $\mathcal{M}_\kappa$  are exactly the ordinals  $\theta < \kappa^+$ : those of sets are the  $\theta < \kappa$ , those of proper classes the  $\theta$  with  $\kappa \leq \theta < \kappa^+$ . The same proper-class spectrum is obtained if the carrier is required to be exactly  $\text{Ord}^{\mathcal{M}_\kappa} = \kappa$ .* This is source 34’s [theorem XVI.8.1](#) and source 12’s [theorem 21.1](#) (iv), by the same cardinality and regularity count; source 35 adds the last sentence (transport to the carrier  $\kappa$  by an ambient bijection) and that internal and external well-foundedness agree because every external witness of ill-foundedness is an available class.

In this example  $\Omega$  has external length  $\kappa$ , while  $\Omega + 1$ ,  $\Omega \cdot 2$ , and  $\Omega^{[\Omega]}$  have the corresponding ordinary ordinal lengths  $\kappa + 1$ ,  $\kappa \cdot 2$ , and  $\kappa^\kappa$ . There is no conflict with the absence of a largest internal class well-order. The external ordinal  $\kappa^+$  is not represented by a class well-order in  $\mathcal{M}_\kappa$ , and the model does not possess the collection of all its classes as a same-level object. This full spectrum is background already present in the repository; the next refinement records the effect of restricting definitions.

### XVI.8.5.2 Definability changes the external ceiling

Use the fixed countable language  $\{\in\}$ . A presentation consists of formulas for its carrier and relation, evaluated over  $V_\kappa$ . Let  $S_0$ ,  $S_{\text{ord}}$ , and  $S_{\text{set}}$  be the external sets of order types of genuine well-orders with presentations using, respectively, no parameters, finitely many ordinal parameters, and finitely many arbitrary set parameters from  $V_\kappa$ . Put

$$\delta_0 = \sup S_0, \quad \delta_{\text{ord}} = \sup S_{\text{ord}}, \quad \delta_{\text{set}} = \sup S_{\text{set}}.$$

These are definitions in the ambient universe, which has the satisfaction relation of the set structure  $V_\kappa$ . They are not proposed as uniform truth definitions inside  $V_\kappa$ .

[merge] In [theorem XVI.8.6](#),  $\delta_{\text{set}}$  is  $\Theta_L$  for  $L = \{\in\}$  and the set-parameter spectrum is the interval  $[0, \delta_{\text{set}})$ , by source 34's [proposition XVI.8.2](#) applied to the full model, which is a GBC realization containing the predicate;  $\text{cf}(\delta_0) = \omega$  is also there. Whether the inequalities  $\delta_0 \leq \delta_{\text{ord}} \leq \delta_{\text{set}}$  are strict in the pure language, and  $\text{cf}(\delta_{\text{set}})$ , stay open; with a named global well-order the analogue of  $\delta_0 = \delta_{\text{set}}$  holds ([theorem XVI.8.3](#); [note XVI.8.16](#)). The reflection-tree example below is the standard mechanism of Hamkins's answer to Glazer's MathOverflow question, as source 35 says; it is not new.

**Theorem XVI.8.6** (Definability-sensitive spectrum bounds). *With these conventions,*

$$\kappa < \delta_0 \leq \delta_{\text{ord}} \leq \delta_{\text{set}} < \kappa^+, \quad \text{cf}(\delta_0) = \omega.$$

*None of the three spectra has a maximum. Each of the other two suprema has cofinality at most  $\kappa$ . Allowing arbitrary class parameters instead recovers the full spectrum of [Note XVI.8.5](#).*

*Proof.* There are countably many parameter-free formula pairs, and at most  $\kappa$  formula pairs with finite parameters from  $V_\kappa$ . The same bound holds for ordinal parameters. Thus

$$|S_0| \leq \aleph_0, \quad |S_{\text{ord}}| \leq \kappa, \quad |S_{\text{set}}| \leq \kappa.$$

Every member lies below  $\kappa^+$  by [Note XVI.8.5](#). The ambient successor cardinal  $\kappa^+$  is regular, so the supremum of at most  $\kappa$  of its members is still below  $\kappa^+$ .

Given any presentation of  $A$ , form the tagged carrier  $(\{0\} \times A) \cup \{(1, 0)\}$ , retaining the old order in the first part and putting the new point last. This defines  $A + 1$  with exactly the same permitted parameters. Its external type is strictly larger. Hence no spectrum has a maximum. A countable nonempty set of ordinals without a largest member has a supremum of cofinality  $\omega$ . The parameter-free presentation of  $\Omega$  and its successors gives  $\delta_0 > \kappa$ . Inclusion of the permitted parameter families gives the remaining inequalities and cardinal bounds on cofinality.

If class parameters are unrestricted, use a carrier and its ordering relation themselves as parameters. Every class presentation is then definable, so there is no remaining restriction.  $\square$

The same suprema result if one restricts to proper-class carriers: given any definable set order, append a copy of  $\Omega$  to obtain a definable proper-class order of greater external type. We make no claim that the inequalities between the three definability suprema are strict. Their exact values require additional information about  $V_\kappa$ . In particular, the counting argument does not assign an exact cofinality to  $\delta_{\text{set}}$ .

It is also important not to identify these spectra with an automatic GBC model  $(V_\kappa, \text{Def}(V_\kappa))$ . The definable classes always give the expected elementary comprehension and replacement, but a global well-order definable from a set parameter need not exist. The spectrum theorem takes place inside the full model and merely restricts which presentations are counted.

### XVI.8.5.3 Internal well-foundedness and external well-foundedness

For a class model  $(M, \mathcal{X})$ , internal well-foundedness quantifies over the subclasses in  $\mathcal{X}$ . A transitive first-order universe  $M$  does not by itself make this equivalent to external well-foundedness. The relevant additional correctness condition is the usual  $\beta$ -model condition: relations declared well-founded internally must be genuinely well-founded externally.

In GBC, a class relation is well-founded if and only if it has no descending  $\omega$ -sequence coded by a set. For the nontrivial direction, Global Choice recursively chooses a smaller member of any nonempty class with no minimal member; Class Replacement collects the resulting  $\omega$ -sequence. Thus two GBC realizations with the same first-order universe agree about well-foundedness of every relation they share. This invariance concerns their *internal* judgment, and does not imply that judgment is externally correct.

Here is the standard reflection-tree mechanism giving a transitive counterexample; compare Hamkins’s answer in [90]. Assume a countable transitive model of ZFC exists, and choose  $M = L_\alpha$  of least possible height. Fix a primitive recursive increasing sequence  $k_i$  large enough to cover the first  $i$  axioms in a recursive enumeration of ZFC. Let  $T$  consist of finite increasing ordinal sequences  $(\beta_i)$  such that  $L_{\beta_i}$  satisfies those axioms and

$$L_{\beta_i} \prec_{\Sigma_{k_i}} L_{\beta_{i+1}} \quad \text{whenever both entries occur.}$$

This is definable using satisfaction for set structures. Reflection produces an external infinite branch. An  $M$ -set branch would have  $\lambda = \sup_i \beta_i < \alpha$ ; eventual elementarity for every formula would give  $L_\lambda \models \text{ZFC}$ , contradicting minimality. The Kleene–Brouwer order of  $T$ , with extensions preceding their prefixes, is therefore internally well-founded but externally ill-founded in  $(M, \text{Def}(M))$ . Internally, a descending sequence would yield a branch by successive coordinate stabilization. Externally, the branch itself yields descending finite prefixes.

The inaccessible-height situation is much better. Every ambient  $\omega$ -sequence of elements of  $V_\kappa$  belongs to  $V_\kappa$ : regularity bounds its coordinate ranks, and the graph then has rank below  $\kappa$ . Consequently *any* GBC realization with first-order universe  $V_\kappa$  is correct about well-foundedness of its admitted relations. This gives a second proof of the correctness used in [Note XVI.8.5](#), and explains exactly why that external calculation is safe.

### XVI.8.6 Source 32: external spectra and the ceiling of definability

We now give a precise model-relative answer to “how much farther than Ord?” This section takes place in an external ZFC metatheory and assumes a strongly inaccessible cardinal  $\kappa$ . This is a sufficient setting for the results, not a claim that such a cardinal follows from ZFC or is necessary for every related phenomenon.

Put  $M = V_\kappa$ . Fix a class predicate  $G$  coding a bijection  $\kappa \rightarrow V_\kappa$ , and let  $A \subseteq V_\kappa$  be an arbitrary additional predicate. Tuples and relations may be coded as unary predicates using ordinary set pairing. Define

$$\mathcal{X}_A = \text{Def}(V_\kappa; \in, G, A), \tag{S32.11}$$

where *all set parameters from  $V_\kappa$  are allowed*. The parameters  $G, A$  are fixed; they are not varied separately for each definition within this one class realization.

The distinction between different admitted class collections over one set universe is central in work on class-theoretic potentialism [84]. Here it lets us isolate a numerical invariant of definability rather than assigning an absolute length to “the definable classes” without specifying a language or a model.

### XVI.8.6.1 Why this setting has honest external well-orders

**Lemma XVI.8.7** (The inaccessible-rank model). *Both  $(V_\kappa, \mathcal{X}_A)$  and  $(V_\kappa, \mathcal{P}(V_\kappa))$  satisfy GBC. For every class relation on  $V_\kappa$ , its internal class well-foundedness in either model is equivalent to external well-foundedness.*

*Proof.* The set structure  $V_\kappa$  satisfies ZFC. A subset of any  $x \in V_\kappa$  belongs to  $V_\kappa$ , so separation with arbitrary class predicates holds. If a class function is evaluated on a set  $x \in V_\kappa$ , then  $|x| < \kappa$ . Its values form fewer than  $\kappa$  many sets of rank below  $\kappa$ . Regularity of  $\kappa$  bounds all their ranks below  $\kappa$ , so the image belongs to  $V_\kappa$ . This verifies Class Replacement even for arbitrary external class predicates. The predicate  $G$  gives Global Choice. For  $\mathcal{X}_A$ , elementary comprehension holds by substituting the definitions of its finitely many class parameters; for the full power set it is automatic.

Every external sequence  $f : \omega \rightarrow V_\kappa$  belongs to  $V_\kappa$ : the ranks of its countably many values have supremum below  $\kappa$ , and its graph then has rank below  $\kappa$ . Consequently an external descending  $\omega$ -sequence is an internal set witness to failure of well-foundedness. Conversely an internal descending sequence is certainly external. External dependent choice and lemma XVI.2.8 give the equivalence.  $\square$

The last assertion is not valid for arbitrary countable or nonstandard models. Such models may admit internally well-founded presentations that are externally ill-founded. We use the inaccessible setting precisely to rule out that ambiguity, rather than silently identifying internal and external order types everywhere.

*Note XVI.8.8* (Source 32, Theorem 8.2, “The full-class spectrum”). *In  $(V_\kappa, \mathcal{P}(V_\kappa))$ , the external order types of class well-orders are exactly the ordinals below  $\kappa^+$ , and those of proper-class well-orders exactly*

$$[\kappa, \kappa^+). \quad (\text{S32.12})$$

*The set-like proper-class type is  $\kappa$ , the external type of the internal  $\Omega$ .* This is source 34’s theorem XVI.8.1 and source 12’s theorem 21.1 (iv), with the same proof.

Thus full second-order semantics produces every length below the next external cardinal, not merely finite expressions in  $\kappa$ . It does not produce a greatest type:  $\kappa^+$  is a supremum outside the range, not an extra class ordinal in that model. Restricting to definable classes produces a much smaller, structured ceiling.

### XVI.8.6.2 The definability ceiling theorem

Let  $S_A$  be the external set of ordinal types of the  $\mathcal{X}_A$ -admitted class well-orders. There are only a set of these presentations externally, so the following definition is ordinary metatheoretic set formation:

$$\delta_A = \sup\{\beta + 1 : \beta \in S_A\}. \quad (\text{S32.13})$$

**Theorem XVI.8.9** (Definability ceiling). *The realized spectrum is exactly the initial segment*

$$S_A = \{\beta : \beta < \delta_A\}. \quad (\text{S32.14})$$

Moreover,

$$\kappa < \delta_A < \kappa^+, \quad \text{cf}(\delta_A) = \omega, \quad \kappa^{\delta_A} = \delta_A, \quad (\text{S32.15})$$

where the exponentiation and cofinality in (S32.15) are external ordinal operations. In particular,  $\delta_A$  is not itself represented by any class well-order in  $\mathcal{X}_A$ .

*Proof. Initiality and no last type.* Suppose  $\beta \in S_A$ , represented by  $W$ , and  $\gamma < \beta$ . The point of  $W$  at external position  $\gamma$  is an element  $x \in V_\kappa$ . Restricting  $W$  below  $x$  is definable with the additional allowed set parameter  $x$  and has type  $\gamma$ . Thus  $S_A$  is downward closed. It is closed under successor because  $W + 1$  is a definable class presentation. Therefore it has no largest member, and it is exactly the initial segment in (S32.14). Its supremum is not represented. The internal ordinal class has external type  $\kappa$ , so  $\kappa \in S_A$  and  $\kappa < \delta_A$ .

*A countable cofinal sequence of bounds.* Externally enumerate all first-order formula pairs for domains and binary relations in the fixed finite language with  $G, A$ :

$$(\varphi_0, \psi_0), (\varphi_1, \psi_1), \dots$$

Each formula pair is arranged to use one code for its finite tuple of set parameters. For each ordinary natural number  $n$ , apply [corollary XVI.7.15](#) to the first  $n + 1$  pairs, with all such set parameters. Let  $D_n$  be the resulting definable diagonal well-order and put

$$\theta_n = \text{otp}(D_n).$$

Each  $\theta_n$  belongs to  $S_A$ , so  $\theta_n < \delta_A$ . Every definable well-order  $W$  uses some formula pair, say the  $j$ th. For all  $n \geq j$ , the diagonal theorem says that  $W$  embeds into  $D_n$  and that  $D_n$  does not embed into  $W$ . These are actual external well-orders by [lemma XVI.8.7](#). Ordinary ordinal comparison therefore gives

$$\text{otp}(W) < \theta_n.$$

Hence  $(\theta_n)_{n < \omega}$  is externally cofinal in  $\delta_A$ .

Each  $\theta_n < \kappa^+$  by [note XVI.8.8](#). Since  $\kappa^+$  is regular and uncountable, the supremum of this countable sequence is strictly below  $\kappa^+$ . The ordinal  $\delta_A$  is a nonzero limit with no largest represented type, so a finite subset cannot be cofinal. Its cofinality is therefore exactly  $\omega$ .

*Closure and the fixed-point equation.* If  $\alpha, \beta \in S_A$  and  $\alpha \geq 2$ , choose definable class presentations of those types. Their finite-support power is definable in the same structure and is a well-order by [note XVI.4.10](#). Externally its type is the ordinary ordinal  $\alpha^\beta$ , by [lemma XVI.4.9](#) applied in the external universe. Thus  $S_A$  is closed under this exponentiation, as well as under sums and products.

In particular, since  $\kappa \in S_A$ , for every  $\beta < \delta_A$  we have  $\kappa^\beta < \delta_A$ . Continuity of ordinary exponentiation at the limit  $\delta_A$  gives

$$\kappa^{\delta_A} = \sup_{\beta < \delta_A} \kappa^\beta \leq \delta_A.$$

For every ordinal  $\beta$  and base at least 2, ordinary induction gives  $\beta \leq \kappa^\beta$ . Taking suprema yields the reverse inequality. This proves all of ([S32.15](#)).  $\square$

[merge] [Theorem XVI.8.9](#) is source 34's [proposition XVI.8.2](#) and [corollary XVI.8.4](#) at  $V_\kappa$  for the language  $\{\in, G, A\}$ , by a different route: source 34 bounds each formula pair by its own parameter-free sum, source 32 by the diagonals of finite lists of formula pairs ([corollary XVI.7.15](#)). The equation  $\kappa^{\delta_A} = \delta_A$  is proved here only by source 32; source 33's [corollary XVI.8.17](#) adds  $\omega^\delta = \delta$  and closure under ordinal arithmetic. [Corollary XVI.8.11](#) is proved only by source 32.

*Remark XVI.8.10* (What the ceiling does and does not mean). The spectrum statement uses set parameters essentially: they permit restriction below an arbitrary point of a presentation. It is not a theorem about parameter-free definability. Likewise, “definable with arbitrary class parameters” would mean something different if the class parameter were allowed to change separately for each presentation. Here  $A$  and  $G$  are fixed before  $\delta_A$  is formed.

The countable sequence  $(D_n)$  above is at this point an *external sequence of individually admitted classes*. It is not asserted to be a single  $\mathcal{X}_A$ -admitted family. If it were such a family, its sum could already reach the forbidden ceiling. The distinction is not bookkeeping: it is exactly where truth enters.

### XVI.8.6.3 Further structural consequences

**Corollary XVI.8.11.** *For fixed  $\kappa$  and  $G$ , the ordinals  $\delta_A$ , as  $A \subseteq V_\kappa$  varies, are unbounded in  $\kappa^+$ . More precisely,*

$$\sup_{A \subseteq V_\kappa} \delta_A = \kappa^+.$$

*Proof.* Given  $\theta < \kappa^+$ , transfer a well-order of type  $\theta$  to a subset of  $V_\kappa$  and code its domain and relation in one unary predicate  $A$ . That order is then definable from  $A$ , so  $\theta \in S_A$  and  $\theta < \delta_A$ . The reverse bound follows from [theorem XVI.8.9](#) for each  $A$ .  $\square$

The necessary conditions  $\text{cf}(\delta_A) = \omega$  and  $\kappa^{\delta_A} = \delta_A$  are not a classification of possible ceilings. In fact the spectrum is closed under more than ordinary exponentiation: it is closed under every fixed finite presentation constructor developed here, including  $A \mapsto E(A)$ . Determining which such closure properties are sufficient, or how these ordinals are related to other definability invariants, remains a substantive question.

A useful schematic comparison is therefore

| admitted presentations over $V_\kappa$   | external spectrum               |
|------------------------------------------|---------------------------------|
| set-like class well-orders               | $\{\beta : \beta \leq \kappa\}$ |
| $\text{Def}(V_\kappa; G, A)$ well-orders | $\{\beta : \beta < \delta_A\}$  |
| all class well-orders                    | $\{\beta : \beta < \kappa^+\}.$ |

In the first row the set-order types are below  $\kappa$ , and the single proper set-like type is  $\kappa$ . In the other rows many different non-set-like types appear. None of these external spectra is being asserted to be an admitted universal family in the model it describes.

### XVI.8.7 Source 32: a truth predicate reaches the old ceiling exactly

Let  $T_A$  be the full satisfaction predicate for the *set-sized external structure*  $(V_\kappa, \in, G, A)$ , with finite assignments coded in  $V_\kappa$ . Such a predicate exists externally and is an element of  $\mathcal{P}(V_\kappa)$ . It is not definable in that same structure with set parameters, by the usual diagonal argument for truth. Form the enlarged definable class realization

$$\mathcal{X}_{T_A} = \text{Def}(V_\kappa; \in, G, T_A).$$

The predicate  $A$  is recoverable from the truth values of its atomic formulas, so  $\mathcal{X}_A \subseteq \mathcal{X}_{T_A}$ .

**Theorem XVI.8.12** (Exact truth presentation and strict jump). *There is an  $\mathcal{X}_{T_A}$ -definable class well-order whose external type is exactly  $\delta_A$ . Consequently,*

$$\delta_A < \delta_{T_A}. \tag{S32.16}$$

*Proof.* Use the fixed external effective enumeration of formula pairs from the proof of [theorem XVI.8.9](#). In the language with  $T_A$ , evaluation of these pairs is uniform in their natural-number codes and set parameters. Validity of each evaluated fiber is still an elementary condition, by [lemma XVI.2.8](#); its

external correctness follows from [lemma XVI.8.7](#). Fix once and for all the global ordering of the formula-tag and parameter-code index class obtained from  $G$ .

The diagonal construction for the first  $n + 1$  formula pairs can now be carried out uniformly in  $n$ . It gives one admitted family  $(D_n)_{n < \omega}$  in  $\mathcal{X}_{T_A}$ . Its  $n$ th fiber is exactly the individually definable order used in the ceiling proof: for a fixed standard  $n$ , the finitely many evaluations can be replaced by their actual formulas, eliminating the truth predicate from that one fiber.

Define the class order

$$L = \sum_{n < \omega} (D_n + 1). \quad (\text{S32.17})$$

It is definable from  $G, T_A$  and is a class well-order by [proposition XVI.3.4](#). Every finite partial sum of (S32.17) belongs to  $\mathcal{X}_A$ , because it involves only finitely many of the individually definable  $D_n$ . Thus each finite partial sum has external type strictly below  $\delta_A$ . Since these are nested initial segments whose union is  $L$ , continuity of the external ordinal sum gives

$$\text{otp}(L) \leq \delta_A.$$

On the other hand, every  $D_n$  embeds into  $L$ . The ordinals  $\theta_n = \text{otp}(D_n)$  are cofinal in  $\delta_A$ , so  $\text{otp}(L) \geq \delta_A$ . Hence  $\text{otp}(L) = \delta_A$  exactly.

The new spectrum therefore contains  $\delta_A$ . It is successor closed and is the initial segment below its own ceiling, by [theorem XVI.8.9](#) applied with  $T_A$  as the extra predicate. This implies (S32.16).  $\square$

This theorem gives a precise interpretation of one step beyond a definability boundary. Truth does not merely yield some unrelated longer order. It assembles the formerly nonuniform finite-syntax bounds into a presentation of the old supremum itself. The construction is parallel in spirit to class-theoretic truth hierarchies, but its conclusion here follows from the explicit diagonal argument rather than from an assumed global iterated-truth principle.

[merge] [Theorem XVI.8.12](#) is the strongest of the four truth results: source 34's [theorem XVI.7.4](#) produces, internally and from an assumed full satisfaction class, an order dominating every definable one; source 33's [theorem XVI.8.19](#) shows at  $V_\kappa$  that truth raises the height, with the bounds of the new height; source 32 shows that truth represents the old height exactly. Its [corollary XVI.8.13](#) gives one family with no uniform code, as source 33's [corollary XVI.7.22](#) and source 34's [corollary XVI.7.6](#) do for theirs.

**Corollary XVI.8.13** (The old bounds cannot have been uniformly admitted). *The particular family  $(D_n)_{n < \omega}$  used above has no uniform code in  $\mathcal{X}_A$ .*

*Proof.* Such a code would make (S32.17) an  $\mathcal{X}_A$ -admitted class well-order of type  $\delta_A$ , contradicting [theorem XVI.8.9](#).  $\square$

One can externally repeat the construction: set  $A_0 = A$  and let  $A_{n+1}$  code the full truth predicate for the structure with  $A_n$ . Then

$$\delta_{A_0} < \delta_{A_1} < \delta_{A_2} < \cdots < \kappa^+.$$

Each individual step is covered by [theorem XVI.8.12](#). This assertion does not automatically supply one admitted internal hierarchy of all these truth predicates; combining them is again a uniformity question. The same caution applies at limit stages.

## XVI.8.8 Source 33: external spectra, definability heights, and truth

### XVI.8.8.1 A full-class model at an inaccessible cutoff

In this section the surrounding metatheory is ordinary external ZFC. Assume  $\kappa$  is strongly inaccessible and let

$$M = V_\kappa, \quad \mathcal{X} = \mathcal{P}(M).$$

Relations and tuples are coded as elements of  $M$ , so writing all subclasses as  $\mathcal{P}(M)$  covers binary relations as well. The set structure  $M$  satisfies ZFC. Every subset of  $M$  is an available class in  $(M, \mathcal{X})$ . Full class comprehension holds externally. Class replacement holds because a set of  $M$  has external cardinality below  $\kappa$ , and regularity bounds the ranks of fewer than  $\kappa$  many output values. A global ordering can be chosen externally and belongs to  $\mathcal{X}$ .

*Note XVI.8.14* (Source 33, Lemma 9.1, “Correct well-foundedness at the cutoff”). *Every class well-order of  $(V_\kappa, \mathcal{P}(V_\kappa))$  is externally well-founded, and conversely every externally well-founded class order is internally a well-order.* This is source 32’s lemma XVI.8.7 for the full model and source 34’s  $\beta$ -model remark after theorem XVI.8.1: an external descending sequence of elements of  $V_\kappa$  has ranks bounded below  $\kappa$  by regularity and uncountability, so it belongs to  $V_\kappa$ .

*Note XVI.8.15* (Source 33, Theorem 9.2, “Exact full-class spectrum”). *In the full-class model, the external order types of class well-orders are exactly*

$$\{\alpha : \alpha < \kappa^+\}; \tag{S33.9.1}$$

*those with proper-class carriers exactly the  $\alpha$  with  $\kappa \leq \alpha < \kappa^+$ ; and the set-like proper-class order  $\Omega^M$  has external type  $\kappa$ .* This is source 34’s theorem XVI.8.1, with the same proof.

The endpoint  $\kappa^+$  is an external bound, not a last represented class order. For each  $\alpha < \kappa^+$ , its successor still lies below  $\kappa^+$ . This reconciles note XVI.8.15 with the internal no-greatest-order theorem.

### XVI.8.8.2 Arithmetic viewed from outside

If a class exponent order  $\Gamma$  has external type  $\gamma$ , the finite-support construction has external type

$$\text{otp}(P(\Gamma)) = \kappa^\gamma, \tag{S33.9.2}$$

where the exponent on the right is *ordinal* exponentiation. Indeed, all exponent points and ordinal coefficients below  $\kappa$  are available as elements of  $M$ , and every finite code on them belongs to  $M$ . The external collapse is the ordinary finite-support presentation of that ordinal power.

All powers in (S33.9.2) still lie below  $\kappa^+$  when  $\gamma < \kappa^+$ : their finite-support presentations have cardinality at most  $\kappa$ . This gives a concrete sense in which very long ordinal expressions can have the same underlying class size.

For the fixed point of theorem XVI.6.26, set

$$t_0 = \kappa, \quad t_{n+1} = \kappa^{t_n}.$$

Its external type is  $\sup_{n < \omega} t_n$ . Continuity of ordinal exponentiation shows that this is the least fixed point of  $\xi \mapsto \kappa^\xi$  above  $\kappa$ . It is still below  $\kappa^+$ .

[merge] The external type (S33.9.2) is source 29’s full-model check after corollary 108.20 and source 34’s substitution rule in section XVI.10; the type  $\sup_n t_n$  of the fixed point is source 34’s theorem XVI.6.9,  $\varepsilon_{\kappa+1}$ .

### XVI.8.8.3 The smaller definable spectrum

Fix a set-like global ordering  $G$  in the full class model and let  $\text{Def}(M; G)$  consist of all first-order definable subclasses using  $G$  and finite tuples of parameters from  $M$ . This is a legitimate GBC class realization: comprehension is built into the definition, and replacement follows from the same rank and cardinality bound used above. Its well-orders are externally correct by the proof of [note XVI.8.14](#).

Define, externally,

$$\delta_G = \sup\{\text{otp}(W) : W \text{ has a first-order } G\text{-definable presentation with set parameters in } M\}. \quad (\text{S33.9.3})$$

Let  $\delta_G^0$  be the same supremum with no set parameters. This supremum is a set ordinal in the external metatheory. We make no claim that it is an ordinal or a represented well-order of the definable class model itself.

*Note XVI.8.16* (Source 33, Theorem 9.3, “Countably cofinal definability height”). *Under the inaccessible-rank hypotheses,*

$$\delta_G^0 = \delta_G, \quad \kappa < \delta_G < \kappa^+, \quad \text{cf}(\delta_G) = \omega. \quad (\text{S33.9.4})$$

*No  $G$ -definable class well-order has type  $\delta_G$ . The full class model does have a class well-order of that external type.* This is source 34’s [theorem XVI.8.3](#) and [corollary XVI.8.4](#) for  $L = \{\in, G\}$ , with  $\delta_G = \Theta_L$  and  $\delta_G^0 = \sup \mathcal{S}_0^L$ . The proof differs: source 34 bounds the instances of one formula pair by one parameter-free sum; source 33 uses the diagonals  $D_n$  of its [theorem XVI.7.20](#), one for each complexity level. It is printed as a second route. The last sentence is source 34’s [theorem XVI.8.1](#).

*Source 33’s proof.* For each external standard  $n$ , interpret the parameter-free formula for  $D_n$  from [theorem XVI.7.20](#) in  $(M, \in, G)$ , and let  $d_n = \text{otp}(D_n)$ . The order is externally well-founded. Every  $G$ -definable presentation has a fixed standard finite formula complexity, so it embeds into some  $D_n$ . Conversely every  $D_n$  is itself  $G$ -definable without set parameters. Therefore

$$\delta_G = \delta_G^0 = \sup_{n < \omega} d_n.$$

Every  $d_n < \kappa^+$  by [note XVI.8.15](#). The successor cardinal  $\kappa^+$  is regular in the external metatheory, so the supremum of this countable sequence is still strictly below  $\kappa^+$ .

The definable spectrum has no largest type: taking a tagged successor is a definable operation and strictly increases external ordinal type. Thus its supremum is not attained and has no finite cofinal subset. The countable cofinal family above gives  $\text{cf}(\delta_G) = \omega$ . The definable orders  $\Omega + 1$  and their further successors show that  $\delta_G > \kappa$ .

Nonattainment follows again from successor closure. Since  $\delta_G < \kappa^+$ , the full-class spectrum theorem supplies a full class well-order with that type, though not a  $G$ -definable one.  $\square$

[merge] [Corollary XVI.8.17](#) extends source 32’s  $\kappa^{\delta_A} = \delta_A$  ([theorem XVI.8.9](#)) to closure under ordinal sum, product and power and to  $\omega^{\delta_G} = \delta_G$ . The same argument gives  $\omega^{\Theta_L} = \Theta_L$ , and  $\theta^{\Theta_L} = \Theta_L$  for the external type  $\theta$  of  $\text{Ord}^M$ , for every transitive  $\beta$ -model and language of [proposition XVI.8.2](#): the parameter spectrum is the interval  $[0, \Theta_L)$ ; finite-support powers of  $L$ -definable presentations are  $L$ -definable with the joined parameters; and their external types are the ordinal powers, because the model contains every finite partial function between its sets and is correct about well-foundedness. [Theorem XVI.8.19](#) is weaker than source 32’s [theorem XVI.8.12](#) on exactness and adds the upper bound and cofinality of the new height.

**Corollary XVI.8.17** (Arithmetic closure of the definability ceiling). *For all external ordinals  $\alpha, \beta < \delta_G$ ,*

$$\alpha + \beta < \delta_G, \quad \alpha \cdot \beta < \delta_G, \quad \alpha^\beta < \delta_G.$$

Moreover,

$$\omega^{\delta_G} = \kappa^{\delta_G} = \delta_G. \quad (\text{S33.9.5})$$

*In particular,  $\delta_G$  is an external epsilon number, not just an unspecified ordinal of countable cofinality.*

*Proof.* Let  $S$  be the spectrum whose supremum is  $\delta_G$ . Given  $\alpha, \beta < \delta_G$ , choose  $a, b \in S$  with  $a \geq \max(2, \alpha)$  and  $b \geq \beta$ . The explicit sum, product, and power constructions preserve first-order definability, allowing the two original parameter tuples together. Their external types are  $a + b$ ,  $a \cdot b$ , and  $a^b$ , respectively. Each belongs to  $S$  and is strictly below its unattained supremum. Monotonicity of ordinary ordinal arithmetic gives the first three inequalities; zero and one cause no difficulty.

For  $\lambda = \omega$  or  $\kappa$ , the base order of type  $\lambda$  is definable, and  $\lambda^a \in S$  whenever  $a \in S$ . Continuity in the exponent and cofinality of  $S$  give

$$\lambda^{\delta_G} = \sup_{a \in S} \lambda^a \leq \delta_G.$$

Ordinal exponentiation with base at least two satisfies  $\lambda^\xi \geq \xi$ , as follows by transfinite induction. Hence equality holds. The case  $\lambda = \omega$  is the epsilon-number assertion.  $\square$

*Remark XVI.8.18* (Two different cofinalities). The equality  $\text{cf}(\delta_G) = \omega$  is entirely external. It does not say that the internal class  $\text{Ord}^M$  has a countable cofinal sequence. Indeed  $\text{Ord}^M$  has external type  $\kappa$ , which is regular and uncountable. Nor does it provide a  $G$ -definable uniform sequence of relations cofinal in the definable spectrum; [corollary XVI.7.22](#) forbids exactly that uniformization.

#### XVI.8.8.4 Truth strictly raises the definability height

A full first-order truth predicate for  $(M, \in, G)$  is an external subset of the class of formula-assignment codes, so it belongs to the full class part. Call it  $T$ . It evaluates formulas of  $\mathcal{L}_G$ ; it does *not* evaluate formulas of the expanded language containing  $T$  itself.

**Theorem XVI.8.19** (A strict truth jump in order height). *Let  $\delta_{G,T}$  be the definability height in the fixed expanded language  $\{\in, G, T\}$ , allowing set parameters. Then*

$$\delta_G < \delta_{G,T} < \kappa^+, \quad \text{cf}(\delta_{G,T}) = \omega. \quad (\text{S33.9.6})$$

*The two class realizations have exactly the same set universe and the same set ordinals.*

*Proof.* Using  $T$ , all  $G$ -formula pairs together with all finite parameter tuples can now be evaluated in one uniform family, with no bounded-complexity restriction. Apply the first-order well-orderhood test from [note XVI.2.12](#) to each decoded relation and replace failures by the empty order. The resulting family is  $G, T$ -definable and contains every  $G$ -definable class well-order.

Let  $K$  be its diagonal sum of successor fibers. Every  $G$ -definable well-order embeds into  $K$ , so externally  $\text{otp}(K) \geq \delta_G$ . The  $G, T$ -definable successor  $K + 1$  has type strictly greater than  $\delta_G$ . Hence  $\delta_{G,T} > \delta_G$ .

The proof of [note XVI.8.16](#) applies verbatim to any fixed finite collection of named predicates whose class realization satisfies GBC. At  $V_\kappa$  the rank argument supplies this requirement for  $G, T$ . It gives the remaining bound and cofinality in [\(S33.9.6\)](#). No sets were added; only the allowed class definitions were enlarged.  $\square$

This result makes precise a form of “farther than Ord” that cannot be captured merely by listing longer ordinal expressions. The height of attainable *definable* order types can increase while the set ordinals, all sets, and even the ambient full-class spectrum remain fixed. The role of truth expansion is consistent with the broader potentialist view of changing class resources over a fixed set model [84].

#### XVI.8.8.5 What fails outside the full inaccessible model

For any set-sized external model with carrier  $M$ , genuinely well-founded orders on subsets of  $M$  have external type below  $|M|^+$ . Equality with the full interval of types need not follow. The class part may omit many relations, the set model may not be externally correct about well-foundedness, and small external subsets of  $M$  need not be sets of  $M$ .

Accordingly, neither the exact interval (S33.9.1) nor the specific cutoff  $\kappa$  should be asserted for arbitrary models of GBC or KM. The inaccessible construction is an explicit semantic laboratory, not an additional hypothesis smuggled into the elementary GBC theorems of the earlier sections.

### XVI.9 How far the constructions reach, and what requires more axioms

The preceding results give several answers to “how much farther than Ord?” They answer different versions of the question and should not be compressed into a single purported largest class ordinal.

First, elementary presentations already go beyond every fixed finite combination of ordinal blocks. If  $\alpha$  is a set ordinal, the power  $\Omega^{[\alpha]}$  is a definable class well-order, and these are proper initial segments of  $\Omega^{[\Omega]}$ . Iterating the same finite-support constructor inside hereditary syntax gives

$$\Omega, \quad \Omega^{[\Omega]}, \quad \Omega^{[\Omega^{[\Omega]}]}, \quad \dots$$

as proper initial segments of  $\mathbf{E}$ . Appending an endpoint or a new block to  $\mathbf{E}$  immediately gives further orders. None of these explicit constructions requires the existence of an unknown class-valued transfinite history.

Second, no single uniform family is cofinal among all class well-orders under order embedding. This is stronger than saying that there is no largest element: it blocks a catalog indexed by sets with one uniform evaluation relation. A syntax can describe an enormous domain and still have a definable extension outside its reach.

Third, definability imposes a relative ceiling in an external model. For a fixed transitive  $\beta$ -model and a fixed finite collection of named predicates, the set-parameter definable order types form an initial segment  $[0, \Theta)$ . Naming a suitable truth predicate strictly enlarges the range available in that language. Under a named global well-order,  $\Theta$  has external cofinality  $\omega$ . This does not make  $\Theta$  countable, nor does it make the external cofinal sequence an admitted uniform class sequence.

Fourth, under the full interpretation over  $V_\kappa$ , the precise external ceiling for all class presentations is  $\kappa^+$ . This bound is relative to the chosen universe. It is not an absolute object that can be appended to Ord inside the original theory. The difference between explicit definability and arbitrary available classes is responsible for the difference between  $\Theta$  and  $\kappa^+$ .

#### XVI.9.1 The comparison and recursion boundary

The established class-recursion literature supplies the implications

$$\text{GBC} + \text{ETR} \vdash \text{CWO}, \quad \text{GBC} + \text{ETR} \vdash \text{CTH}.$$

The first follows by recursively matching the least unmatched points of two orders; the second also follows from the defining elementary recursion for the history. Gitman and Hamkins identify full ETR with clopen class-game determinacy and, in its full all-length formulation, with iterated elementary truth. Gitman, Hamkins, Holy, Schlicht, and Williams identify  $\text{ETR}_{\text{Ord}}$  with the class forcing theorem [22, 24]. These are theorems about stronger existence principles, not prerequisites for the finite graph manipulations used here.

For fixed small lengths, iteration conventions matter. For example,  $\text{ETR}_1$  is just an elementary comprehension instance; the existence of one full truth predicate is already a stronger assertion. We therefore do not replace the all-length equivalence by the unqualified formula “ $\text{ETR}_\Gamma$  equals  $\Gamma$ -iterated truth” for every  $\Gamma$ .

There is also a useful boundary between arbitrary rankings and continuous rankings. Hamkins and Woodin prove that every well-founded class relation has a ranking into some class well-order over  $\text{GBC}^-$ , while ETR supplies continuous rankings. Their comparison question asks whether appropriate converse implications hold [27, Theorems 4–6 and Question 7]. The present GB refinement identifies the strength of the particular condensation-history principle with CWO; it does not convert all elementary class recursions into finite normal forms.

[merge] The implications displayed above are recorded by all four sources and by this report (theorem 108.19 and the paragraph after it). Source 34’s last sentence identifies the strength of the condensation-history principle with CWO over GB (theorem XVI.5.8); with source 35’s corollary XVI.6.19 and theorem XVI.6.21, the fixed-point extension principle FPE is a further equivalent over GB. Whether CWO implies ETR is Hamkins and Woodin’s Question 7, which no source settles (section 113.28).

## XVI.9.2 Source 35: the boundary between comparison and class recursion

The preceding constructions use elementary comprehension, set-valued recursion, and Class Replacement. They do not solve arbitrary recursions whose individual stages are classes. For an elementary formula  $\varphi(x, i, F, A)$  and a class well-order  $\Gamma$ , a class recursion asks for a single class  $F$  satisfying

$$F_i = \{x : \varphi(x, i, F \restriction \Gamma_{<i}, A)\} \quad (i \in \Gamma).$$

The earlier history on the right may be a proper class, even when  $i$  has a set of predecessors. This is the content of elementary transfinite recursion, ETR, rather than the ordinary set-valued recursion theorem.

Over GBC, ETR is equivalent to the existence, for every class parameter and every class well-order, of an iterated first-order truth predicate along that order. It is also equivalent to determinacy of clopen games on classes [22, Theorems 8–9]. This supplies a precise reason to track the formalism when writing an iteration beyond Ord: the length and the type of the values are separate resources.

For a fixed  $\Gamma$ ,  $\text{GBC} + \text{ETR}_\Gamma$  proves that  $\Gamma$  is comparable with every class well-order by initial-segment embeddings. One recursively matches each point of  $\Gamma$  with the least unmatched point of the other order; if that construction stops, its inverse supplies the opposite comparison [35, Lemma 3.17]. Finite concatenations of the same recursion length add no strength, because the solution on one piece can be used as a parameter for the next. This observation does not justify a uniform iteration over all finite pieces.

The distinction is already visible at the important fragment  $\text{ETR}_{\text{Ord}}$ . Over GBC, it is equivalent to the class forcing theorem and to the existence of Ord-iterated truth predicates, among several other formulations [24, Main Theorem]. These are established calibration theorems. They do not identify arbitrary well-order comparability with full ETR.

The name “elementary transfinite recursion” also occurs in a different weak-set-theory setting. Frittaion and Genovesi prove that their first-order theory **C**, which includes Axiom Beta, proves  $\Delta_0$  transfinite recursion and generates relativized constructible hierarchies [91]. Their base theory and recursion scheme differ from the class-valued scheme displayed above. Applying that result to the present comparison problem would require an explicit interpretation and a proof that the relevant class solutions are obtained; the shared terminology alone supplies no such implication.

For clarity, the established implication chain over **GBC**, and over the weaker **GBC**<sup>−</sup> base used in the cited paper, is

$$\begin{aligned} \text{ETR} &\implies \text{continuous rankings for all well-founded class relations} \\ &\implies \text{CWO} \\ &\implies \text{weak class-well-order comparability.} \end{aligned}$$

Here a continuous ranking assigns to a point the least available rank strictly exceeding every predecessor rank; weak comparability permits arbitrary suborder embeddings. Hamkins and Woodin establish the first two implications in their Theorems 5–6 and ask in Question 7 whether the displayed principles are equivalent [27]. The present article neither proves those converses nor treats the repository’s condensation characterization of **CWO** as a proof of them.

Another independent distinction concerns the ambient model. Two externally isomorphic orders need not have their isomorphism available in a specified class realization. Glazer’s question about definable class well-orders explicitly separates genuine external well-foundedness from internal recognition, and separates external isomorphism from definability of the isomorphism [90]. Its discussion includes a truth-encoding proposal at length  $\text{Ord}^\omega$ ; we do not require that proposal as a lemma here. The bounds and separation theorems above are proved directly for admitted classes and maps. In a  $\beta$ -correct realization, their selected well-orders are also genuine external well-orders. Without that correctness hypothesis an internally valid construction may have an externally ill-founded interpretation.

These qualifications suggest a workable formalization policy. Store a notation, its carrier, its comparison relation, and its well-foundedness proof as separate data. State whether an interpreter is one available class or an external formula scheme. Record initial-segment embeddings separately from arbitrary embeddings, and require an explicit history when class-valued iteration is used. With these distinctions, long notations remain useful while their limits are mathematical theorems rather than hidden changes of universe or truth resources.

[merge] The citations of Frittaion and Genovesi’s 2026 preprint, of the correction to the countdown argument recorded in the revised class-forcing paper, and of Glazer’s MathOverflow question are source 35’s; their checking status is recorded in [section 1.11](#).

### XVI.9.3 Source 32: order length is not recursion strength

#### XVI.9.3.1 Three different uses of recursion

An elementary transfinite recursion along a supplied class well-order  $\Gamma$  asks for a class  $S \subseteq \Gamma \times V$  whose sections satisfy a rule of the form

$$S_\gamma = \{x : \varphi(x, S \upharpoonright \Gamma_{<\gamma}, Z)\}, \tag{S32.18}$$

where  $\varphi$  has only set quantifiers and  $Z$  is a fixed class parameter. The sections  $S_\gamma$  are classes, not necessarily sets. ETR asserts the existence of solutions for the relevant class well-orders. The distinction between class-valued recursion and finite or set-valued recursion is standard in the literature on second-order set theory [35, 84].

The proofs in this manuscript use three quite different mechanisms. Finite syntax allows recursive evaluation of a single finite tree. Set-valued recursion with a set history constructs, for example, an  $\omega$ -sequence of finite term codes or the cofinal map in [proposition XVI.3.7](#). Class-valued recursion constructs all the equivalence relations in [note XVI.5.20](#), with previous relations themselves as class data. Only the third is an invocation of ETR.

Even a recursion whose stage order is the set  $\omega$  can be class-valued: its stages might be increasingly complicated satisfaction classes. Therefore “the index is only countable” is not a reason to replace a class-valued recursion by the ordinary recursion theorem of ZFC. Conversely, the existence of  $E(\Omega)$  is not an ETR theorem, since its points are finite codes and well-foundedness was proved by support localization.

### XVI.9.3.2 Comparison principles and what is left open

Hamkins and Woodin prove that ETR implies initial-segment comparability of class well-orders and discuss reverse implications relating ETR, continuous rankings, and weaker comparison principles [\[27\]](#). We use their theorem only where explicitly stated. No claimed solution of those reverse-implication questions is part of the present work.

It is tempting to argue that two class well-orders can always be compared by recursively matching their least unmatched points. The difficulty appears when the matched initial history is proper: that history is no longer a set on which the ordinary set recursion theorem operates. It is equally tempting to take the union of all partial class matches, but this invokes a collection of class objects outside elementary class comprehension. Both arguments need additional justification.

Our diagonal theorem was designed to avoid this issue. Its contradiction is local to a single known block  $W_i + 1$ . Likewise, the division theorem obtains canonical isomorphisms from set-sized local ranks. These examples illustrate how to obtain substantial structural results without solving the general comparison problem.

In the external spectrum theorems, ordinary order types can of course be compared in the metatheory. That comparison is not being pulled back as an admitted isomorphism in  $\mathcal{X}_A$ . For example, the assertion that a definable suborder has an external ordinal type below another does not, by itself, prove that its initial-segment isomorphism is definable over  $(V_\kappa, \in, G, A)$ .

### XVI.9.3.3 Why there is no universal final ordinal

Three rigorous negatives replace a vague search for “the biggest ordinal beyond Ord”. First,  $W + 1$  is always a strictly larger presentation. Second, [note XVI.7.14](#) defeats any one admitted uniform family. Third, the exact externally realized spectrum changes with the admitted class collection: it is bounded by  $\delta_A$  for one definable realization and by  $\kappa^+$  for the full realization, with truth strictly increasing the former.

None of this contradicts the fact that every ordinary set well-order is isomorphic to a unique ordinal. The problematic step would be to apply the set collapse theorem to a relation whose predecessor segments are proper. The theorem’s set-likeness hypothesis is doing real work.

## XVI.9.4 Source 32: conclusion

The ordinal class is a boundary for set-like orderings, not for definable well-order presentations. Finite tuples, finite supports, and finite hereditary trees already produce a rich arithmetic beyond it. Every class well-order has a canonical first division by  $\Omega$ , and no admitted uniform family can be cofinal among all admitted class well-orders.

The strongest distinctions arise when uniformity is made explicit. A general condensation history, once admitted, must terminate by the order's own length, but existence of that history is a separate recursion principle. At an inaccessible set-universe cutoff, all definable class well-orders have a sharply structured external ceiling of countable cofinality, yet a truth predicate assembles a presentation of exactly that previously unavailable ceiling. Full classes extend farther still, through every external type below  $\kappa^+$ .

Thus the rigorous answer to “how far beyond Ord?” is not one terminal ordinal. It is an arithmetic of presentations, a hierarchy of admissible constructions, and a model-relative spectrum whose boundary moves when the available definitions become uniform.

### **XVI.9.5 Source 33: conclusion and status of the contribution**

The order of all set ordinals is a boundary for set-like orders, not a boundary for class well-orders. Explicit sums, products, finite-support powers, and coherent fixed points pass beyond it in elementary class set theory. The price is not inconsistency but proper-class initial segments and careful tracking of what is uniformly coded.

The structural analysis is quite concrete. Set intervals divide every class well-order canonically into  $\Omega$ -blocks and a final set remainder. An exhausting condensation tower gives finite ordinal digits and an embedding into a polynomial class order. The important existential issue is whether the tower is supplied by an explicit formula or requires a recursion principle.

The definability analysis has a different conclusion: there is no final uniform catalogue. Every fixed complexity bound can be diagonally exceeded, even when arbitrary set parameters are allowed. At an inaccessible rank model this yields a countably cofinal, arithmetically closed external ceiling strictly above the internal Ord, and truth strictly raises that ceiling without changing any set ordinal.

These are proved structural answers and a research program. The article is not a claim to have settled the general published comparison problem, not a report of a completed Lean formalization, and not evidence of historical priority. The most valuable next checks are an independent mathematical review of the bounded-definability construction and a formal proof of the supplied-tower digit theorem with every size assertion made explicit.

## **XVI.10 Rigorous formalization routes**

### **XVI.10.1 Two-sorted class theory**

For the reverse-mathematical result, a two-sorted formalization is the most faithful route. Use a type of sets, a type of admitted classes, membership of sets in classes, and codes for ordered pairs. Class relations are classes of pair codes. The elementary comprehension and Class Replacement schemes must be explicit assumptions of the formalized object theory. A class well-order quantifies over the admitted class sort, exactly as in the mathematical definition.

In this setting, a supplied history is one class of stage–point pairs. Its slices are defined by comprehension; they are not members of a newly created class of all slices. The polynomial carrier consists of finite graphs of sets. The greedy proof uses only a least point in a supplied well-order and ordinary recursion on a set. The resulting theorem can therefore track the absence of Choice at the level of the object theory.

A proof assistant's unrestricted collection of predicates on the set type should not silently replace the admitted class sort. That would usually provide full external semantics and could make

comparability automatic. Such a proof may be correct for that strong interpretation while failing to establish a theorem over arbitrary Henkin models of GB.

### XVI.10.2 Universe levels and ordinary order types

A second route treats  $\Omega$  as all ordinals small relative to one universe. In Lean’s ordinary ordinal development, `Ordinal.{u}` lives in `Type (u+1)` and represents order types of `Type u` carriers. Its complete order can be assigned an order type at the larger universe level. A tagged endpoint, finite product, or finite-support function space then produces an ordinary order in that larger universe. Mathlib’s ordinal library explicitly distinguishes these levels and their lifts [30].

This route is well suited to validating algebraic laws and the hereditary tree construction. It also makes clear why  $\Omega + 1$  is harmless: it lies beyond the smaller universe’s ordinals, not beyond the ordinals at every level. Moving all objects back to the smaller universe would require a smallness theorem that fails at exactly the proper-class boundary.

For a theorem about the exact strength over GB, the universe route is a semantic test rather than a replacement for a formal object-theory proof. Its strong ambient supply of subsets and functions cannot be used as evidence that every weak class realization contains the required isomorphism or history.

### XVI.10.3 Full inaccessible-universe semantics

Assume an inaccessible  $\kappa$  in an external ZFC universe and interpret sets by  $V_\kappa$  and classes by all its external subsets. Every point and every finite code belongs to  $V_\kappa$ . Class relations become external sets, so ordinary ordinal arithmetic computes their lengths. This interpretation gives the exact  $\kappa^+$  spectrum and the substitution rule

$$\Omega \rightsquigarrow \kappa, \quad P(B) \rightsquigarrow \kappa^{\text{otp}(B)}, \quad E \rightsquigarrow \varepsilon_{\kappa+1}.$$

It provides a strong consistency check on indexing and orientation of products. It does not prove a universal theorem over weak class theories simply by being one model of them.

### XVI.10.4 Unrolling and higher sorts

There is a more structural way to pass beyond the original sets. The unrolling construction uses well-founded extensional class graphs with a distinguished top to represent virtual sets. A class well-order with an appended top then represents an ordinal of the unrolled structure. Williams develops the resulting interpretations and explains how their strength depends on the ground class theory [35, Chapter 2]. This is a natural framework if one wants actual ordinal-like objects for class-order types, rather than working presentation by presentation.

One must prove the required graph comparisons and the axioms of the unrolled structure; they are not consequences of having written down a quotient notation. Similarly, a third sort of hyperclasses can collect class presentations, but its comprehension and replacement principles must be stated. Adding a sort moves the collection problem upward. It does not supply an absolute class of all orders across every higher level.

### XVI.10.5 A concrete formalization plan for ProveIt

The proof dependencies suggest the following small modules. The names are proposed organization, not claims of existing checked files.

| Module                 | Main content                                                                    | Required boundary                              |
|------------------------|---------------------------------------------------------------------------------|------------------------------------------------|
| Class orders           | Tagged carriers, admitted-subclass minima, initial embeddings, anti-embedding   | GB                                             |
| Finite-support powers  | Finite list comparison, greedy minimum, split and flatten isomorphisms          | GB; no Choice instance                         |
| Canonical blocks       | Set-interval predicate, local ordinal ranks, least representatives              | GB                                             |
| Canonical histories    | Supplied histories, floors, finite changes, normal-form initiality, equivalence | GB; existence as a named principle             |
| Hereditary syntax      | Finite tree validation, structural comparison, specialization, fixed-point map  | GB via the set-subset criterion                |
| Definability and truth | Formula codes, validity compiler, uniform diagonal, external spectra            | Truth and model assumptions tracked separately |

The most valuable first target is the choice-free power theorem. Its invariant concerns an actual nonempty subclass and the prefix selected from it; an implementation must not quietly replace this by a finite sample. Next formalize the fixed-cap step in normal-form initiality: it is what upgrades an arbitrary embedding to an initial embedding. These two points carry the mathematical content of the base-theory refinement.

For the hereditary syntax, define comparison by recursion on the sizes of two finite trees before asserting that the resulting order is well-founded. Define the height-bounded stages syntactically. This avoids accidentally using  $\text{ETR}_\omega$  to construct a sequence of proper-class stages. The ordinary specialization proof then gives a useful independent semantic specification.

No natural-number program can literally contain an arbitrary ordinal coefficient. A computational implementation should therefore state its coefficient interface: natural numbers, a specified notation system for set ordinals, or an abstract well-order with a comparison oracle. Claims of decidability apply to the chosen interface, not to every set ordinal or every formula-defined class presentation.

[merge] No module of the plan above exists in the repository; no statement of this Part is formalized (section 1.5). The ProveIt files the sources name are `SetTheory/ZF/Lean/ZF/Zf.lean` (source 32's Section 11.6, printed below), whose declarations `Sep_form`, `Repl_form`, `ZFax` and `ZFprov` and import `FirstOrder.Calculus` exist as source 32 says. Source 32 also reports `Ordinal.univ` and `Ordinal.type_lt_ordinal` in `Mathlib/SetTheory/Ordinal/Univ.lean`, with `Ordinal.univ_id` deprecated in favour of the latter ("since 2026-03-20"). These remain attributed API/deprecation claims; this review has not rechecked their external history. Both repository manifests pin `v4.32.0`, revision `81a5d257c8e410db227a6665ed08f64fea08e997`.

## XVI.10.6 Source 35: five formalization routes and a proof-assistant design

**First-order set theory with definable classes.** In a ZFC development, write each class by a formula and regard theorems involving arbitrary definitions as schemes. Carrier membership, comparison, finite supports, finite trees, and the explicit witnesses constructed in this article can all be handled in this way. A theorem for each fixed complexity level is legitimate; substituting a single purported truth predicate for all levels is not. This route is economical when the intended output is a specific notation system with explicitly defined operations.

**GB and GBC.** A two-sorted first-order theory makes class quantification explicit. Elementary comprehension permits fixed class parameters but forbids class quantifiers in the defining formula.

Finite-support normal forms and finite-tree evaluation remain ordinary classes of sets. A family of classes is represented by one binary class relation with sections, not by treating its proper-class sections as members. Global Choice permits arbitrary carriers to be recoded uniformly and supplies the general descending-sequence argument; constructions using only ordinal codes often need less choice.

**GBC + ETR.** Elementary transfinite recursion supplies a class-coded solution when each stage may itself be a proper class and the recursion follows an arbitrary admitted class well-order. It justifies general recursively defined comparison and iteration constructions. Its equivalence with clopen class-game determinacy, and the related equivalences for  $\text{ETR}_{\text{Ord}}$ , explain why this is a substantive additional axiom rather than a routine use of set recursion [22, 24]. The finite hereditary constructions in this article were arranged to avoid assuming it. Producing one explicit very long class order does not supply arbitrary recursions along that order.

**KM and unrolling.** Impredicative comprehension allows classes defined with class quantifiers. Unrolling instead represents larger objects by class membership codes and compares those codes by class isomorphisms. The exact axiom statement matters: Williams proves that KM plus Class Collection is bi-interpretable with  $\text{ZFC}_I^-$ , which includes Separation and Collection and has a largest inaccessible cardinal. Here inaccessibility includes the required powersets below that cardinal. For  $\text{GBC} + \text{ETR}$ , the corresponding theory is the weaker  $\text{wZFC}_I^-(0) + \Sigma_0\text{-Transfinite Recursion}$ , not full  $\text{ZFC}^-$  with Collection [35, Definition 2.1, Theorem 2.2, Corollary 2.32]. An externally well-founded collapse additionally requires the relevant  $\beta$ -correctness. An internal interpretation alone does not turn every represented order into an externally genuine ordinal.

**Higher-order theories and universe hierarchies.** One may allow hyperclasses whose elements are classes, or work in a larger universe in which the previous universe is a set. Such a move makes a previous collection of class orders available as an object at the new level. The level must be recorded: its ordinal operations are ordinary operations in the larger setting, while its lower-level interpretation may be a proper class order. Repeating this construction never produces a same-level object containing every order at every level. It produces a hierarchy of formally distinct domains.

#### XVI.10.6.1 A proof-assistant design with explicit universes

A direct Lean development should begin with a model of sets and an explicit collection of admitted predicates and relations. Its class-well-order structure should record a carrier predicate, a strict linear order on that carrier, and minimality for every admitted nonempty subclass. Set-likeness must be a separate field or predicate. Requiring it in the definition of every class well-order would exclude the main examples by construction.

The initial implementation can consist of the following independent interfaces:

1. Classes and class functions over a fixed set model, together with elementary comprehension and Class Replacement.
2. General class well-orders, arbitrary order embeddings, and initial embeddings, with each distinction retained in theorem statements.
3. Finite-support polynomials and their greatest-disagreement order, followed by explicit sum and product isomorphisms.
4. Finite hereditary syntax, its canonical comparison, and the compatible finite-stage embeddings defining the fixed-point order.

5. A separate semantics in an ambient inaccessible-height model, including the spectrum and definability theorems above.

An alternative begins with universe-indexed types. The type of ordinals of one universe lives in a larger universe; its lexicographic square and finite hereditary notation types can be formed there. This is an effective way to verify explicit order algebra. It does not by itself formalize the distinction between an arbitrary subset and an admitted class of a particular GB model. That distinction requires the model interface just described.

There are likewise two different uses of well-founded recursion. A proof assistant's recursion on a genuinely well-founded type can evaluate finite syntax directly. Applying the same mechanism to a model's *internally* well-founded class relation would silently add external correctness unless its hypotheses are translated and proved. Keeping the syntax layer, internal class semantics, and external realization separate exposes this obligation. The discussion here is a formalization design; it is not a claim that a Lean implementation has been compiled or kernel-checked.

### XVI.10.7 Source 32: five rigorous formalization routes

The right formalization depends on whether the goal is to check the arithmetic, to establish its minimal axioms, or to compare models with different admitted classes. No one encoding makes these three tasks identical.

#### XVI.10.7.1 ZFC with definable-class schemas

In a purely first-order treatment, replace each class symbol by a formula with a fixed finite tuple of parameters. A theorem about a fixed finite number of classes becomes a schema of first-order theorems. The constructions of sums, products, finite-support powers, and hereditary terms are syntactic transformations of formulas. Their proofs can be represented in an ordinary first-order proof system.

This route is especially faithful to the phrase “definable class well-order”. It also exposes the limit of the approach: a variable ranging over formula codes does not come equipped with an internal semantic evaluator. One may manipulate codes syntactically, prove substitution lemmas, and handle each fixed finite collection of formulas; one may not introduce a full satisfaction predicate for the ambient universe without an additional assumption.

A global well-order needs attention. ZFC alone does not assert a parameter-definable global well-order of its universe. One should either work over a structure with an explicitly supplied global predicate, assume a definable global-order hypothesis, or weaken the claims so that they do not require Global Choice. The GBC results above should not be translated into parameter-free ZFC assertions by simply erasing the class parameters.

#### XVI.10.7.2 A two-sorted admitted-class model

For questions about GBC itself, use a structure with a set sort  $M$ , a class sort  $\mathcal{X}$ , an internal set-membership relation, and an interpretation relation  $x \in C$  for  $x \in M$ ,  $C \in \mathcal{X}$ . Tuples and graphs are internally encoded in  $M$ . An embedding is required to have a graph in  $\mathcal{X}$ .

The well-order predicate must quantify over admitted subclasses:

$$\text{WO}_{\mathcal{X}}(D, R) \implies \forall S \in \mathcal{X} (\emptyset \neq S \subseteq D \implies S \text{ has an } R\text{-least point}).$$

Alternatively, after formalizing lemma XVI.2.8, use the elementary internal condition forbidding descending functions whose codes are *sets of the model*. These are not automatically all external functions from an external  $\omega$ .

This matters in Lean. A bare declaration  $R : M \rightarrow M \rightarrow \text{Prop}$  followed by ambient `WellFounded`  $R$  usually means well-foundedness for the proof assistant’s full external predicate and sequence universe. It is stronger than the internal condition of an arbitrary Henkin class model. Similarly, setting the class sort equal to all predicates  $M \rightarrow \text{Prop}$  chooses full external classes, not a general GBC realization. To study  $\mathcal{X}_A$ , encode the admissible predicates and admissible graphs explicitly, together with closure under elementary definitions.

For the inaccessible-rank models of [lemma XVI.8.7](#), a separate absoluteness theorem then relates internal well-ordering to external well-foundedness. That theorem is a bridge to be proved, not a convention to apply to all models.

### XVI.10.7.3 GBC with explicit recursion packages, or stronger class theory

An ETR interface should take a stage presentation, an elementary formula code, and admitted parameters, and return an admitted history satisfying ([S32.18](#)). The condensation development can then be split cleanly in two: the termination invariant is proved from a supplied history; a separate theorem invokes the ETR interface to obtain that history. A stronger theory such as Morse–Kelley class theory can also supply the requisite recursion, but that should not obscure the weaker conditional theorem [[35](#)].

This separation gives an auditable dependency boundary. The explicit polynomial hierarchy needs no recursion package at all: formula ([S32.9](#)) supplies its code directly. Its verification consists of successor and limit identities. By contrast, an arbitrary  $W$  enters the existence theorem only after the ETR assumption has been made.

### XVI.10.7.4 Higher universes and ordinary ordinal libraries

A practical route to checking the arithmetic is to view the ordinals of one Lean universe as a type in a larger universe. Mathlib’s current ordinal-universe interface provides `Ordinal.univ` and `Ordinal.type_lt_ordinal`; the latter identifies the order type of the smaller-universe ordinals with the corresponding larger-universe universal ordinal. The old name `Ordinal.univ_id` is marked deprecated in the documentation inspected on 4 October 2026 [[92](#)].

This makes the presentation  $\Omega$  into an ordinary ordinal in a higher universe, after which the usual ordinal library can verify powers and initial embeddings. It is an excellent arithmetic test bed. It does not identify the predicates admitted by an arbitrary  $(M, \mathcal{X})$ , and it does not establish that a construction was provable in bare GBC. A universe-level smallness notion is also not automatically the model’s internal “is a set” predicate. The inaccessible-universe interpretation should never be read as a proof in ordinary ZFC that a strongly inaccessible set cardinal exists.

A useful implementation architecture therefore has an abstract presentation layer and a separate realization functor into higher-universe ordinals. The functor certifies arithmetic identities once their maps are defined, while the abstract layer tracks which graphs and histories are admitted by the chosen class theory.

### XVI.10.7.5 Unrolling into virtual sets

Another approach represents virtual sets by well-founded extensional class membership codes. A class well-order, with an added top point, can serve as a code for an ordinal in an unrolled structure. This is a change of interpretation, not a collapse to an actual ordinal in the original set universe. Williams develops the unrolling approach and the dependence of its properties on the underlying second-order theory [[35](#)].

For the present project, the attraction is that arithmetic on long orders can be compared with ordinary arithmetic on the corresponding virtual ordinals. The danger is assuming all the axioms of the target theory before proving them. In particular, existence of suitable code comparisons and set-forming operations needs its own theorem. An unrolled ordinal representing  $\Omega + \Omega$  is not a counterexample to the original model's assertion that its von Neumann ordinals form the class `Ord`.

### XVI.10.7.6 Connection to the inspected ProveIt foundation

The inspected file

`SetTheory/ZF/Lean/ZF/Zf.lean`

works with first-order formulas and explicitly coded ZF axioms. Among the declarations inspected are `Sep_form`, `Repl_form`, `ZFax`, and `ZFprov`; the file imports `FirstOrder.Calculus`. Its documented internal-recursion development concerns finite recursion and closure for definable set-like relations [81]. These are relevant foundations, but they do not already constitute a formalization of non-set-like class recursion.

A compatible extension would first add syntax for finitely many class predicate parameters and prove substitution and satisfaction bridges. A second layer would package admitted classes and their elementary-comprehension closure. The arithmetic could then be developed with no ETR import. Condensation existence would live in a module whose assumptions explicitly include the recursion package, while termination from a supplied hierarchy would remain in the weak layer.

Within a proposed `ClassOrders` namespace, useful modules would be `Basic`, `FiniteSupport`, `Arithmetic`, `Condensation`, and `DefinabilitySpectrum`. These names describe a proposed organization, not files created in the repository. The first machine-checked milestones should be least-representative quotients, no self-compression, and the finite-support comparison laws. The model-relative ceiling theorem should follow only after the syntax/semantics boundary has been formalized.

**Status.** No Lean or Rocq proof was produced or checked for this article. No repository build or modification was performed. The formalization discussion is a source-informed implementation plan, not a verification claim.

## XVI.10.8 Source 33: formalization approaches and their tradeoffs

### XVI.10.8.1 ZFC with definable-class schemas

One can express each explicit construction as a theorem schema in ordinary ZFC. Fix formulas defining the domain, order, and any needed global ordering, substitute those formulas into the construction, and prove the resulting first-order assertion. This is particularly well suited to finite-support exponentiation and the bounded-complexity diagonal.

The limitation is quantification. A schema over formulas is not a single internal quantifier over all definable classes. The diagonal proof makes this limitation visible rather than hiding it: the evaluator exists at each fixed level, but a uniform evaluator for every level is not thereby supplied. For formalization, formula substitution and the distinction between a metatheoretic natural number and an object-theoretic variable must be explicit.

The use of a named  $G$  can be handled either by assuming its defining formula has the required global-order properties or by working in a language with an additional class predicate and the corresponding separation/replacement instances. Pure ZFC without a definable global order does not automatically satisfy the parameter-free formulation of [corollary XVI.7.23](#).

### XVI.10.8.2 Two-sorted GB, GBC, and NBG

A two-sorted theory is the most faithful framework for the core article. The set sort contains every point, finite code, and ordinal coordinate. The class sort contains domains, relations, embeddings, and uniform towers. Elementary comprehension creates the needed classes, and replacement recognizes when their set-indexed images are sets.

Terminology varies: some formulations of NBG include global choice as part of the default theory and some distinguish it. Here GBC always includes a set-like global choice order. No argument should be transferred to a choiceless or Power-Set-free version merely by changing the theory's name.

The central size invariant is a predicate saying that a specified subclass has a set with exactly its members. For example,

$$\text{SmallInterval}(x, y) \iff \exists z \forall t [t \in z \leftrightarrow t \in [x, y]_W].$$

It must not be replaced by external cardinality or by the fact that an implementation stores a finite approximation. Quotient elements should be least representatives. These design choices let the core statements remain inside the original two sorts.

### XVI.10.8.3 Elementary transfinite recursion and comparison

A general recursion of the form

$$S_\gamma = \{x : \varphi(x, S \upharpoonright \gamma, A)\}, \quad \gamma \in \Gamma,$$

with  $\varphi$  first-order and  $A$  a class parameter, is what  $\text{ETR}_\Gamma$  supplies. The stages  $S_\gamma$  are classes, so ordinary set recursion does not suffice. Even recursion of length  $\omega$  with class-valued stages can encode a full satisfaction predicate [22].

The known implication

$$\text{GBC} + \text{ETR} \implies \text{initial comparability of class well-orders}$$

is established in Hamkins–Woodin [27, Theorem 6]. This supplies a conventional ordinal-style comparison theory when it is needed. The finite-support operations, canonical division, supplied-tower digit map, and diagonal theorems do not use that implication.

One should also distinguish  $\text{ETR}_\Omega$  from full ETR over every class well-order. The exact strength of the class forcing theorem identifies it with the former, among several equivalent principles [24]. A notation such as  $\text{ETR}_{\Omega[\Omega]}$  therefore carries real information about the permitted recursion lengths.

### XVI.10.8.4 KM, stronger recursion, and unrolling

Kelley–Morse theory allows impredicative class comprehension, where the defining formulas may quantify over classes. The corresponding second-order transfinite recursion principle is equivalent to KM over GBC [26]. This is a stronger setting than the elementary recursions used in the conditional condensation results.

Stronger class comprehension still does not make proper classes ordinary members of classes. To treat class well-orders as ordinal-like objects in a larger first-order universe, one may instead *unroll*: use well-founded extensional class membership codes and identify codes by isomorphism. Williams describes, in particular, the unrolling of KM plus Class Collection to a model of  $\text{ZFC}^-$  with a largest cardinal, and analyzes weaker theories as well [35]. Antos–Friedman use a related coding framework for beta-models of an explicitly strengthened Morse–Kelley theory [28].

These are interpretive constructions with hypotheses, not permission to write “the class of all class ordinals” inside ordinary GBC. Collection, well-foundedness correctness, and the exact set theory obtained by unrolling must be tracked separately. This manuscript uses unrolling as a formalization option, not as an unproved shortcut in its elementary proofs.

### XVI.10.8.5 Inaccessible universes and full semantics

The  $V_\kappa$  model of [section XVI.8.8](#) translates the class orders into ordinary external ordinals. It is particularly effective for testing arithmetic formulas and explaining the spectrum endpoint  $\kappa^+$ . It also supports all full subclasses, so it is stronger than a minimal definable-class realization.

A full powerset of classes is not harmless over an arbitrary set model. For example, if a transitive model is externally countable, its full class part includes an external countable cofinal enumeration of its ordinals. Treating that enumeration as a class function on its  $\omega$  contradicts class replacement. The regular inaccessible cutoff avoids exactly this failure. This is why the hypothesis is proved relevant, rather than being used only as an informal picture of a “large enough universe.”

### XVI.10.8.6 Lean universes: relative largeness rather than an absolute class

Mathlib’s ordinal type is universe indexed. In its documented interface, `Ordinal.{u}` lives in `Type (u+1)`, and `Ordinal.type` assigns an ordinal to a well-order on a type of the chosen universe [30]. Thus the order on all `Ordinal.{u}` can itself receive an order type one universe higher. Abstractly, define

$$\Omega_u = \text{type}(\text{Ordinal}^{\{u\}}, <) \in \text{Ordinal}^{\{u+1\}}.$$

Its successor, square, and higher powers then use ordinary ordinal arithmetic at that higher level.

This approach is excellent for concrete relative-universe models. It does not identify the smaller-universe ordinals with a set ordinal in the same smaller universe. Nor does Lean provide a single type of ordinals over *all* universes. Universe lifting is part of the result, not a technicality to suppress.

There are two distinct formalization projects:

- (a) **Ambient type-theoretic mathematics.** Use ordinary well-orders on large types, smallness predicates for predecessor types, and larger-universe ordinals. This is the shorter route to arithmetic and representation theorems.
- (b) **A theorem about class set theory.** Define a two-sorted model interface, an explicit available-class sort, elementary comprehension, class replacement, and a named global order. Prove each implication using only that interface. This is the route that can certify a stated GBC versus ETR axiom bound.

A structure that simply interprets “class” as *every* predicate  $U \rightarrow \text{Prop}$  gives full external semantics. It must not be used to claim an elementary GBC proof when the argument secretly quantifies over predicates unavailable in a weaker realization. The explicit available-class sort prevents this mistake.

The current article provides interfaces and proof obligations, not a Lean implementation. No displayed mathematical interface is advertised as compiler-tested code.

### XVI.10.8.7 Transport to surreal carriers

Under global choice, every proper class of sets can be enumerated in a set-like order of type  $\Omega$  by restricting a global order. Hence proper class carriers of the orders studied here can be put in class

bijection with the surreal numbers **No**, and their order relations transported to that carrier. This connects the article with the repository’s surreal well-order projects.

The transported order is not the natural ordered-field relation on **No**. That relation is not a well-order; for example, the negative integers descend indefinitely. Nor is the symbol  $\Omega$  a surreal number larger than every set ordinal. Each surreal is represented by a set-length sign sequence, and an ordinal longer than its birthday bounds it above. There is no surreal with proper-class birthday in the ordinary construction.

Finally, ordinal arithmetic is not surreal field arithmetic. Already  $1 + \omega = \omega$  in ordinal addition, whereas adding the surreal number 1 to the surreal  $\omega$  gives a strictly larger number. Reusing symbols must not erase which operations or which ordering are being studied.

## XVI.10.9 Source 33: a formalization and verification plan for ProveIt

### XVI.10.9.1 Suggested module boundary

A proposed new development could live under `SetTheory/ClassWellOrders/`; this is a suggested location, not a claim that the directory already exists. Its mathematical dependency graph should separate the following components.

| Component     | Main specification                                                                                         | Trust boundary                                            |
|---------------|------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------|
| Presentations | Domains, class relations, embeddings, initial images; least-subclass and descending-sequence formulations. | Explicit class-model interface.                           |
| FiniteSupport | Finite maps with a greatest-difference comparison; split, group, and flatten maps.                         | Finite combinatorics plus ordinary set well-orders.       |
| Arithmetic    | Sums, products, powers, and uniform lexicographic sums.                                                    | Elementary comprehension and replacement.                 |
| SetIntervals  | Convexity, least representatives, set-like blocks, and canonical $\Omega$ -division.                       | Internal sethood, not external size.                      |
| Condensation  | Supplied towers, polynomial truncations, ordinal digits, termination and order preservation.               | Separate supplied-tower theorem from existence under ETR. |
| Definability  | Formula codes, each partial satisfaction predicate, the well-orderhood test, and the diagonal compiler.    | Schema-level indexing must remain explicit.               |
| RankModels    | Correctness of $V_\kappa$ , full spectrum, definability height, and truth jump.                            | External inaccessible hypothesis.                         |

The successor obstruction should be proved early and imported by every diagonal argument. It is short, robust, and avoids the temptation to assume initial comparability as an unrecorded global fact.

### XVI.10.9.2 The most important proof obligations

For the structural side, the critical obligations are that interval sethood is internal, quotient representatives are sets, the ordinal coordinate in (S33.5.4) exists, and the digit-extraction process terminates by well-foundedness of the stage order. For the definability side, they are that bounded

satisfaction is genuinely available, the well-orderhood test has only set quantifiers, and the family of all parameter tuples is jointly definable before the diagonal sum is formed.

A formalization of [theorem XVI.7.20](#) should not package all the evaluators into a predicate assumed to satisfy unrestricted truth. A syntactic compiler that takes a *metatheoretic* numeral  $n$  to the formula defining  $D_n$  is appropriate. A purported internal evaluator for every resulting formula would need a separate existence theorem and would contradict cofinality if it were definable in the unchanged language.

### XVI.10.9.3 Executable checks included with this article

The archive includes a small Python verification program for finite positional models. It checks greatest-difference comparison, splitting an exponent sum, flattening nested powers, and the partition into fibers of truncation. These tests can catch a reversed product convention or an incorrect significance order in the finite coding layer.

They do *not* verify that a proper-class order is well-founded, that a class relation is a set, that partial truth exists, or that a class recursion is licensed. In a genuinely finite order every interval is a set, so replacing set-interval condensation by naive finite testing would collapse everything at the first step. The tests intentionally avoid that false analogy.

A useful next implementation would prove the finite checker correct, then prove that the class construction uses the verified combinatorial maps. Until that bridge and the foundational arguments are formalized, the Python output remains a consistency check on conventions, not a mathematical certificate for the class-theoretic theorems.

[merge] The program described above is shipped as `code/33-heights-finite_checks.py`, its recorded run as `data/33-heights-verification_results.json` ([appendix A.13](#)).

## XVI.11 Ledgers, checks, and source audits of sources 32–35

[merge] The four sources' proof ledgers, verification records and source audits, as delivered (source 34's Appendix A; source 35's Appendix A; source 32's Appendices A–C; source 33's Appendices A–C). Their file names are the delivery names; the shipped names are in [appendix A.13](#) and the README. The finite checks were rerun for this write on copies, with the recorded results ([appendix A.13](#)).

### XVI.11.1 Source 34: proof and provenance ledger

The proofs in this report were independently checked during preparation for the following specific risks: an illicit proper-class element, an unacknowledged use of choice, a class-valued recursion disguised as finite recursion, a noninitial embedding used as an initial one, and an external well-order assertion without the required model hypothesis. These checks are mathematical review within this preparation process, not external peer review or a kernel check.

The exact repository dependency is Source 29 of [77], especially the source labels `swo:bw:ch:floors`, `swo:bw:ch:finite-changes`, `swo:bw:ch:normal-form-theorem`, `swo:bw:ch:convex-restriction`, and `swo:bw:ch:equivalence`. The repository's polynomial lemma invokes Global Choice; [Theorem XVI.4.2](#) replaces that invocation. The remaining arguments are re-established here with their weaker dependencies. The endpoint-transport corollary for a universal carrier is not included in the choice-free strengthening.

The hereditary finite-tree pattern is standard in ordinal notation. Its appearance in the BIRS problem collection concerns a set-sized  $\Omega$ , commonly  $\omega_1$  [85]. The present development supplies

proper-class semantics, finite-code well-foundedness, and the corresponding fixed-point interpretation. It does not claim to have invented hereditary Cantor normal form.

The uniform-sum and parameter-spectrum arguments are proved in full and presented as a synthesis. No bibliographic search can certify their historical novelty, and no such certification is asserted. The explicit resolution claimed here is limited to the base-theory question in the inspected ProveIt report.

The accompanying source is a single self-contained LaTeX file with an internal bibliography. Rebuild it with two runs of `pdflatex -interaction=nonstopmode -halt-on-error beyond_ord.tex`, or with `latexmk -pdf beyond_ord.tex`. The PDF was compiled and inspected for layout. No Lean or Rocq proof is included, and the mathematical result is not represented as a formalization.

[merge] The five labels source 34 names are this report’s [lemmas 108.12](#) and [108.17](#), [proposition 108.13](#), and [theorems 108.16](#) and [108.19](#); the “polynomial lemma” is [note 108.15](#), and the endpoint-transport corollary [corollary 108.20](#). Source 34’s single file and PDF are not shipped; Part XVI is its text.

### XVI.11.2 Source 35: proof status and reproducibility

The article supplies mathematical proofs, independently checked during its preparation. It is not a refereed publication and does not contain a Lean-verified proof. The following ledger records what the principal claims actually require.

| Claim                                 | Base or setting                     | Principal verification obligation                                                                                           |
|---------------------------------------|-------------------------------------|-----------------------------------------------------------------------------------------------------------------------------|
| Finite-support powers are well-orders | GB                                  | The minimization uses uniquely determined finite prefixes, with no selection of a class sequence.                           |
| Arithmetic identities                 | GB                                  | Explicit support splitting, flattening, and inverse maps.                                                                   |
| Canonical history criterion           | GB                                  | Floors at limits, finite changes, and capped reconstruction of every smaller polynomial.                                    |
| CWO $\leftrightarrow$ CTH             | GB                                  | Common-schedule convex restriction and the successor obstruction. Neither principle is assumed to be a theorem of the base. |
| Hereditary fixed point                | GBC                                 | Bounded coefficient specialization rules out descending sequences; root formation is an isomorphism.                        |
| Local fixed-point completion          | GBC                                 | Uniform finite traces, least-stage representatives, preservation of initial embeddings, and finite-support continuity.      |
| Uniform-family strict bound           | GB plus a supplied index well-order | A successor copy of each input is a block of the sum.                                                                       |
| Fixed-complexity separation           | Fixed- $n$ scheme                   | Partial truth at one fixed complexity and a definable well-order test on ordinal carriers.                                  |
| Full and definable spectra            | Ambient ZFC, inaccessible $\kappa$  | External cardinality and regularity; the full class part is specified.                                                      |

The accompanying program `artifacts/finite_notation_checks.py` performs exhaustive finite checks of the split and flatten maps for bases 2,3 and small finite exponent sets. It also compares a collection of hereditary terms against exact numerical interpretations at bases 5,7,11,

each larger than every coefficient used. It writes its counts and ordered examples to `artifacts/finite_notation_results.json`. These checks detect coding-convention errors such as reversing the product order or flattening the two exponent coordinates in the wrong direction. They do not establish infinite or class well-foundedness; that conclusion comes from the proofs in the article.

The archive contains a self-contained LaTeX source, the compiled PDF, the illustrative program and its recorded output, and a README with build instructions. The LaTeX source uses standard mathematical packages and an inline bibliography, so it requires no bibliography database, external images, or network connection. Run `pdflatex` until the cross-references and contents stabilize (normally three runs from a clean directory); `latexmk -pdf` automates these passes.

Repository statements were tied to the explicit commit in the bibliography. The external literature was consulted on 4–5 October 2026. An unverified priority claim, a numerical experiment, and a theorem proved from stated assumptions are different kinds of evidence; the article keeps them separate. Future work should begin by formalizing the new choice-free proof and the fixed-point completion theorem, then compare the exact results with a broader literature search.

[merge] Source 35’s “fixed-point construction and local criterion” are now proved over GB as well (theorem XVI.6.21). Its program is shipped as `code/35-completion-finite_notation_checks.py`, and its recorded output as `data/35-completion-finite_notation_results.json`. The program always writes `finite_notation_results.json` beside itself, here in `code/`: rerun it on a copy (appendix A.13).

### XVI.11.3 Source 32: dependency and claim audit

| Result                                                     | Sufficient setting                     | Scope of the claim                                                                                 |
|------------------------------------------------------------|----------------------------------------|----------------------------------------------------------------------------------------------------|
| Set-like boundary,<br><a href="#">note XVI.2.9</a>         | GBC                                    | Canonical local-rank proof; standard foundational result.                                          |
| Finite-support powers,<br><a href="#">note XVI.4.10</a>    | GBC                                    | Explicit presentation;<br>countable-obstruction localization to set orders.                        |
| Hereditary fixed point,<br><a href="#">note XVI.6.24</a>   | GBC                                    | Finite syntax, not general class recursion; no novelty priority asserted.                          |
| $\Omega$ -division, <a href="#">theorem XVI.3.6</a>        | GBC                                    | Sharp formulation from canonical set-interval blocks; block antecedent credited to the repository. |
| General termination,<br><a href="#">note XVI.5.20</a>      | GBC plus a supplied hierarchy          | Termination invariant is unconditional on further recursion axioms once the history exists.        |
| Hierarchy existence                                        | GBC + $\text{ETR}_{W+1}$               | Sufficient, not proved necessary.                                                                  |
| Exact polynomial heights,<br><a href="#">note XVI.5.21</a> | GBC                                    | Direct formula; prior repository mechanism re-established.                                         |
| Uniform diagonal,<br><a href="#">note XVI.7.14</a>         | GBC                                    | Defeats arbitrary embeddings from the diagonal into any fiber; no comparability assumption.        |
| Full spectrum, <a href="#">note XVI.8.8</a>                | External ZFC,<br>inaccessible $\kappa$ | Full class realization; ordinary external order types.                                             |

| Result                                                        | Sufficient setting                        | Scope of the claim                                                                       |
|---------------------------------------------------------------|-------------------------------------------|------------------------------------------------------------------------------------------|
| Definability ceiling,<br><a href="#">theorem XVI.8.9</a>      | Same external setting;<br>fixed $G, A$    | All set parameters allowed;<br>internal/external correctness supplied<br>by $V_\kappa$ . |
| Exact truth presentation,<br><a href="#">theorem XVI.8.12</a> | Same setting, enlarged<br>predicate $T_A$ | Represents $\delta_A$ itself; does not<br>compute $\delta_{T_A}$ .                       |
| General initial comparison                                    | GBC + ETR                                 | Literature result, not a new theorem<br>of this article.                                 |

The most important proof checks concern size rather than algebraic manipulation. A quotient uses least representatives instead of class-valued elements. A uniformly coded family is one relation on set tuples. A limit condensation stage is one admitted section of one admitted history. A finite list of formulas is evaluated by finitely many substitutions, whereas evaluation at a variable formula code requires truth. Finally, external ordinal spectra are formed only after moving to a set-sized external model.

No proof above deduces a new large-cardinal inconsistency, a same-level set of all ordinals, full ETR from mere presentation closure, or a resolution of general class-order comparability over bare GBC. These would be different claims requiring different arguments.

#### XVI.11.4 Source 32: computational checks and reproducibility

The accompanying Python script checks finite digit comparisons, support splitting, grouping of nested exponents, initial support embeddings, and hereditary base representations of ordinary natural numbers. It also checks the algebra of tail-deletion equivalence relations on bounded digit arrays. The run completed 689,808 exact assertions without failure; the category counts are recorded in `finite_checks.json`.

These computations are regression tests for the concrete coding conventions. They do not prove the infinitary results. In particular, every interval in a finite order is a set, so an actual finite test of the distinction between a set interval and a proper-class interval would be vacuous. The tail-deletion tests therefore verify only the stated finite mask formulas; they do not claim to simulate class condensation. Likewise, no finite program here verifies GBC, ETR, an inaccessible cardinal, or an external truth predicate.

The source is self-contained LaTeX with an internal bibliography. Build it with a standard TeX distribution, for example by running `pdflatex beyond_ord.tex` repeatedly until references stabilize. No nonstandard font files or external bibliography database are required. The separate verification-status file records the compilation and rendering checks performed for the delivered PDF.

[merge] The “accompanying Python script” is `code/32-ceilings-finite_checks.py`, `finite_checks.json` is `data/32-ceilings-finite_checks.json`, and the “separate verification-status file” is `32-ceilings-PROOF_STATUS.md`. The source and its PDF are not shipped.

#### XVI.11.5 Source 32: source inspection record

The repository was read on 4 October 2026. Because it was active during inspection, a root-tree read and later file reads need not represent one atomic snapshot. The inspected root tree reported commit

8f7d4a5c8cb87e66534d88ec6698f6f46d32a152.

The relevant research-status file reported blob

5333d792f02b0d578b7a9907a30d06b5f154e14a,

and the inspected first-order Lean foundation reported blob

b33db57cfb71e00c50fa3c57ea355ee4a9a4d523.

The status file was read in full; the Lean inspection covered its header and initial 150 lines, including the displayed first-order axiom declarations. The merged report’s README was inspected for scope and attribution. No claim is made to have audited all of the merged mathematical proofs or all of the repository’s formal code.

The literature search focused on primary sources concerning class well-orders, elementary transfinite recursion, class realizations, and unrolling. It supports the attributions made in the article but is not an exhaustive priority search for every theorem proved here. The exposed exact interfaces in the Mathlib documentation were checked separately rather than inferred from an older memory of their names.

[merge] The “root tree” 8f7d4a5c8 is a commit (2026-10-04 16:32 PDT, tree 08039c482), at which this article is blob 72eee5cc8, the text with Parts I–XV; the two blobs it records are the files it names, both unchanged at the time of this write.

### XVI.11.6 Source 33: axiom and proof-status ledger

| Statement                                         | Sufficient assumptions                       | Status here                                                                                          |
|---------------------------------------------------|----------------------------------------------|------------------------------------------------------------------------------------------------------|
| Descending-sequence test; set-like classification | GBC                                          | Standard background, with proofs and conventions.                                                    |
| Successor obstruction; uniform-family diagonal    | GBC                                          | Complete written proofs; no comparison axiom.                                                        |
| Finite-support power and arithmetic laws          | GBC                                          | Complete written proofs; finite convention checks supplied.                                          |
| Canonical $\Omega$ -division                      | GBC                                          | Complete written proof with least-representative quotient.                                           |
| Polynomial condensation                           | GBC                                          | Explicit uniform formula and proof; related long-condensation work already exists in the repository. |
| Finite-digit embedding                            | GBC plus a supplied uniform exhausting tower | Complete written proof; tower existence is not assumed free.                                         |
| Converse from a polynomial embedding              | GBC + $\text{ETR}_{\Gamma+}$                 | Conditional written theorem.                                                                         |
| Exhaustion of arbitrary $W$ along $W + 1$         | GBC + $\text{ETR}_{W+1}$                     | Sufficient bound proved; optimality not established.                                                 |
| Explicit finite-power fixed point                 | GBC                                          | Finite-tree coding and direct limit proof; not arbitrary class recursion.                            |

| Statement                                    | Sufficient assumptions                     | Status here                                                         |
|----------------------------------------------|--------------------------------------------|---------------------------------------------------------------------|
| Bounded-definability diagonal and cofinality | GBC, fixed named $G$ ; standard finite $n$ | Schema of complete written proofs; no uniform full truth predicate. |
| Exact full-class spectrum                    | External ZFC and inaccessible $\kappa$     | Complete proof for $(V_\kappa, \mathcal{P}(V_\kappa))$ only.        |
| Definability height and arithmetic closure   | Same cutoff, fixed $G$                     | External supremum theorem; not an internal cofinal sequence in Ord. |
| Strict truth-height jump                     | Same cutoff, truth $T$ available           | Complete written proof; language changes explicitly.                |
| General class initial comparison from ETR    | GBC + ETR                                  | Established literature, cited rather than claimed new.              |
| Unrolling and stronger recursion             | Theory-dependent extra principles          | Literature interface only; no new equivalence claimed.              |

None of the class-theoretic proofs in this manuscript has been checked by Lean, Rocq, or another proof assistant as part of this delivery. The finite Python checks establish only the enumerated finite identities. No axiom ledger entry should be upgraded on the basis of those tests.

### XVI.11.7 Source 33: notation and error-prevention guide

| Notation                    | Meaning                                                                                        |
|-----------------------------|------------------------------------------------------------------------------------------------|
| $\Omega$                    | The class order $(\text{Ord}, \in)$ , not a set ordinal.                                       |
| $A \cong B$                 | An available class order isomorphism, or its explicit external interpretation where specified. |
| $A \hookrightarrow B$       | An available order embedding; its image need not be initial.                                   |
| $A \preceq_{\text{init}} B$ | An order embedding whose image is an initial segment.                                          |
| $A \cdot B$                 | $B$ -many ordered copies of $A$ , with $B$ the significant coordinate.                         |
| $A^{[B]}$                   | Finite-support ordinal exponentiation; not all functions $B \rightarrow A$ .                   |
| $P(\Gamma)$                 | The class of finite Ord-coefficient polynomials on exponent order $\Gamma$ .                   |
| $\Gamma^+$                  | The order $\Gamma + 1$ with a new top stage; not a successor cardinal.                         |
| $\kappa^+$                  | The external successor cardinal of the inaccessible $\kappa$ in the spectrum analysis.         |
| $F_b$                       | A section of one uniform condensation-tower relation.                                          |
| $D_n$                       | A separately defined diagonal presentation for each fixed standard finite syntax level $n$ .   |
| $\delta_G$                  | The external supremum of types definable with $G$ and set parameters over $V_\kappa$ .         |
| $T$                         | Truth for the language with $G$ , not truth for its own expanded language.                     |

The most common invalid shortcuts are collecting proper classes as members, using a full truth evaluator in a bounded-truth argument, confusing a schema with one uniform class, treating internal

well-foundedness as automatically external, and using an arbitrary class recursion without recording ETR. The constructions above were organized to avoid these shortcuts.

[merge] In this report source 33's  $\Omega$  is printed  $\Omega$ , its  $A^B$  is  $A^{[B]}$ , its  $P_\Gamma$  is  $P(\Gamma)$ , and its direct limit  $E$  is  $\mathbb{T}$  (section 1.3.4).

### XVI.11.8 Source 33: repository and source audit

The repository paths reviewed were the main README, the surreal report catalogue, and the surreal-well-orders guide, accessed on 4 October 2026. The catalogue blob returned by the connector was `b7b69377ff172577b642b4fb78bfb2b09989dcd0`; the well-orders guide blob was `d2e24b58617bbbe56aadbdeb11c2018da51ae79`. These are file-content identifiers, not claimed commit identifiers. The guide's declared scope and status were used for continuity and to avoid misrepresenting existing work as new. The full 860-page report was not reviewed line by line.

Primary external sources were consulted in their arXiv abstract or HTML versions, the author's exposition for stronger recursion, and the official mathlib documentation. Bibliographic years identify the cited version or publication; they do not assert that an older open-question statement is still unresolved as of the delivery date. A targeted search found the Hamkins–Woodin comparison question but did not establish a later definitive resolution.

The source audit and proof-status file supplied in the archive give a machine-readable-path companion to this appendix. The article has no external figure or font-file dependency; its bibliography is included in the LaTeX source.

[merge] The two blobs are the current `Algebra/SurrealNumbers/docs/README.md` (introduced in `c14a866bc`) and this report's README (as of `e50dde15b`); source 33 gives no commit, so its reading lies between `c14a866bc` and the arrival `e3839ad2c`, and in that range this article is the text with Parts I–XV. “The source audit and proof-status file” are `33-heights-SOURCE_AUDIT.md` and `33-heights-PROOF_STATUS.md`; the PDF and `MANIFEST.sha256` are not shipped.

## XVI.12 What this Part answers

[merge] Dated notes, 4 October 2026, in the form of section 112; where an earlier status section or question index says otherwise, these notes supersede it, and the places concerned carry dated notes of their own.

- (a) *The strength of complete condensation histories over GB without global choice* (note 108.4; item (b) of section 112; source 20's research question 113.111; the GBC theorem is source 29's theorem 108.19): **answered**, twice independently. Over GB with ZF sets and no form of choice, CWO, CTH, terminating histories on some schedule, and initial embeddings  $W \preceq_{\text{init}} P(W)$  are equivalent (theorem XVI.5.8 and note XVI.5.19), and so is the fixed-point extension principle FPE (corollary XVI.6.19 and theorem XVI.6.21). Not answered: whether GB proves CWO (no source claims it), and whether CWO implies ETR (Hamkins and Woodin's Question 7; source 29's research question 113.219).
- (b) *The strength of tower or hierarchy existence* (source 32's research question 113.258, source 33's research question 113.259, and the ledgers' “optimality not established” in sections XVI.11.3 and XVI.11.6): **answered** by item (a) and, over GBC, already by source 29, because towers and hierarchies of equivalence relations are nested histories (remark XVI.5.24); only CWO  $\Rightarrow$  ETR remains. Source 32's claim to answer the termination question repeats source 20 (remark XVI.1.1).

- (c) *Source 33's remark XVI.5.28 and research question research question 113.263, initial image of the digit map: answered:* the map is always initial (remark XVI.5.29); under  $\text{ETR}_{\Gamma+1}$  an arbitrary embedding into  $P(\Gamma)$  yields an initial one (remark XVI.5.31).
- (d) *Source 35's research question 113.270, a choice-free completion theorem: answered* positively by this write (theorem XVI.6.21).
- (e) *Source 31's research question 113.239, definable-class versions of the spectra:* answered in part, for the external order types at a strongly inaccessible height. For the classes definable over  $V_\kappa$  in a fixed finite language with set parameters, the realized types form an interval  $[0, \Theta_L)$  with  $\kappa < \Theta_L < \kappa^+$  (proposition XVI.8.2); with a named global well-order  $\text{cf}(\Theta_L) = \omega$  and parameter-free definitions are cofinal (theorem XVI.8.3 and corollary XVI.8.4),  $\kappa^{\Theta_L} = \omega^{\Theta_L} = \Theta_L$  (theorem XVI.8.9 and corollary XVI.8.17), the ceilings exhaust  $\kappa^+$  as the predicate varies (corollary XVI.8.11), and a truth predicate represents the old ceiling exactly and raises it (theorems XVI.8.12 and XVI.8.19); in the pure language,  $\kappa < \delta_0 \leq \delta_{\text{ord}} \leq \delta_{\text{set}} < \kappa^+$  with  $\text{cf}(\delta_0) = \omega$  (theorem XVI.8.6). The rest of research question 113.239 stays open: the analogues of source 31's thresholds for global choice, enumeration, coding and Class Replacement, heights  $\lambda$  that are not inaccessible, and the exact values of the ceilings.
- (f) *Source 12's full-class model (theorem 21.1 (iv), a theorem):* proved again by all four sources (theorem XVI.8.1 and notes XVI.8.5, XVI.8.8 and XVI.8.15); its hereditary calibration  $\text{otp}(\mathbf{E}) = \varepsilon_{\kappa+1}$  is new (theorem XVI.6.9).
- (g) *Not settled:* Hamkins and Woodin's Question 7; source 15's research question 113.48, whether GB codes all finite condensations uniformly, which source 35 asks again (research question 113.260); and the questions of section 113.28.

[merge] *New against the repository* (checked against the passages of Parts I–XV cited in this Part; none of the four sources claims historical priority): the choice-free power theorem (theorem XVI.4.2 and note XVI.4.4) and source 34's set-subset criterion (lemma XVI.2.2); the equivalence over GB; the cofinality of a limit exponent (proposition XVI.4.7) and bounded specialization (lemma XVI.4.8); the increasing cofinal map  $\Omega \rightarrow W$  (proposition XVI.3.7); the identities  $2^{[\Omega+1]} \cong \Omega \cdot 2$ ,  $2^{[\Omega \cdot 2]} \cong \Omega^2$  (proposition XVI.4.14); the hereditary order, its fixed point, leastness, height cuts, calibration and general base (theorems XVI.6.3, XVI.6.5 to XVI.6.7 and XVI.6.9 and corollary XVI.6.10, with the routes of sources 35, 32 and 33); the fixed-point completion, the local criterion and FPE (theorems XVI.6.17 and XVI.6.18 and corollaries XVI.6.19 and XVI.6.20); the type-level uniform-family diagonal (theorem XVI.7.2 and its three copies); the truth jumps (theorems XVI.7.4, XVI.8.12 and XVI.8.19 and corollary XVI.7.5); the bounded-complexity diagonals and separations (corollaries XVI.7.6 and XVI.7.12 and theorems XVI.7.11 and XVI.7.20); the definability ceilings (proposition XVI.8.2, theorems XVI.8.3, XVI.8.6 and XVI.8.9, note XVI.8.16, and corollaries XVI.8.11 and XVI.8.17); source 33's conditional converse (proposition XVI.5.30); and this write's theorem XVI.6.21 and remarks XVI.5.29 and XVI.5.31. *Inherited or re-proved:* the set-like boundary, the successor obstruction, uniform sums, division by  $\Omega$  and its uniqueness (sources 15, 16 and 18), the block lemma, the GBC descending-sequence test (source 15), polynomial histories (sources 15, 23 and 29), termination (source 20), floors, finite changes, normal forms, anchored restriction and the fixed-schedule criterion (source 29), the full spectrum (source 12), and self-similar quotients (source 18; corollary XVI.5.22 at every set stage). The reflection-tree example, the epsilon notation and the class-recursion calibrations are credited by the sources to Hamkins, Rathjen (through Jeon), Gitman, Hamkins, Holy, Schlicht and Williams.

[merge] *Reviews.* The Hilbert's-tenth research tree reviewed the four archives in a bounded intake (Computability/HilbertTenthProblem/Papers/research-wip/native-stream-queue/revie

w\_beyond\_ord\_e3839ad2c.md, commit fcc4098ec): it read 2,468 archive-member lines, including 1,665 manuscript lines, checked source 34's choice-free power theorem and set-subset criterion in full (theorem XVI.4.2 and lemma XVI.2.2) and "found no defect", confirmed that this report states the GBC equivalence and leaves the GB base open at the sources' pins, and found no demonstrably wrong computational-interface claim; it did not audit the floor, finite-change, reconstruction and restriction dependencies of the GB equivalence, nor the fixed-point, condensation and spectrum proofs, and certifies none of the four manuscripts. A second note there (review\_beyond\_ord\_placement\_111c38012.md, commit b16786caf) authenticates the placement byte for byte and adds no mathematical review. A third (ordinal\_two\_type\_effectivity\_boundary.md, commit c6082d075) proves that no uniform effective procedure decides, for computable well-orders of  $\mathbb{N}$  promised to have type  $\omega$  or  $\omega + 1$ , which type occurs; it is consistent with the sources' explicit restrictions of their notations to supplied coefficient orders and selected effective systems (source 34's section XVI.10, source 35's Section 6.4 in section XVI.6.6) and refutes no claim. None of these covers the text written for this Part. The claims most in need of review are the full dependency analysis of the base change from GBC to GB (repeated by this write against Part XIV, note XVI.5.10), source 32's exact truth presentation (theorem XVI.8.12), source 35's separation on Ord (theorem XVI.7.11), and this write's theorem XVI.6.21.

[merge] *Later bounded publication review.* The subsequent review\_beyond\_ord\_write\_62b16914e.md and separate review\_beyond\_ord\_gb\_62b16914e.md in the same research tree examine the actual Part XVI publication. The selected GB history, floors, finite changes, normal forms, anchored restriction and completion arguments pass, including the internal finite-code induction in theorem XVI.6.21. This is neither a full audit nor a formalization. Truth presentation, separation and spectrum proofs remain outside that scope. Finite notation relative to supplied coefficient orders does not provide a paid fixed-arity ordinary-integer computation history.

**Review remark R1 (coverage counterevidence).** The earlier phrase "2,468 selected lines of the four manuscripts" counted non-manuscript material as manuscript reading. The pinned intake receipt instead counts  $392 + 318 + 584 + 371 = 1,665$  TeX lines and 803 other archive-member lines, totaling 2,468. Its 446 context lines are separate. The corrected wording above does not enlarge the earlier proof coverage.

**Review remark R2 (dependency-pin counterevidence).** The earlier claim that this repository pins v4.31.0 is false at 62b16914e: both the root and surreal lake-manifest.json give inputRev: v4.32.0, with revision 81a5d257c8e410db227a6665ed08f64fea08e997. This corrects the repository pin, not any separately consulted documentation. The named API/deprecation claims remain attributed to source 32, without a new audit of Mathlib history.

**Review remark R3 (output-path counterevidence).** The early guide said source 35 writes artifacts/finite\_notation\_results.json relative to its working directory. Line 161 of the placed program instead constructs Path(\_\_file\_\_).with\_name("finite\_notation\_results.json"), which writes beside the script. The later delivery instructions already state that convention. This is an inert source observation; no supplied program was run.

[merge] *Independent check (dated note, 4 October 2026).* An adversarial verification of the four statements this write added to Part XVI, theorem XVI.6.21 and remarks XVI.5.24, XVI.5.29 and XVI.5.31, was made for the batch-97 write (a working note of that session, not shipped). It rechecked source 34's set-subset criterion, every use of global choice in source 35's proofs of its 3.5, 5.3, 5.7, 5.8, 5.9 and 5.10, the internal induction in item (3) of theorem XVI.6.21, the identification of

towers with histories, the identification of the digit map with the normal-form map, and source 33's converse, and found no mathematical gap and no counterexample. [Theorem XVI.6.21](#) is valid after two editorial fixes; the three remarks are valid after adding a missing nonemptiness hypothesis ([remarks XVI.5.24](#) and [XVI.5.31](#)) or separating two readings of a question ([remark XVI.5.29](#)). The fixes are made, each with a dated note. The check is a careful reading by the intake, not a formal verification or an external review.

**Review remark H5 (qualification of earlier review passes).** The preceding working-note report said that it “found no mathematical gap and no counterexample” and that the remarks were valid after the listed fixes. The frozen Hilbert’s-tenth reviews of [62b16914e](#) likewise passed the tower/history and digit/converse chain without its empty-domain qualifications. A bounded review of [a21a42d8c](#), recorded in `review_horizons_xvi_corrections_a21a42d8c.md` in that research tree, found the residual cases now repaired in [remarks XVI.5.29](#) and [XVI.5.31](#):  $W = 1, \Gamma = 0$  has an exhausting tower but no canonical history under the printed definition;  $W = 0, \Gamma = 1$  has an initial embedding but is outside the exact-tower definition. The earlier unqualified passes remain historical evidence and are qualified by these counterexamples. The nonempty arguments, the embedding endpoints with their new empty cases, and the choice-free completion theorem remain valid within this bounded review. No full review of Part XVI is asserted.

## Part XVII

# Finite-support arithmetic and definability horizons beyond Ord

[merge] (4 October 2026, batch 97.) This Part prints source 36, batch-97 manuscript 01 ([section 1.12](#)), whole and in its own order, as Part XV prints source 31. Source 36 is a fifth independent answer to the request that produced sources 32–35: how far definable class well-orders reach beyond Ord, what their arithmetic is, and how they can be named and formalized. It read this report at commit [e1d2f3048](#), the pin of source 34, with Parts I–XV. It did not see Part XVI, which prints sources 32–35 and was written on 4 October 2026, and it arrived fifteen minutes after their placement, too late to join their merge.

*What it adds to Part XVI.* Explicit normal-form addition and multiplication on the points of  $E$ , representing sums and products of their initial segments; the addition rule also applies to points of every  $\Omega^{[B]}$  ([theorems XVII.5.1](#) and [XVII.5.2](#)); the exact predecessor decomposition of  $A^{[B]}$  for an arbitrary base and a complete criterion for its set-likeness ([theorems XVII.3.5](#) and [XVII.3.6](#)), with  $a^{[\Omega \cdot B]} \cong \Omega^{[B]}$  for set ordinals  $a \geq 2$  ([corollary XVII.3.7](#)); a choice-free presentation of every proper class well-order on the carrier Ord ([proposition XVII.2.4](#)); a choice-free transfer theorem for finite-support term operators ([theorem XVII.6.2](#)); the epsilon-term functor  $\text{Ep}$  on class well-orders ([theorem XVII.6.4](#)); over every transitive model of ZFC of height  $\kappa$ , the calibrations  $\text{otp}(E) = \varepsilon_{\kappa+1}$  and  $\text{otp}(\text{Ep}(E)) = \varepsilon_{\varepsilon_{\kappa+1}}$  and a parameter-free order of type  $\zeta_{\kappa+1}$  ([theorems XVII.6.6](#) and [XVII.6.7](#)); the definable spectrum of every transitive model, with its definability horizon an  $\varepsilon$ -fixed point above  $\zeta_{\kappa+1}$ ,  $\varepsilon_{\mathfrak{H}(M)} = \mathfrak{H}(M)$  ([theorem XVII.6.9](#) and [proposition XVII.6.11](#)), stronger than the closure properties proved in Part XVI; and the horizons  $\mathfrak{H}_G$  over  $V_\kappa$  are unbounded in  $\kappa^+$  as the named enumeration  $G$  itself varies, with no further predicate ([theorem XVII.7.11](#)).

*What it proves again.* Its set-localization lemma, its power calculus, its hereditary order with its fixed point and towers, its uniform diagonal, its  $V_\kappa$  horizon theorem, its bounded-complexity

diagonal and its truth promotion are theorems of sources 32–35, proved independently on the same day. Each is printed as delivered and followed by a numbered credit Note that names the statements of Part XVI (notes XVII.2.A, XVII.3.A, XVII.4.A, XVII.7.B, XVII.7.D, XVII.7.E and XVII.7.G and the others of this Part). Its least-fixed-point theorem (theorem XVII.4.5) states leastness only against isomorphisms  $\Omega^{[X]} \cong X$ ; its proof gives source 34’s stronger form, against initial pre-fixed points, which note XVII.4.B states with credit to source 34. The sentences in which source 36 presents its horizon theorems as “proved results of this investigation” carry dated credit notes (after Section XVII.1.5 and in Appendix C); none is changed. No statement of source 36 was found false.

*Numbering.* The sections of this Part are numbered XVII.1–XVII.11, so that the questions part and the appendices keep their numbers (Sections 113–115, Appendices A–D), as in Parts XV and XVI. Sections XVII.1–XVII.8 are source 36’s Sections 1–8, and its statement  $k.m$  is printed as XVII. $k.m$ ; its equation  $(k.m)$  is tagged (S36. $k.m$ ), and its starred equation  $(*)$  is tagged (S36.\*). Section XVII.9 is its Section 9, whose ten research questions are printed with the other sources’ questions (section 113.30); Section XVII.10 is its Appendix A (proof status, source audit and reproducibility); Section XVII.11 records what the Part answers. So that source 36’s numbers are kept, the credit Notes written for the merge are numbered XVII. $k.A$ , XVII. $k.B$ , ... within each section, and the [merge] paragraphs add no numbered statement. Appendix D.28 maps every numbered statement.

*Notation* (section 1.3.5 lists every renaming). As in Part XVI,  $\Omega$  is the presentation  $(\text{Ord}, \in)$  (source 36’s bold  $\Omega$ );  $A^{[B]}$  is the finite-support power, source 36’s  $A^B$ , printed  $A^{[B]}$  where the operands are class orders (in a term display  $\Omega^t \alpha$  the superscript is a term, and  $\Omega^n$  for finite  $n$  abbreviates  $\Omega^{[n]}$ ); and  $\mathbf{E}$  is the hereditary term order, source 36’s sans-serif  $\mathsf{T}_\Omega$ , whose height stages  $T_n$  are printed  $\mathsf{E}^{\leq n+1}$ . Source 36’s sans-serif  $\mathbf{E}$  for the epsilon-term functor is printed  $\mathsf{Ep}$ , because  $\mathbf{E} = \mathbf{E}$  is the hereditary order here. Its horizons  $H(M)$ ,  $H_0(M)$ ,  $H_p(M)$ ,  $H_G$ ,  $H_{G,T}$  are printed  $\mathfrak{H}(M)$ ,  $\mathfrak{H}_0(M)$ ,  $\mathfrak{H}_p(M)$ ,  $\mathfrak{H}_G$ ,  $\mathfrak{H}_{G,T}$ , because  $H$  and  $H_i$  are histories here;  $H_{\kappa+}$  in proposition XVII.8.1 keeps its usual meaning. Its truth predicate keeps the letter  $T$ , as source 33’s does in Part XVI.  $X \preccurlyeq_{\text{init}} Y$  and  $X \prec_{\text{init}} Y$  are initial and proper initial embeddings, and  $L_{<x}$  is the predecessor class  $L_{<x}$ .

*Status.* Source 36 calls itself a research manuscript with conventional written proofs and “independent review during preparation”. It claims no publication priority, no resolution of a recognized open problem, no referee and no proof-assistant certification (section XVII.10). The Hilbert’s-tenth research tree reviewed its archive in a bounded intake (commit 39bb02ece) and found no defect in the proofs it read; what that review covers is recorded in section XVII.11.

## XVII.1 The question and its three different answers

The usual well-order of all ordinals is not the end of definable well-ordering. It is the end of *set-like* proper class well-ordering. Once an element is allowed to have a proper class of predecessors, there are elementary presentations of

$$\text{Ord} + 1, \quad \text{Ord} + \text{Ord}, \quad \text{Ord}^2, \quad \text{Ord}^{[\text{Ord}]},$$

and much longer orders. This article makes these expressions precise, calculates with them, and explains the reach and limits of systematic notations.

This is closely aligned with Reshetnikov’s 2021 question about definable well-ordered class relations [95]. His examples already identify the essential phenomenon. Modern second-order set theory explicitly uses orders beyond  $\text{Ord}$  and arithmetic on them [84]. The ProveIt corpus contains a substantial neighboring development of labelled class orders, set-like cores, block decomposition,

and condensation histories [93]. Our emphasis is on the lengths of class orders and the definability resources needed to present them.

### XVII.1.1 An elementary example on the same carrier

Let the carrier be  $\text{Ord}$  itself. Keep the positive ordinals in their usual order and put 0 after all of them:

$$\alpha R \beta \iff (0 < \alpha, \beta = 0) \vee (0 < \alpha, 0 < \beta, \alpha < \beta).$$

Every nonempty admitted subclass has a least  $R$ -element: use its least positive ordinal if one exists, and otherwise use 0. The resulting order has type  $\text{Ord} + 1$ . Its last point has a proper class of predecessors.

There is no new set ordinal here. A relation has been defined on a class of ordinary sets. Trying to perform the usual von Neumann collapse at the last point would require all its predecessors to become one set. The set-sized collapse theorem does not permit that step.

Throughout the article,  $\Omega$  denotes the presentation  $(\text{Ord}, \in)$ . It is a symbol for an ordered class, not an extra member adjoined to  $\text{Ord}$ . Its operations are ordinal order operations, not cardinal arithmetic and not surreal field arithmetic.

### XVII.1.2 Three interpretations of length

A complete answer needs three levels of interpretation.

1. **Individual presentations.** Given specified class orders, can we define their sum, product, power, or a fixed-point notation system? This is a question about explicit elementary class constructions.
2. **An external horizon over a fixed model.** If  $M$  is a transitive set model, every externally well-founded class presentation over  $M$  has an ordinary order type in the ambient universe. We can take the supremum of the definable ones there.
3. **A universal internal notation system.** Can one class of set codes, with one available evaluator, name or dominate all class well-orders of the same universe? A diagonal argument gives a negative answer.

The first question has remarkably long constructive answers. The second has exact structural bounds but depends on the model and on which predicates may be used in definitions. The third fails even when domination is weakened to arbitrary increasing embeddability.

### XVII.1.3 Main results and a map of the notation scale

The elementary part is developed over  $\text{GB}$ , with Power Set but without a tacit choice axiom. It constructs finite-support powers, proves their algebraic laws and exact predecessor decompositions, and gives a complete set-likeness criterion. The notation class  $\mathbf{E}$  consists of finite hereditary  $\Omega$ -normal forms. It satisfies

$$\Omega^{[\mathbf{E}]} \cong \mathbf{E},$$

and is the least such fixed point under initial embedding. All recursion needed for this construction operates on finite set codes.

A second operator,  $\text{Ep}$ , is the classical epsilon-term functor [97], extended to class orders by localization. If its input has external type  $\beta$ , its output has type  $\varepsilon_\beta$ . Here  $\varepsilon_\varepsilon$  is the increasing

continuous enumeration of the fixed points of  $\alpha \mapsto \omega^\alpha$ . Write  $\zeta_\xi$  for the increasing continuous enumeration of the fixed points of  $\xi \mapsto \varepsilon_\xi$ .

For external calibration, fix a transitive  $M \models \text{ZFC}$  and put  $\kappa = M \cap \text{Ord}$ . The right column below uses ordinary external *ordinal* arithmetic.

| Presentation                                  | Construction                   | External order type over $M$           |
|-----------------------------------------------|--------------------------------|----------------------------------------|
| $\Omega$                                      | Usual ordinal order            | $\kappa$                               |
| $\Omega + 1$                                  | Append a greatest point        | $\kappa + 1$                           |
| $\Omega \cdot 2$                              | Two consecutive copies         | $\kappa \cdot 2$                       |
| $\Omega^2$                                    | Pairs, last coordinate major   | $\kappa^2$                             |
| $\Omega^{[\Omega]}$                           | Finite ordinal digit strings   | $\kappa^\kappa$                        |
| $\mathbf{E}$                                  | Hereditary finite digit trees  | $\varepsilon_{\kappa+1}$               |
| $\mathbf{Ep}(\mathbf{E})$                     | Epsilon terms over those trees | $\varepsilon_{\varepsilon_{\kappa+1}}$ |
| $\sum_{n < \omega} \mathbf{Ep}^n(\mathbf{E})$ | Uniform nested finite syntax   | $\zeta_{\kappa+1}$                     |

The exact subscripts use the closure of a transitive ZFC model under the ordinary epsilon and zeta functions: externally  $\varepsilon_\kappa = \zeta_\kappa = \kappa$ . This is proved below; it is not an assumption that  $\kappa$  is a cardinal in the ambient universe.

The trees are set codes. A point displayed as  $\Omega^\Omega$  is a code whose *predecessor order* has that length. It is not a proper class inserted as an element of another class. This distinction makes the notation usable in ordinary class theory.

#### XVII.1.4 The definability horizon

Let  $\mathfrak{H}(M)$  be the external supremum of order types of externally well-founded orders definable over  $M$ , allowing finitely many set parameters. The article proves

$$\text{Spec}(M) = [0, \mathfrak{H}(M)), \quad \zeta_{\kappa+1} < \mathfrak{H}(M) < |\kappa|^+, \quad \varepsilon_{\mathfrak{H}(M)} = \mathfrak{H}(M).$$

The proper-class presentations realize exactly  $[\kappa, \mathfrak{H}(M))$ ; arbitrary proper definable carriers give the same spectrum as the carrier  $\text{Ord}^M$ .

A sharper result holds at an inaccessible height. Work externally in ZFC, let  $M = V_\kappa$  for strongly inaccessible  $\kappa$ , and name a predicate  $G$  coding a bijection  $\kappa \rightarrow V_\kappa$ . For the corresponding horizon  $\mathfrak{H}_G$ ,

$$\kappa < \mathfrak{H}_G < \kappa^+, \quad \text{cf}(\mathfrak{H}_G) = \omega, \quad \varepsilon_{\mathfrak{H}_G} = \mathfrak{H}_G.$$

Presentations with *no set parameters* are already cofinal in  $\mathfrak{H}_G$ , although  $G$  remains in the language. The proof constructs one dominating class order for each fixed level of formula complexity. These form an effective external schema of formulas, not a single available semantic evaluator.

Two further results explain how horizons can be crossed:

$$\mathfrak{H}_G < \mathfrak{H}_{G,T} \quad \text{when } T \text{ names full truth for } (V_\kappa, \in, G), \quad \sup_G \mathfrak{H}_G = \kappa^+.$$

Naming  $T$  gives a presentation of  $\mathfrak{H}_G$  itself. If every class is available, the external spectrum is exactly  $[0, \kappa^+)$ . Thus a fixed definability regime and the full class collection over the same sets have different precise cutoffs.

### XVII.1.5 Status and the role of ProveIt

Long class orders, basic class arithmetic, and the epsilon operator are established background. We give complete proofs of the particular constructions and structural statements used here. The integrated horizon theorem, its parameter-free cofinality conclusion, truth promotion, and variation with  $G$  are presented as proved results of this investigation. The source search does not establish publication priority for these combinations.

No recognized major open problem is claimed solved. In particular, the converse from general class-well-order comparability to elementary transfinite recursion is not established here. It is posed in the cited literature [35, 27]; the targeted current search located no verified later resolution. Our explicit constructions do not require that converse.

The repository audit records inspected sources and a pinned commit. It does not turn the repository’s research manuscripts into imported axioms. None of the principal proofs depends on accepting an unreviewed theorem from those manuscripts. The formalization roadmap explains how this work could connect to ProveIt’s ordinal-code development [94].

[merge] (4 October 2026.) Source 36 did not see Part XVI (part XVII). Its “integrated horizon theorem” and its “parameter-free cofinality conclusion” (theorem XVII.7.5), its bounded-complexity diagonal (proposition XVII.7.6) and its truth promotion (theorem XVII.7.9) are theorems that sources 32, 33 and 34 proved independently on 4 October 2026; notes XVII.7.D, XVII.7.E and XVII.7.G give the correspondences. Its variation with  $G$  (theorem XVII.7.11) refines source 32’s corollary XVI.8.11, which varies an additional predicate with  $G$  fixed. What is new against Part XVI is listed in section XVII.11. The sentences above are printed as delivered; the same credit applies to the “Main result” of source 36’s title page (Appendix C).

## XVII.2 Class well-orders and the set boundary

Our base theory in this part is GB with the axioms of ZF, including Power Set, for its sets. Neither the Axiom of Choice for sets nor Global Choice is assumed. Classes have sets as their members. Elementary class comprehension permits fixed class parameters, and Class Replacement takes the image of a set under a class function to be a set. These conventions matter: the constructions below concern relations on classes of sets, not objects having proper classes as members.

**Definition XVII.2.1.** A *class well-order* is a class  $L$ , together with a strict linear ordering  $<_L$ , such that every nonempty available subclass of  $L$  has a least element. Its predecessor class at  $x \in L$  is

$$L_{<x} = \{y \in L : y <_L x\}.$$

The order is *setlike* if every  $L_{<x}$  is a set. An *initial embedding*  $j : L \rightarrow K$  is an order embedding whose image is downward closed in  $K$ ; it is *proper* when it is not onto.

We write  $L \preceq_{\text{init}} K$  when such an initial embedding exists, and  $L \prec_{\text{init}} K$  when a proper one exists. The latter assertion includes an actual class map. It does not presuppose that arbitrary class well-orders are comparable. Likewise,  $\Omega$  denotes the particular presentation  $(\text{Ord}, \in)$ . An expression involving the order type of a proper class is an abbreviation for a presentation considered up to class isomorphism. We do not form a class of equivalence classes whose members would themselves be proper classes.

### XVII.2.1 Localization and internal well-foundedness

**Lemma XVII.2.2** (Set localization). *A class linear order  $L$  is a class well-order if and only if every nonempty set  $s \subseteq L$  has a least element.*

*Proof.* The forward implication is immediate. For the converse, suppose that a nonempty class  $C \subseteq L$  has no least element. For each  $x \in C$ , there is  $y \in C$  with  $y <_L x$ . The least ordinal  $\beta$  such that a suitable  $y$  belongs to  $V_\beta$  is uniquely determined by  $x$ . For a fixed ordinal  $\alpha$ , Class Replacement bounds these least ordinals as  $x$  ranges over the set  $C \cap V_\alpha$ . Consequently there is an ordinal  $F(\alpha) > \alpha$  such that

$$x \in C \cap V_\alpha \implies \exists y \in C \cap V_{F(\alpha)} (y <_L x).$$

Choose  $F(\alpha)$  to be the least such ordinal, obtaining a set-valued class function.

Take  $c \in C$ , choose  $\alpha_0$  with  $c \in V_{\alpha_0}$ , and define  $\alpha_{n+1} = F(\alpha_n)$ . This is ordinary recursion producing a sequence of sets, with fixed class parameters. It is available in GB; it is not a recursion producing a sequence of classes. Put  $\theta = \sup_{n < \omega} \alpha_n$ . The set  $C \cap V_\theta$  is nonempty. If  $x$  belongs to it, then  $x \in V_{\alpha_n}$  for some  $n$ , and there is a smaller member of  $C \cap V_{\alpha_{n+1}}$ . Thus  $C \cap V_\theta$  has no least element, contrary to the hypothesis.  $\square$

*Note XVII.2.A* ([merge]; source 34's set-subset criterion). [Lemma XVII.2.2](#) is source 34's [lemma XVI.2.2](#) (Part XVI), proved independently, with the same hypotheses: GB with ZF sets, a class *linear* order, no form of choice. The proofs differ in the last step. Source 34 selects a unique predecessor below each point (least rank, then least in that set) and builds a descending set sequence; source 36 closes an ordinal under the rank bound  $F$  and exhibits the set  $C \cap V_\theta$  with no least element, so it needs no order-least selection. Source 36's proof of [theorem XVII.6.2](#) repeats the argument with the sets  $L(x)$  of least-rank lower points. The caveat after [lemma XVI.2.2](#) applies here too: the criterion is for linear orders. Part XVI's completion theorem without choice ([theorem XVI.6.21](#)) rests on this lemma.

This lemma allows well-foundedness to be checked using only set quantifiers, with the ordering as a class parameter. In particular, two GB-expansions with the same sets agree about a common class relation's internal well-foundedness. This useful distinction is emphasized in the class-theoretic literature [84].

Internal well-foundedness must nevertheless be distinguished from well-foundedness in an external metatheory. If  $(M, \mathcal{X}) \models \text{GB}$ , the sets and classes quantified over above are those of that structure. An externally visible descending sequence need not be a set of  $M$ . Later sections explicitly impose external well-foundedness when taking external ordinal order types. No external correctness assumption is needed for the internal theorems of this section.

### XVII.2.2 The canonical beginning and a standard carrier

**Theorem XVII.2.3** (The ordinal initial segment). *Every proper class well-order  $L$  has a canonical initial segment isomorphic to  $\Omega$ . It consists exactly of the points with set predecessor classes. In particular, every setlike proper class well-order is isomorphic to  $\Omega$ .*

*Proof.* Let

$$S = \{x \in L : L_{<x} \text{ is a set}\}.$$

This is a class by elementary comprehension. It is initial: if  $y < x$  and  $L_{<x}$  is a set, then  $L_{<y}$  is its subclass and hence a set. For  $x \in S$ , let  $\rho(x)$  be the unique ordinal order type of the set well-order  $L_{<x}$ . The ordinary order-type theorem uses no choice. Its uniqueness makes  $\rho$  a class function.

The map  $\rho$  is an order embedding. Moreover, every ordinal below  $\rho(x)$  is  $\rho(y)$  for a unique  $y < x$ . Therefore its range is an initial subclass of  $\text{Ord}$ . If this range were not all of  $\text{Ord}$ , the least missing ordinal would show that it is a set ordinal  $\lambda$ . Applying Class Replacement to the inverse map on  $\lambda$  would then make  $S$  a set. Since  $L$  is proper, the class  $L \setminus S$  would have a least member  $p$ . Initiality of  $S$  would give  $L_{<p} = S$ , a set, contradicting  $p \notin S$ . Thus  $\rho[S] = \text{Ord}$ , as required.  $\square$

Accordingly, passing beyond  $\text{Ord}$  means allowing points with proper class predecessor classes. It does not mean finding a set ordinal larger than every ordinal. The first new point in  $\Omega + 1$ , for example, has all of  $\Omega$  below it.

*Note XVII.2.B* ([merge]; the set-like boundary). [Theorem XVII.2.3](#) is the set-like boundary of Part XVI, source 34's [theorem XVI.3.1](#) (with source 35's [note XVI.2.4](#), source 32's [note XVI.2.9](#) and source 33's [note XVI.2.14](#)), by the same proof; for well-orders of the surreal carrier it is source 11's [theorem 15.1](#). Source 34 adds that a proper class well-order which is not set-like has an initial copy of  $\Omega + 1$ .

**Proposition XVII.2.4** (Reduction to the carrier  $\text{Ord}$ ). *Every proper class well-order has an isomorphic presentation on the carrier  $\text{Ord}$ . The transport is definable from the given presentation and requires no additional choice principle.*

*Proof.* On the carrier  $L$ , define  $x \triangleleft y$  when either  $\text{rank}(x) < \text{rank}(y)$ , or their ranks agree and  $x <_L y$ . A nonempty subclass first has a least occurring rank and then a least member at that rank under  $<_L$ . Thus  $\triangleleft$  is a class well-order. The predecessors of  $y$  are contained in  $L \cap V_{\text{rank}(y)+1}$ , so it is setlike. By [Theorem XVII.2.3](#), there is a canonical isomorphism  $e : \Omega \rightarrow (L, \triangleleft)$ . Transport the original relation  $<_L$ , rather than  $\triangleleft$ , along  $e$ .  $\square$

The supplied well-order orders each rank level, which is why this argument does not need Global Choice. It is not an argument that an arbitrary proper class can be well-ordered. Related rank-first constructions appear in the standard analysis of Global Choice [19]. If the input presentation is first-order definable with specified parameters, both the enumeration just constructed and the transported relation are definable with those parameters.

[merge] [Proposition XVII.2.4](#) is new to this report in this form. It complements source 29's [corollary 108.20](#), whose transfer to the surreal carrier **No** uses global choice, which a well-order of **No** amounts to over **GB** ([theorem 13.1](#)). Nothing contradicts: the carrier  $\text{Ord}$  needs no global choice because the supplied order breaks the ties inside each rank level, as the paragraph above says, and source 34's reduction to the surreal carrier keeps global choice for that reason ([section 1.4](#), addendum for sources 32–35).

## XVII.3 Finite-support ordinal arithmetic

Arithmetic on class well-orders is established mathematical practice [84]. We give the constructions explicitly because they remain meaningful when predecessor classes are proper. The finite-support description agrees with familiar set ordinal exponentiation and with its formal development in Isabelle [98].

The sum  $A + B$  is the tagged disjoint union, with the  $A$ -copy first. The product  $A \cdot B$  has carrier  $A \times B$ , ordered by the second coordinate first:

$$(a, b) < (a', b') \iff b <_B b' \text{ or } (b = b' \text{ and } a <_A a').$$

Thus it comprises a  $B$ -ordered sequence of copies of  $A$ . The empty and singleton presentations are denoted by 0 and 1. Both constructions preserve class well-orders: for products, minimize the second coordinate occurring in a nonempty subclass and then the first.

### XVII.3.1 Powers and their structural laws

**Definition XVII.3.1** (Finite-support power). Let  $A \neq 0$  be a class well-order, with least element  $0_A$ . For a class well-order  $B$ , the carrier of  $A^{[B]}$  consists of finite set graphs  $f$  whose domain is a finite subset of  $B$ , and whose values belong to  $A \setminus \{0_A\}$ . Missing entries are interpreted as  $0_A$ . For distinct  $f, g$ , let  $b$  be the largest exponent where their interpreted values differ, and put

$$f < g \iff f(b) <_A g(b).$$

Every code is a set, even when  $A$  and  $B$  are proper classes. In particular, this definition does not quantify over a collection of all class functions from  $B$  to  $A$ .

**Theorem XVII.3.2** (Power calculus). *Finite-support powers are class well-orders. There are explicit class isomorphisms*

$$A^{[0]} \cong 1, \quad A^{[1]} \cong A, \quad 1^{[B]} \cong 1, \quad (\text{S36.3.1})$$

$$A^{[B+C]} \cong A^{[B]} \cdot A^{[C]}, \quad (\text{S36.3.2})$$

$$(A^{[B]})^{[C]} \cong A^{[B \cdot C]}. \quad (\text{S36.3.3})$$

*The sum and product are associative, and*

$$A \cdot (B + C) \cong A \cdot B + A \cdot C.$$

*All these assertions are valid for the indicated class presentations in GB.*

*Proof.* The power ordering is linear because a nonempty finite disagreement set has a largest member. For transitivity, take the larger of the determining exponents in two successive comparisons; the coefficient comparison there gives the required comparison of the first and third codes. To prove well-foundedness, take a nonempty set  $Q$  of codes. Let  $S_B$  be the union of their supports, and let  $S_A$  consist of  $0_A$  and all their nonzero coefficients. These are sets with induced well-orders. Collapse them to set ordinals  $b$  and  $a$ , respectively. Transporting the codes embeds  $Q$  into the ordinary finite-support presentation of the set ordinal  $a^b$ . Therefore  $Q$  has a least element. Lemma XVII.2.2 proves the class assertion.

For (S36.3.2), split a finite support into its  $B$ -part and its  $C$ -part. A disagreement in the  $C$ -part dominates every disagreement in the  $B$ -part, exactly as in the product on the right. For (S36.3.3), an outer code assigns to finitely many  $c \in C$  a nonzero finite code on  $B$ . Flatten its entries to pairs  $(b, c)$ . Conversely, group a finite graph on  $B \times C$  by its second coordinate. The largest outer disagreement and then the largest inner disagreement give exactly the product ordering on exponents. The unit laws are immediate. Associativity of sums and products, and the displayed distributive law, follow by retagging the relevant tuples. All maps and their inverses act on sets.  $\square$

For an empty base one may separately stipulate  $0^{[0]} = 1$  and  $0^{[B]} = 0$  for nonempty  $B$ . We keep the main power statements at nonempty bases. Familiar distinctions from commutative arithmetic remain: for example  $1 + \Omega \cong \Omega$ , whereas  $\Omega + 1 \not\cong \Omega$ :  $\Omega + 1$  has a greatest point and  $\Omega$  does not.

**Lemma XVII.3.3** (Transport of initial segments). *An initial embedding  $j : B \rightarrow C$  induces an initial embedding  $A^{[B]} \rightarrow A^{[C]}$  by transporting supports. If  $A$  has at least two elements and  $j$  is proper, the induced embedding is proper.*

*Proof.* Any nonzero digit outside  $j[B]$  occurs above all exponents in that initial segment. A code with such a digit is therefore above every code supported inside  $j[B]$ . This proves initiality. In the proper case, let  $c$  be the least point outside  $j[B]$ , and let  $1_A$  be the least member of  $A \setminus \{0_A\}$ . The singleton code with value  $1_A$  at  $c$  has exactly the transported  $A^{[B]}$  as its predecessor class. Indeed a smaller code must be supported below  $c$ , and every such code is smaller.  $\square$

*Note XVII.3.A* ([merge]; the power theorem of Part XVI). [Definition XVII.3.1](#) is source 34's [definition XVI.4.1](#). [Theorem XVII.3.2](#) is source 34's choice-free power theorem [theorem XVI.4.2](#) with its laws (S34.1), (S34.2) and (S34.3), also proved by source 35 ([note XVI.4.4](#), over GB; its laws (S35.5) and (S35.6)) and, over GBC, by sources 32 and 33 ([notes XVI.4.10 to XVI.4.13](#)); for the base  $\Omega$  it is source 29's [note 108.15](#) over GBC. Source 36's well-foundedness proof is the collapse route: a set of codes uses a set of exponents and a set of coefficients, whose collapses send it into the finite-support presentation of an ordinary ordinal power, and [lemma XVII.2.2](#) lifts the result to classes. That is source 34's second proof, and the route of sources 32 and 33 with set subsets in place of descending sequences; source 34's first proof and source 35's are greedy minimizations. [Lemma XVII.3.3](#) is source 35's [lemma XVI.4.5](#) for initial embeddings and the paragraph before [proposition XVI.4.3](#); source 33's conventions  $0^0 = 1$ ,  $0^B = 0$  are those of the paragraph after [theorem XVII.3.2](#).

**Proposition XVII.3.4** (Continuity of the presented power). *If  $B$  is nonempty and has no greatest point, the canonical initial copies of  $A^{[B_{<b}]}$ , for  $b \in B$ , exhaust  $A^{[B]}$ . If  $b$  is the greatest point of  $B$ , then*

$$A^{[B]} \cong A^{[B_{<b}]} \cdot A.$$

*Proof.* In the first case, a nonzero code has a largest support exponent  $c$ . Choose  $b > c$ . Its support is then contained in  $B_{<b}$ . The zero code is in every copy, and the copies are initial by [Lemma XVII.3.3](#). In the second case,  $B \cong B_{<b} + 1$ , so the assertion follows from (S36.3.2).  $\square$

The first statement is a presentation-level continuity law. It can be written as the elementary class condition  $\text{supp}(f) \subseteq B_{<b}$  on pairs  $(b, f)$ . It does not require a collection whose members are the proper classes  $A^{[B_{<b}]}$ , nor an unrestricted supremum operation on all class order types.

[merge] The first clause of [proposition XVII.3.4](#) is the case  $B_b = B_{<b}$  of source 35's continuity law (S35.7), which source 35 also states in this form; the second clause,  $A^{[B]} \cong A^{[B_{<b}]} \cdot A$  at a greatest point, is new in this form, and is (S34.2) with  $C = 1$ . Source 35's [proposition XVI.4.7](#) computes the cofinality of the first case. The uniform sums of the next paragraph are source 34's sums ([section XVI.3](#)) and source 32's [proposition XVI.3.4](#).

The same discipline permits uniform ordered sums. Suppose one class relation specifies fibers  $A_b$ , for  $b \in B$ , and another class relation specifies a well-order on each fiber. The carrier

$$\{(a, b) : b \in B, a \in A_b\}$$

ordered by  $b$  first and by its fiber order second is a class well-order. A nonempty subclass has a least occurring index and then a least point in that fiber. This observation allows arbitrarily long, already specified sums. The hypothesis of a single supplied definition of the fibers is essential: writing a formal family of class names does not by itself supply the class relation needed for the construction.

### XVII.3.2 Predecessor normal forms and set-likeness

**Theorem XVII.3.5** (Exact predecessor decomposition). *If  $f \in A^{[B]}$  has support  $b_0 > \dots > b_{n-1}$  and values  $a_i$ , then*

$$(A^{[B]})_{<f} \cong \sum_{i < n} A^{[B_{<b_i}]} \cdot A_{<a_i}. \quad (\text{S36.*})$$

*The empty support gives the empty sum.*

*Proof.* For  $g < f$ , its largest disagreement with  $f$  must occur at a point  $b_i$  of the support of  $f$ . At a position where  $f$  has value zero, a disagreement could only make  $g$  larger. Fixing this index  $i$ , the code  $g$  agrees with  $f$  above  $b_i$ , takes an arbitrary value below  $a_i$  at  $b_i$ , and has an arbitrary finite tail below  $b_i$ . These choices give precisely  $A^{[B_{<b_i}]} \cdot A_{<a_i}$ , with the coefficient as major coordinate. The blocks are ordered by increasing  $i$ : agreeing with one more leading digit places a code above all codes that dropped earlier. This identifies both the carrier and its ordering.  $\square$

For the base  $\Omega$ , the coefficients are positive set ordinals, so (S36.\*) reads

$$(\Omega^{[B]})_{<f} \cong \sum_{i < n} \Omega^{[B_{<b_i}]} \alpha_i. \quad (\text{S36.3.4})$$

This licenses the notation  $\Omega^{b_0} \alpha_0 + \cdots + \Omega^{b_{n-1}} \alpha_{n-1}$  for a *point code*. In its order-type interpretation, the exponent is  $B_{<b_i}$ , not a class somehow made into a member of  $B$ . The distinction remains essential when  $B_{<b_i}$  is proper.

For a concrete example, let  $B = \Omega + 1$ , and name its final point  $\top$ . The code with coefficient 1 at  $\top$ , coefficient 2 at the ordinal point 3, and coefficient 7 at 0 has predecessor presentation

$$\Omega^{[\Omega]} + \Omega^3 \cdot 2 + 7.$$

The first exponent is  $\Omega$  because the predecessors of  $\top$  are the entire first copy of  $\text{Ord}$ . The other two predecessor classes have the ordinary set order types 3 and 0. The formula therefore handles a proper exponent cut and set exponent cuts in one normal form, with no change of foundational meaning.

[merge] For the base  $\Omega$ , (S36.3.4) is source 34's predecessor formula (S34.4), with the same proof, and the polynomial reading of Parts IX and XIV. Theorem XVII.3.5 for an arbitrary class base  $A$ , where the blocks are  $A^{[B_{<b_i}]} \cdot A_{<a_i}$ , is new to this report.

**Theorem XVII.3.6** (Complete set-likeness criterion). *Suppose  $A$  has at least two elements and  $B \neq 0$ . Then  $A^{[B]}$  is setlike if and only if at least one of the following holds:*

1.  $A$  is a set and  $B$  is setlike;
2.  $B$  is a singleton and  $A$  is setlike.

*Proof.* Digits supported at the least exponent, together with the zero code, form an initial copy of  $A$ . Thus set-likeness of  $A^{[B]}$  implies set-likeness of  $A$ . If some  $b \in B$  has a proper predecessor class, the singleton code with coefficient  $1_A$  at  $b$  has  $A^{[B_{<b}]}$  below it. This contains a copy of  $B_{<b}$ , obtained by putting coefficient  $1_A$  at one exponent at a time. That copy is proper by Class Replacement applied to the inverse map if its image were a set. Hence  $B$  must be setlike.

If  $A$  is proper and  $B$  has a second point, the singleton code at that second point has an entire copy of  $A$  below it. This rules out set-likeness, proving necessity of the alternatives.

Conversely, suppose  $A$  is a set and  $B$  is setlike. Below a nonzero code with largest exponent  $b$ , every support is contained in the set  $B_{<b} \cup \{b\}$ . All such finite graphs belong to the power set of  $(B_{<b} \cup \{b\}) \times A$ . Its appropriate subclass is a set, so the predecessor class is a set. The zero code has no predecessors. The singleton-exponent alternative follows from  $A^{[1]} \cong A$ .  $\square$

Thus  $\Omega^2$  already passes the setlike boundary. More generally,  $\Omega^{[B]}$  is setlike precisely when  $B$  has at most one point. A proper class carrier alone, however, does not force such a passage.

**Corollary XVII.3.7** (Collapse of set bases). *For every set ordinal  $a \geq 2$  and every class well-order  $B$ ,*

$$a^{[\Omega]} \cong \Omega, \quad a^{[\Omega \cdot B]} \cong \Omega^{[B]}.$$

*Proof.* The first power is setlike by Theorem XVII.3.6 and proper because singleton supports give an injection from Ord. Apply Theorem XVII.2.3. The second assertion follows from  $(a^{[\Omega]})^{[B]} \cong a^{[\Omega \cdot B]}$ .  $\square$

For example,

$$2^{[\Omega]} \cong \omega^{[\Omega]} \cong \Omega, \quad \omega^{[\Omega+1]} \cong \Omega \cdot \omega, \quad \omega^{[\Omega \cdot \Omega]} \cong \Omega^{[\Omega]}.$$

These are identities of ordered presentations, not cardinal arithmetic.

[merge] Theorem XVII.3.6 is new to this report; Part XVI shows set-likeness and its failure only in examples (the proofs of propositions XVI.4.3 and XVI.4.14 and source 32's remark after note XVI.4.11 that  $\Omega^{[\Omega]}$  is not set-like). Corollary XVII.3.7 generalizes source 34's proposition XVI.4.3 ( $a^{[\Omega]} \cong \Omega$ ,  $a^{[\Omega+1]} \cong \Omega \cdot a$ ), source 35's proposition XVI.4.6 ( $\beta^{[\Omega]} \cong \Omega$ ) and source 33's proposition XVI.4.14 ( $2^{[\Omega+1]} \cong \Omega \cdot 2$ ,  $2^{[\Omega \cdot 2]} \cong \Omega^2$ ) to every exponent of the form  $\Omega \cdot B$ .

## XVII.4 Hereditary $\Omega$ -normal forms

Finite supports can themselves have finite-support exponents. The right way to iterate this observation is to give a single finite syntax. This avoids a purported recursion that would collect a new proper class at each stage.

**Definition XVII.4.1** (The term class). A raw term is a finite rooted ordered tree with a positive ordinal coefficient on each edge. Write an empty node as 0, and a nonempty node as

$$[(t_0, \alpha_0), \dots, (t_{k-1}, \alpha_{k-1})].$$

Compare raw terms recursively by lexicographic comparison of these lists: compare exponent subtrees first, their coefficients second, and then the remaining entries. A proper prefix is smaller. A term is *normal* when all its subterms are normal and  $t_0 > \dots > t_{k-1}$ . The class of normal terms is  $\mathbf{E}$ .

The recursion here is on finite syntax trees. More explicitly, one can code a tree by a finite prefix-closed subset of  $\omega^{<\omega}$ , with consecutive child indices at each node, and a finite ordinal labeling of its edges. Comparisons are computed from pairs of proper subtrees. Normality is then checked at its finitely many nodes. These are uniform first-order definitions; neither a truth predicate nor class-valued transfinite recursion occurs.

The constant  $\bar{\alpha}$ , for  $\alpha > 0$ , is the single-entry term  $[(0, \alpha)]$ , and  $\bar{0} = 0$ . There are no separate constant atoms duplicating these terms. We also write a node suggestively as

$$\Omega^{t_0} \alpha_0 + \dots + \Omega^{t_{k-1}} \alpha_{k-1}.$$

This is syntax with the predecessor semantics of Theorem XVII.3.5.

The word *finite* describes the number of nodes and labels, not the size of an ordinal label. There are proper class many possible coefficients. A tree is a set carrying finitely many of them, so the whole notation domain can be a proper class even though each tree has finite shape. A parameter-free definition of this domain is compatible with individual terms having arbitrary ordinal labels. For computational use one must additionally specify how those labels are represented and compared; a finite alphabet of executable labels describes a smaller notation domain.

### XVII.4.1 Well-foundedness from set ordinal evaluation

**Theorem XVII.4.2** (Localization of hereditary normal forms). *The syntactic ordering on  $\mathbf{E}$  is a class well-order. For every set ordinal  $\kappa \geq 2$ , terms whose coefficients are below  $\kappa$  admit an injective order-preserving evaluation into the ordinary ordinals, given by*

$$|0|_\kappa = 0, \quad |[(t_i, \alpha_i)]_{i < \kappa}|_\kappa = \sum_{i < \kappa} \kappa^{|t_i|_\kappa} \alpha_i. \quad (\text{S36.4.1})$$

*Evaluation also reflects strict order and equality.*

*Proof.* We use the ordinary ordinal radix comparison principle at base  $\kappa$ . In a finite expansion with decreasing exponents and coefficients below  $\kappa$ , a tail supported below  $\gamma$  has value below  $\kappa^\gamma$ . To see the relevant bound, if the largest exponent is  $\delta$  and its coefficient is  $c < \kappa$ , induct on the number of lower terms to obtain

$$\kappa^\delta c + \text{tail} < \kappa^\delta (c + 1) \leq \kappa^{\delta+1}.$$

For exponents below  $\gamma$ , this is at most  $\kappa^\gamma$ . The successor and limit laws for ordinary ordinal exponentiation justify the last comparison. Hence a larger leading exponent dominates the whole smaller expansion, and a larger first unequal coefficient dominates its lower tail. Common leading parts can be removed from a comparison because ordinal addition is strictly increasing in its right argument. This proves the radix comparison principle. The general base expansion, rather than only base  $\omega$ , is also developed in Mathlib [99].

Induction on the maximum of the two finite tree heights now shows that the evaluated exponent subtrees have exactly their syntactic ordering. The radix comparison principle therefore applies at the roots. It proves preservation and reflection of comparison and equality, as well as the required decreasing-exponent condition at each root.

Finally let  $Q \subseteq \mathbf{E}$  be a nonempty set. The ordinal coefficients occurring anywhere in its trees form a set. Choose one ordinal  $\kappa \geq 2$  above them all. Evaluation embeds  $Q$  into the ordinals, and its image is a set by Replacement. It follows that  $Q$  has a least member. Lemma XVII.2.2 finishes the proof.  $\square$

No special closure property of  $\kappa$  is needed for this localization: it need only bound the coefficients. The theorem is an internal proof in the stated base theory, not an appeal to a larger universe.

**Proposition XVII.4.3** (Root decomposition). *Removing the root identifies*

$$\mathbf{E} \cong \Omega^{[\mathbf{E}]}.$$

*Proof.* The root of a normal term is exactly a finite-support map from normal exponent terms to positive ordinal coefficients. Conversely, attach a new root to any such finite family. A finite family of finite trees is finite, and the two constructions are inverse. Their comparisons agree because both inspect the largest exponent of disagreement first.  $\square$

### XVII.4.2 Strict towers and the least fixed point

Let the height of 0 be zero, and let a nonzero tree's height be one plus the maximum height of its exponent subtrees. For  $n < \omega$ , put

$$\mathbf{E}^{\leq n+1} = \{t \in \mathbf{E} : \text{height}(t) \leq n+1\}.$$

These are uniform restrictions of one previously defined class. Define actual term codes

$$w_0 = [(\bar{1}, 1)], \quad w_{n+1} = [(w_n, 1)].$$

**Theorem XVII.4.4** (Canonical strict towers). *Each  $E^{\leq n+1}$  is initial in  $E$ , and*

$$E^{\leq 1} \cong \Omega, \quad E^{\leq n+2} \cong \Omega^{[E^{\leq n+1}]}, \quad E^{\leq n+1} = E_{<w_n}.$$

*In particular,*

$$\Omega \prec_{\text{init}} \Omega^{[\Omega]} \prec_{\text{init}} \Omega^{[\Omega^{[\Omega]}]} \prec_{\text{init}} \cdots \prec_{\text{init}} E.$$

*Proof.* Height at most one gives exactly the ordinal constants. Every nonconstant normal term has a positive leading exponent, and is therefore above every constant. The least such term is  $w_0$ , since  $\bar{1}$  is the least positive term and 1 is the least positive coefficient. This proves the assertions for  $E^{\leq 1}$ .

Root decomposition identifies  $E^{\leq n+2}$  with  $\Omega^{[E^{\leq n+1}]}$ . If  $E^{\leq n+1} = E_{<w_n}$ , transport of this initial segment through the power construction and Proposition XVII.4.3 identifies  $E^{\leq n+2}$  with the predecessors of the singleton digit at  $w_n$ . That singleton is  $w_{n+1}$ , by Lemma XVII.3.3. Induction proves all the equalities. Moreover  $w_n$  has height  $n+2$ , so it belongs to  $E^{\leq n+2} \setminus E^{\leq n+1}$ ; each inclusion is proper.  $\square$

The code  $w_0$  is a point of  $E$  whose predecessor presentation has type  $\Omega$ . The entire class Ord has not become a member of a class. The same distinction applies to every tower boundary.

*Note XVII.4.A* ([merge]; the hereditary order of Part XVI). Source 36's term class (its sans-serif  $T_\Omega$ , printed  $E$ ) is source 34's  $E$  (definition XVI.6.1): the same finite trees with nonzero set-ordinal coefficients, the same comparison (exponents first, coefficients second, a proper prefix smaller) and the same normality condition; it is also source 35's  $\mathcal{E}$  (note XVI.6.11) and, up to isomorphism, source 33's direct limit  $\mathbb{T}$  (theorem XVI.6.26). Theorem XVII.4.2 is source 34's lemma XVI.6.2 and theorem XVI.6.3, by the same argument; source 34 evaluates at an infinite initial cardinal above the coefficients, source 36 at any ordinal  $\kappa \geq 2$  above them, which the radix comparison principle allows. Proposition XVII.4.3 is theorem XVI.6.6. Theorem XVII.4.4 is theorem XVI.6.5 with the index shifted by one: source 36's height stage  $T_n$ , printed  $E^{\leq n+1}$ , is the cut below  $w_n$ , and  $w_n$  is source 34's term  $\tau_{n+1}$  (S34.6); it is also source 35's note XVI.6.14 (with  $b_n = w_n$ ) and source 33's tower (lemma XVI.6.25). Source 36, like source 34, proves all of this in GB without choice; sources 33 and 35 work in GBC, and Part XVI lowers source 35's version to GB (theorem XVI.6.21).

**Theorem XVII.4.5** (Least  $\Omega$ -exponential fixed point). *The class  $E$  is isomorphic to  $\Omega^{[E]}$ . If a class well-order  $X$  admits a class order isomorphism  $\phi : \Omega^{[X]} \rightarrow X$ , then  $E \prec_{\text{init}} X$ .*

*Proof.* The fixed-point assertion is Proposition XVII.4.3. For leastness, evaluate each finite tree through the given isomorphism:

$$h(0) = \phi(\emptyset), \quad h([(t_i, \alpha_i)]_{i < k}) = \phi(\{(h(t_i), \alpha_i) : i < k\}). \quad (\text{S36.4.2})$$

A valuation on the finite set of nodes is a set. Its equations use only the fixed class parameter  $\phi$ . Thus, once existence and uniqueness are checked, elementary comprehension defines  $h$  as a class map, without a recursion along  $E$ .

These checks can be made simultaneously by induction on finite height. The value  $h(0)$  is the least point of  $X$ . The images of the constants are  $\phi$  applied to the zero code and to singleton digits at that least point. They form an initial copy of  $\Omega$  in  $X$ . Suppose the evaluation on  $E^{\leq n+1}$  is an initial embedding. Transport of finite supports makes its extension on  $E^{\leq n+2} \cong \Omega^{[E^{\leq n+1}]}$  an initial embedding into  $\Omega^{[X]}$ . Composition with  $\phi$  makes it initial in  $X$ . In particular, distinct exponent subtrees remain distinct and correctly ordered, so the graph in (S36.4.2) is a legitimate finite support. The same induction gives unique values at every node.

Every term lies in some  $E^{\leq n+1}$ , and these evaluations agree because they satisfy the same finite equations. If  $x < h(t)$ , choose  $n$  with  $t \in E^{\leq n+1}$ . Initiality at that stage gives  $x = h(s)$  for some  $s \in E^{\leq n+1}$ . Therefore the whole image of  $h$  is initial, proving the assertion.  $\square$

Leastness here does not invoke comparability of arbitrary class well-orders. It compares this explicit term class with each supplied fixed point. Nor is a fixed point a final boundary for class order types. The power law gives

$$\Omega^{[E+1]} \cong \Omega^{[E]} \cdot \Omega \cong E \cdot \Omega,$$

which contains its first  $E$ -copy as a proper initial segment. The simpler successor presentation  $E + 1$  also passes it.

*Note XVII.4.B* ([merge]; leastness against initial pre-fixed points). [Theorem XVII.4.5](#) states leastness only against fixed points given by an isomorphism  $\phi : \Omega^{[X]} \cong X$ ; in that form it is source 35's [note XVI.6.15](#). Its proof gives more, with no change: *if a class well-order  $X$  admits an initial order embedding  $\phi : \Omega^{[X]} \rightarrow X$  (an initial pre-fixed point), then the evaluation  $h$  of (S36.4.2) is a unique initial embedding  $E \rightarrow X$ ; in particular  $E \preccurlyeq_{\text{init}} X$ .* The proof uses of  $\phi$  only that it is an order embedding with initial image:  $h(0) = \phi(\emptyset)$  is the least point of  $X$  because the image of  $\phi$  is initial and contains  $\phi(\emptyset)$  as its least point; the constants go to an initial copy of  $\Omega$  for the same reason; and in the induction a composite of initial embeddings is initial. This stronger statement is source 34's [theorem XVI.6.7](#) (Part XVI), which is credited for it; source 36 did not see it. The phrase “the least such fixed point under initial embedding” in source 36's introduction (Section XVII.1.3) holds in this stronger sense. The remark after the theorem, that leastness invokes no comparability of arbitrary class well-orders, is source 34's remark after [theorem XVI.6.7](#).

## XVII.5 Arithmetic of the represented initial segments

Write  $\|t\| = E_{<t}$ , interpreting this notation as a class presentation. It is useful to give actual algorithms for adding and multiplying these presentations. The algorithms make finitely many structural decisions, together with operations on ordinal coefficients. They are therefore relative procedures on supplied ordinal labels, not a recursive finite-alphabet notation for all ordinals.

### XVII.5.1 Addition by a final-segment isomorphism

**Theorem XVII.5.1** (Normal-form addition). *There is a finite normal-form operation  $f \boxplus g$  on  $E$  such that*

$$\|f \boxplus g\| \cong \|f\| + \|g\|.$$

*The same rule applies to the points of every  $\Omega^{[B]}$ .*

*Proof.* If  $g = 0$ , return  $f$ . Otherwise let  $b$  be the leading exponent of  $g$ . Keep the digits of  $f$  above  $b$ , add its coefficient at  $b$  to that of  $g$  by ordinary ordinal addition, discard its digits below  $b$ , and append the lower tail of  $g$ . A missing coefficient of  $f$  is zero. The resulting coefficient is a positive ordinal, and the exponents remain strictly decreasing.

Fix  $f$ . The map  $R_f(g) = f \boxplus g$  is strictly increasing. If two inputs have different leading exponents, at the larger one the output for that input strictly increases the corresponding coefficient of  $f$ , whereas the other output leaves it unchanged. If their leading exponents agree, unequal leading coefficients are compared by strict monotonicity of ordinary ordinal addition in the right argument. When the leading coefficients also agree, their lower tails are unchanged by the rule and decide the comparison.

Its range is exactly the final segment starting at  $f$ . Certainly  $R_f(0) = f$ . For  $h > f$ , let  $b$  be their largest disagreement. Then  $h(b) > f(b)$ . There is a unique positive ordinal  $\delta$  with  $f(b) + \delta = h(b)$ :

it is the order type of the ordinary ordinal interval from  $f(b)$  to  $h(b)$ . Take  $g$  to have coefficient  $\delta$  at  $b$  and the lower tail of  $h$ . The displayed rule gives  $R_f(g) = h$ .

Consequently  $R_f$  is an isomorphism onto that final segment. Restricting it to the predecessors of  $g$  identifies them with the interval  $[f, f \boxplus g)$ . Prepending the predecessors of  $f$  proves the required sum identity. The argument depends only on the ordered exponent carrier and ordinal coefficients, so applies to  $\Omega^{[B]}$  as asserted.  $\square$

For every point-cut  $D$  of  $\Omega^{[B]}$ , the same proof gives  $D + \Omega^{[B]} \cong \Omega^{[B]}$ . Thus the absorption used in normal-form arithmetic has been established by an explicit class isomorphism.

### XVII.5.2 Multiplication without class-valued recursion

**Theorem XVII.5.2** (Normal-form multiplication). *There is a finite normal-form operation  $f \boxtimes g$  on  $\mathbf{E}$  satisfying*

$$\|f \boxtimes g\| \cong \|f\| \cdot \|g\|.$$

*Proof.* Zero factors give zero. Write a nonzero first factor in root notation as

$$f = \Omega^a \alpha + r,$$

where  $\alpha > 0$  is an ordinal and every exponent in  $r$  is below  $a$ . Put  $A = \|a\|$  and  $D = \|f\|$ . The predecessor theorem gives  $D \cong \Omega^{[A]} \alpha + \|r\|$ .

For each set ordinal  $\beta$ , define a term  $F_\beta$  directly:

$$F_0 = 0, \quad F_\beta = \begin{cases} \Omega^a(\alpha\beta) + r, & \beta > 0 \text{ is a successor,} \\ \Omega^a(\alpha\beta), & \beta > 0 \text{ is a limit.} \end{cases} \quad (\text{S36.5.1})$$

Normal-form addition gives  $F_\beta \boxplus f = F_{\beta+1}$ . Hence  $[F_\beta, F_{\beta+1})$  is a copy of  $D$ . The points  $F_\beta$  increase strictly. They are continuous at limit indices in the following concrete sense: every point below  $F_\lambda$  lies below some  $F_\beta$ ,  $\beta < \lambda$ . This follows from ordinary ordinal continuity  $\alpha\lambda = \sup_{\beta < \lambda} \alpha\beta$ ; at a limit  $F_\lambda$  has no lower tail.

These intervals partition the point-cut  $\Omega^{a \boxplus 1}$ , whose order type is  $\Omega^{[A+1]}$ . Indeed its points have leading exponent at most  $a$  and an ordinal coefficient at  $a$ . Some  $\alpha\beta$  exceeds that coefficient, so the  $F_\beta$  are cofinal. Given a point, choose the least  $\gamma$  with that point below  $F_\gamma$ . Continuity excludes limit  $\gamma$ , placing it in a unique interval  $[F_\beta, F_{\beta+1})$ . Thus

$$(x, \beta) \mapsto F_\beta \boxplus x$$

is an explicit isomorphism  $D \cdot \Omega \cong \Omega^{[A+1]}$ . Restricting the index to any ordinal  $\beta$  also proves  $D \cdot \beta \cong \|F_\beta\|$ . These maps use the single formula (S36.5.1); no sequence of class isomorphisms was recursively selected.

Now let  $b > 0$  be an exponent term and put  $B = \|b\|$ . Remove the least point of  $B$ , writing  $B \cong 1 + B'$ . The power laws and product associativity give

$$D \cdot \Omega^{[B]} \cong (D \cdot \Omega) \cdot \Omega^{[B']} \cong \Omega^{[A+1]} \cdot \Omega^{[B']} \cong \Omega^{[A+B]}.$$

By Theorem XVII.5.1, the last presentation is the point-cut denoted by  $\Omega^{a \boxplus b}$ .

The algorithm is now explicit. For each summand  $\Omega^{b_i} \beta_i$  of  $g$  with  $b_i > 0$ , output  $\Omega^{a \boxplus b_i} \beta_i$ . If  $g$  has an ordinal constant tail  $\beta > 0$ , append  $F_\beta$ . Right distributivity and the identities just proved identify this output with  $D \cdot \|g\|$ . The positive exponents remain strictly decreasing because  $b \mapsto a \boxplus b$  is strictly increasing. They all exceed  $a$ , so an appended  $F_\beta$  preserves normality.  $\square$

For example, the algorithms give

$$(\Omega + 1)\omega = \Omega\omega, \quad (\Omega + 1)(\omega + 1) = \Omega(\omega + 1) + 1,$$

and

$$(\Omega^2 + \Omega + 7)(\Omega^3 \cdot 2 + \omega + 1) = \Omega^5 \cdot 2 + \Omega^2(\omega + 1) + \Omega + 7.$$

Here equality abbreviates the proved isomorphism of predecessor presentations. Arbitrary powers of such presentations are already available through Definition XVII.3.1. We have not proved in this section a normalization algorithm placing every such power back inside  $\mathbf{E}$ ; addition and multiplication closure should not be mistaken for that further assertion.

[merge] (4 October 2026.) Theorems XVII.5.1 and XVII.5.2 are new to this report. They answer the addition and multiplication part of source 34’s agenda item research question 113.275, which asks for algorithms on the initial segments represented by finite trees “proved against class-order isomorphisms”: both are proved by explicit class isomorphisms of the predecessor orders, and the absorption  $D + \Omega^{[B]} \cong \Omega^{[B]}$  after theorem XVII.5.1 extends source 35’s  $\alpha + \Omega \cong \Omega$  (proposition XVI.4.6) to every point-cut. Exponentiation is not answered: source 36 says so above and asks for it as its sixth question (research question 113.300); the dated note at research question 113.275 records the status. The algorithms are relative to the ordinal arithmetic of the coefficients ( $\alpha\beta$ ,  $f(b) + \delta$ , successor or limit  $\beta$ ); the Hilbert’s-tenth review of the archive (commit 39bb02ece) read both proofs, found no defect, and records that these procedures retain ordinal-label primitives and are not an implementation on a finite alphabet. The three displayed products were recomputed by hand at the placement (6571ee1af).

## XVII.6 Epsilon notation and exact external spectra

Finite hereditary powers provide one substantial interval of notation, but they do not exhaust the useful finite constructions. We next extend a standard epsilon-term operator to class well-orders, then calculate exact external order types. The distinction between a concrete presentation and an externally calculated ordinal remains essential throughout.

### XVII.6.1 A transfer principle for finite terms

The method behind Lemma XVII.2.2 applies to many established ordinal notation systems. Here is a formulation that isolates the required uniformity.

**Definition XVII.6.1.** A *finite-support term operator*  $F$  assigns a class of finite, set-coded terms to a linear order  $B$ . Each term  $t$  has a finite set  $\text{supp}_B(t)$  of labels from  $B$ . Validity and comparison are given by fixed first-order definitions, allowing the relation of  $B$  as a class parameter. We require that whenever  $S \subseteq B$  contains the labels of the terms under consideration, validity and comparison in  $F(B)$  agree with validity and comparison in  $F(B \upharpoonright S)$ .

This definition includes an actual restriction property, rather than just the informal assertion that expressions are finite. In particular, a rule that consults the whole predecessor class of an input label would require separate justification.

**Theorem XVII.6.2** (Finite-support transfer). *Work in GB. Suppose  $F$  is a finite-support term operator, its terms on a set input form a set, and  $F$  sends every set well-order to a set well-order. Then  $F$  sends every class well-order to a class well-order. No choice principle is needed.*

*Proof.* Let  $A$  be any nonempty set of terms of  $F(B)$ . Replacement and Union give the set

$$S = \bigcup_{t \in A} \text{supp}_B(t) \subseteq B.$$

The induced order  $B \upharpoonright S$  is a set well-order. By hypothesis  $F(B \upharpoonright S)$  is a set well-order, and its restriction to  $A$  agrees with the original comparison. Thus  $A$  has a least element. The same argument on finite sets of terms proves linearity, including transitivity and antisymmetry.

For completeness, the passage from least elements for sets to least elements for classes does not require dependent choice. If a nonempty class  $C$  had no least element, then for each  $x \in C$  let  $L(x)$  be the nonempty set of lower elements of  $C$  having the least possible rank. This set exists by class separation on an appropriate rank level. Starting with  $A_0 = \{x_0\} \subseteq C$ , form

$$A_{n+1} = \bigcup_{x \in A_n} L(x), \quad A = \bigcup_{n < \omega} A_n.$$

These are sets by ordinary set recursion and Replacement with the fixed class parameters. Every member of  $A$  has a smaller member in  $A$ , contradicting the result for nonempty sets. Hence every nonempty class also has a least element.  $\square$

The theorem supplies a controlled route to further notation systems: specify a finite grammar, prove the restriction property, and prove the ordinary set-order interpretation. It does not authorize substituting classes into an arbitrary ordinal function merely because that function is normal.

[merge] [Theorem XVII.6.2](#) is new to this report as a general method. Its first paragraph is source 34's set-subset criterion ([lemma XVI.2.2](#), here [lemma XVII.2.2](#)) applied to the set of labels of a set of terms; source 35's bounded-specialization principle ([lemma XVI.4.8](#), over GB by [theorem XVI.6.21](#) (1)) is the same transfer for ordinal-labelled terms with an ordinal interpretation, and source 34's and source 36's well-foundedness proofs for  $\mathbf{E}$  ([theorems XVII.4.2](#) and [XVI.6.3](#)) are instances. Its second paragraph is a further proof of [lemma XVII.2.2](#), through the sets of least-rank lower points ([note XVII.2.A](#)).

## XVII.6.2 The epsilon-term functor

The ordinary notation operator  $B \mapsto \varepsilon_B$  is established in the literature; see the explicit syntax in [97, Definition 2.3]. We use a compressed Cantor-normal-form presentation and supply its set and class proofs. The resulting construction will be denoted by  $\text{Ep}(B)$ .

**Definition XVII.6.3** (Normal epsilon terms). For a linear order  $B$ , normal terms are finite tagged trees of the following forms:

1. the zero term 0;
2. a constant  $e_b$ , for  $b \in B$ ;
3. a nonempty list

$$[(t_0, n_0), \dots, (t_{k-1}, n_{k-1})], \quad t_0 > \dots > t_{k-1}, \quad 0 < n_i < \omega,$$

whose intended reading is  $\omega^{t_0} n_0 + \dots + \omega^{t_{k-1}} n_{k-1}$ .

In the third clause all exponent terms must themselves be normal. The singleton list  $[(e_b, 1)]$  is excluded: it would duplicate  $e_b$ .

Here normality and comparison are defined together by finite recursion. Zero is least; constants satisfy  $e_b < e_c$  exactly when  $b <_B c$ . Two list terms are compared lexicographically, first comparing their exponents and then their positive natural coefficients. A proper prefix is smaller. For a list term  $s$  with leading exponent  $t_0$ , the mixed comparison is

$$s < e_b \iff t_0 < e_b, \quad e_b < s \iff e_b \leq t_0. \quad (\text{S36.6.1})$$

If  $t_0 = e_b$ , either the leading coefficient exceeds 1 or a nonempty tail follows, so  $s$  is strictly larger than  $e_b$ . This explains the normal-form exclusion.

Each recursive comparison replaces at least one list by a proper subterm; comparisons between constants consult  $B$  directly. Consequently the combined finite size of the two displayed syntax trees is a termination measure. Labels are leaves: their transitive closures are not traversed. One can formalize validity and comparison by a finite computation record over the nodes of the input trees. There is no recursion through the order  $B$ , and no evaluation of arbitrary set-theoretic formulas.

**Theorem XVII.6.4** (Exact epsilon interpretation and class extension). *If  $B$  is a set well-order of order type  $\beta$ , then*

$$\text{otp}(\text{Ep}(B)) = \varepsilon_\beta.$$

*For an arbitrary class well-order  $B$ , the same finite syntax defines a class well-order  $\text{Ep}(B)$  in GB. The construction preserves the parameters used to define  $B$ .*

*Proof.* First suppose  $r : B \rightarrow \beta$  is the ordinal collapse of a set well-order. Evaluate the terms by

$$\llbracket 0 \rrbracket = 0, \quad \llbracket e_b \rrbracket = \varepsilon_{r(b)}, \quad \llbracket [(t_i, n_i)]_{i < k} \rrbracket = \sum_{i < k} \omega^{\llbracket t_i \rrbracket} n_i.$$

We use the convention that  $\varepsilon_0$  is the first fixed point of  $\xi \mapsto \omega^\xi$ .

Induction on finite term size shows that every value is below  $\varepsilon_\beta$ . Constants have this property because their indices are below  $\beta$ . A finite sum of powers with exponents below an epsilon number is again below that epsilon number. For the empty input  $B$ , there are no constants, and this argument gives values below  $\varepsilon_0$ .

A simultaneous induction on pairs of terms proves that comparison is preserved and reflected. For two lists this is the uniqueness and comparison rule of ordinary Cantor normal form. For a list and a constant of value  $\lambda = \varepsilon_{r(b)}$ , a leading exponent below  $\lambda$  makes the whole list value smaller than  $\lambda$ . A leading exponent above  $\lambda$  makes it larger. Equality of the leading exponent to  $\lambda$  also makes it larger, because the only list that could evaluate to  $\lambda$  is the excluded singleton. The recursive comparison of exponents is justified by the induction hypothesis. Thus evaluation is an order embedding.

To prove surjectivity, use induction on  $\alpha < \varepsilon_\beta$ . Zero is represented. If  $\alpha$  is an epsilon number, then  $\alpha = \varepsilon_\gamma$  for a unique  $\gamma < \beta$ , and the corresponding constant represents it. Otherwise write its nonzero Cantor normal form

$$\alpha = \omega^{\alpha_0} n_0 + \cdots + \omega^{\alpha_{k-1}} n_{k-1}.$$

Every exponent  $\alpha_i$  is strictly below  $\alpha$ . Indeed,  $\omega^\xi \geq \xi$  always, and an exponent equal to  $\alpha$  could occur only in the singleton expression  $\alpha = \omega^\alpha$ , which is the epsilon case already handled. Represent the exponents inductively and form the list. Its exponents are correctly ordered by the embedding property, and it cannot be the excluded singleton because  $\alpha$  is not an epsilon number. This proves the exact set-case order type.

For the class case, the support of a term consists of its finitely many labels  $b$ . Both normality and comparison use only the inherited order between labels, so the restriction property holds. On a set input the collection of finite terms is a set. Theorem XVII.6.2 now applies. Finally, all definitions are fixed finite-syntax definitions relative to the relation  $B$ , so no new parameter is introduced.  $\square$

An order embedding  $B \rightarrow C$  acts on terms by replacing each label with its image. Structural induction shows that this is an embedding  $\text{Ep}(B) \rightarrow \text{Ep}(C)$ . This explains the functor terminology at the level needed here; no collection of all class orders is being formed. For example,  $\text{Ep}(\Omega) \cong \Omega$ : evaluate  $e_\alpha$  as the ordinary set ordinal  $\varepsilon_\alpha$  and use ordinary arithmetic. All such values are sets, and every set ordinal is represented. Applying the operator to a longer presentation can have a very different effect.

[merge] The epsilon-term functor  $\text{Ep}$  on class well-orders ([definition XVII.6.3](#) and [theorem XVII.6.4](#)) is new to this report; source 36 credits its syntax to Marcone and Montalbán [97], and Part XVI's sources credit class epsilon notation to Rathjen through Jeon ([88]; [section 1.4](#), addendum for sources 32–35). It is a first step of the Veblen-style hierarchy of class-order constructors that source 34's [research question 113.272](#) and source 35's [research question 113.273](#) ask for (dated note at [research question 113.272](#)). Source 36's sans-serif  $\mathsf{E}$  is printed  $\text{Ep}$  because  $\mathsf{E}$  is the hereditary order here;  $\text{Ep}(\Omega) \cong \Omega$ , whereas  $\mathsf{E}$  is far longer.

### XVII.6.3 Exact calibration over a transitive set model

From this point through the spectrum calculations, the ambient metatheory is ZFC. Fix a transitive set model

$$M \models \text{ZFC}, \quad \kappa = M \cap \text{Ord}.$$

The symbol  $\kappa$  denotes an ordinary ordinal of the ambient universe, although it is not an element of  $M$ . All displayed order types in this subsection are external order types. Transitivity makes finite syntax absolute, but it does not make arbitrary class well-foundedness absolute.

**Lemma XVII.6.5.** *Let  $\zeta_\alpha$  enumerate the fixed points of  $\xi \mapsto \varepsilon_\xi$ , starting with the least such fixed point. Then*

$$\varepsilon_\kappa = \kappa = \zeta_\kappa.$$

*Proof.* Ordinal arithmetic and the ordinary recursive definitions of the epsilon and zeta enumerations are absolute between  $M$  and the ambient universe. For every  $\alpha < \kappa$ , the model constructs  $\varepsilon_\alpha$  and  $\zeta_\alpha$ , which therefore lie below  $\kappa$ . Both normal enumerations dominate their arguments. Continuity at the limit ordinal  $\kappa$  gives the equalities by taking suprema over  $\alpha < \kappa$ .  $\square$

**Theorem XVII.6.6** (The first hereditary power boundary). *For the presentation  $\mathsf{E}$  of Theorem XVII.4.5,*

$$\text{otp}(\mathsf{E}^M) = \varepsilon_{\kappa+1}, \quad \text{otp}(\text{Ep}(\mathsf{E})^M) = \varepsilon_{\varepsilon_{\kappa+1}}.$$

*Proof.* Every finite tree whose ordinal coefficients lie below  $\kappa$  belongs to  $M$ , by closure under finite coding. Conversely, every tree recognized by  $M$  is such an external finite tree, since transitive models have the standard natural numbers. Thus  $\mathsf{E}^M$  is exactly the hereditary base- $\kappa$  normal-form system, with its usual recursive comparison.

Restricting root decomposition to coefficients below  $\kappa$  shows that the bounded-height stages have types  $\tau_0 = \kappa$  and  $\tau_{n+1} = \kappa^{\tau_n}$ . All finite trees form their increasing union, whose type is  $\sup_{n < \omega} \tau_n$ , the least fixed point of  $\xi \mapsto \kappa^\xi$ . The fixed points of this function are exactly the epsilon numbers strictly above  $\kappa$ . To check this explicitly, use  $\kappa = \omega^\kappa$ . If  $\xi = \kappa^\xi$ , then

$$\xi = \omega^{\kappa \cdot \xi} \geq \kappa \cdot \xi \geq \xi,$$

so  $\kappa \cdot \xi = \xi$  and  $\omega^\xi = \xi$ . Moreover  $\xi > \kappa$ , since  $\xi \geq \kappa$  and  $\kappa^\kappa > \kappa$ . Conversely, an epsilon number  $\xi > \kappa$  satisfies  $\kappa \cdot \xi = \xi$ , hence  $\kappa^\xi = \omega^{\kappa \cdot \xi} = \xi$ . Lemma XVII.6.5 identifies the least such number as  $\varepsilon_{\kappa+1}$ .

Finite syntax is also absolute for the epsilon operator. Apply Theorem XVII.6.4 externally to the set order  $E^M$  to obtain the second equality.  $\square$

The first equality is an exact calibration, not a claim that  $\varepsilon_{\kappa+1}$  is an ordinal available to  $M$ . It also shows that these explicit presentations depend only on  $\kappa$  when compared between transitive models of equal ordinal height.

*Note XVII.6.A* ([merge]; source 34's calibration at every transitive height). The first equality of theorem XVII.6.6 is source 34's theorem XVI.6.9 ( $\text{otp}(E[\kappa]) = \varepsilon_{\kappa+1}$  for an uncountable initial cardinal  $\kappa$ , by the same computation of the least fixed point of  $\xi \mapsto \kappa^\xi$ ), carried to the height  $\kappa = M \cap \text{Ord}$  of every transitive model  $M$  of ZFC, which need not be a cardinal:  $E^M$  is  $E[\kappa]$ , and lemma XVII.6.5 supplies  $\varepsilon_\kappa = \kappa$  where source 34 uses that  $\kappa$  is an uncountable cardinal. Source 34 states the case of a full class model over an inaccessible  $\kappa$ , and source 33 computes the same type as  $\sup_n t_n$  there (section XVI.8.8). The second equality, lemma XVII.6.5 and theorem XVII.6.7 are new to this report. In the proof above,  $\tau_n$  are ordinals (the types of the height stages), not source 34's terms  $\tau_n$  of (S34.6).

**Theorem XVII.6.7** (An explicit zeta boundary). *There is a parameter-free class well-order  $W$ , defined by finite nested syntax and an ordered sum over  $\omega$ , such that for every transitive  $M \models \text{ZFC}$  as above,*

$$\text{otp}(W^M) = \zeta_{\kappa+1}.$$

*Proof.* Put  $A_0 = E$  and  $A_{n+1} = \text{Ep}(A_n)$ , and define

$$W = \sum_{n < \omega} A_n.$$

The uniform definition of this family deserves attention. Attach a natural-number level to a finite term code. At level 0 use the grammar for  $E$ . At level  $n + 1$ , use the epsilon grammar, with each epsilon constant carrying a valid level- $n$  term as its label. Exponent subterms remain at the same level but are proper subtrees. Validity and comparison are consequently determined by a single finite recursive calculation on the complete nested code. The recursion follows the displayed syntax tree, treating base ordinal coefficients as leaves, rather than exploring their transitive closures. Equivalently, one can require a finite computation record verifying all its nodes and comparisons. This defines the family uniformly; it is not an evaluation map for arbitrary formulas defining classes.

Finite induction using Theorem XVII.6.4 proves that every  $A_n$  is a class well-order. The ordered sum is a class well-order: a nonempty subclass has a least occupied natural-number index, and a least element in that summand.

Externally write

$$a_0 = \varepsilon_{\kappa+1}, \quad a_{n+1} = \varepsilon_{a_n}.$$

These are the exact types of the summands. Let  $\lambda$  be the least fixed point of epsilon enumeration above  $\kappa$ . Then  $\kappa < a_0 < \lambda$ , and normality proves that the  $a_n$  increase strictly while remaining below  $\lambda$ . Their supremum is itself a fixed point by continuity and exceeds  $\kappa$ , so it equals  $\lambda$ . Each  $a_n$  is an epsilon number; therefore addition absorbs all earlier summands and

$$\sum_{n < \omega} a_n = \sup_{n < \omega} a_n = \lambda.$$

Finally Lemma XVII.6.5 gives  $\lambda = \zeta_{\kappa+1}$ .  $\square$

### XVII.6.4 The spectrum of definable presentations

The next definition makes precise the external version of the question posed in the earlier discussion of definable class orders [93, 100].

**Definition XVII.6.8.** Let  $\text{Spec}(M)$  consist of the external order types of externally well-founded well-orders on subclasses of  $M$ , where both the carrier and the order are first-order definable over  $M$  with finitely many set parameters. Define the *definability horizon*

$$\mathfrak{H}(M) = \sup \text{Spec}(M).$$

A carrier is *internally proper* if it is not equal to any set belonging to  $M$ .

The ambient universe can form this spectrum using satisfaction for the set structure  $M$ . The definition does not posit a satisfaction predicate for  $M$  inside  $M$ , nor does it turn all classes of the original universe into a class.

**Theorem XVII.6.9** (Spectrum and carrier theorem). *For every transitive set model  $M \models \text{ZFC}$  of height  $\kappa$ ,*

$$\text{Spec}(M) = [0, \mathfrak{H}(M)).$$

*The types with internally proper carriers are exactly*

$$[\kappa, \mathfrak{H}(M)).$$

*Moreover every such proper presentation can be transferred definably to the carrier  $\text{Ord}^M$ , without adding parameters or assuming a definable global choice function.*

*Proof.* If a presentation has type  $\gamma$ , then for each  $\beta < \gamma$  its restriction below the point of index  $\beta$  has type  $\beta$ . That point belongs to  $M$  and can be added as a parameter. Thus the spectrum is downward closed. Taking a tagged copy of the carrier and appending one new tagged point gives a definable successor presentation. The spectrum has no maximum, proving the first formula.

If a definable carrier equals  $a \in M$ , Separation inside  $M$  forms its order as a set relation. External well-foundedness implies that  $M$  regards this set relation as a well-order. Its ordinal collapse belongs to  $M$ , and transitivity makes that collapse externally correct. Its type is therefore below  $\kappa$ .

Now let  $R$  well-order an internally proper carrier  $D$ . Consider the definable initial part

$$P = \{x \in D : \{y \in D : yRx\} \text{ is a set belonging to } M\}.$$

It is initial because a predecessor segment below a predecessor is a definable subset of a set. Its inherited order is setlike internally. If  $P$  were a set in  $M$ , the least element  $x$  of  $D \setminus P$  would have exactly  $P$  as its predecessors. Then  $x \in P$ , a contradiction. Hence  $P$  is internally proper.

Map each  $x \in P$  to the ordinal type of its set of predecessors. This is a definable order isomorphism onto an initial subclass of  $\text{Ord}^M$ . If its image were bounded below  $\kappa$ , it would be a set in  $M$ ; Replacement applied to the inverse would make  $P$  a set in  $M$ . Thus its image is all of  $\text{Ord}^M$ . The original order therefore begins with an initial copy of  $\kappa$ . Together with the first formula and the set-carrier case, this proves the asserted proper spectrum.

Finally, re-order  $D$  by rank, retaining  $R$  within each rank:

$$xEy \iff \text{rank}(x) < \text{rank}(y) \vee (\text{rank}(x) = \text{rank}(y) \wedge xRy).$$

This is a well-order, and every predecessor segment is contained in an internal rank level and is therefore a set in  $M$ . Its canonical setlike collapse gives a definable bijection  $D \rightarrow \text{Ord}^M$ . Transport  $R$  along this bijection. All definitions use the original parameters only; the supplied order on  $D$  provides the tie-breaking that a global choice function would otherwise supply.  $\square$

Allowing all finite set parameters is essential for the interval statement: taking an arbitrary initial segment normally introduces its endpoint as a parameter. The carrier-transfer statement itself does preserve parameter-free definability.

**Proposition XVII.6.10** (Cardinality bound). *Let  $\mu = |\kappa|$ , calculated externally. Then*

$$|M| = \mu, \quad \mathfrak{H}(M) < \mu^+.$$

*Proof.* For each  $\alpha < \kappa$ , the internal rank level  $V_\alpha^M$  is a set of  $M$ . Choice in  $M$  provides a bijection with some ordinal below  $\kappa$ , so externally its cardinality is at most  $\mu$ . Since  $M = \bigcup_{\alpha < \kappa} V_\alpha^M$ , ambient choice gives  $|M| \leq \mu$ ; the reverse inequality follows from  $\kappa \subseteq M$ .

There are at most  $\mu$  formulas with finite tuples of parameters from  $M$ . Every definable carrier has external cardinality at most  $\mu$ , so each realized order type is below  $\mu^+$ . The supremum of at most  $\mu$  such ordinals is still below  $\mu^+$ , proving the strict bound.  $\square$

*Note XVII.6.B* ([merge]; the parameter spectrum of Part XVI). The first formula of [theorem XVII.6.9](#) and [proposition XVII.6.10](#) are source 34's [proposition XVI.8.2](#) for the pure language  $L = \{\in\}$ :  $\mathcal{S}_{\text{par}}^L = [0, \Theta_L)$  with  $\Theta_L < \lambda^+$ ,  $\lambda = |M|$ , so that  $\mathfrak{H}(M) = \Theta_{\{\in\}}$ ; the proofs are the same (downward closure through the endpoint as a new parameter, successor closure, counting). Source 36 adds  $|M| = |\kappa|$ . For  $M = V_\kappa$  they are source 35's  $\delta_{\text{set}}$  ([theorem XVI.8.6](#)), and with a named enumeration  $G$  source 32's and source 33's ceilings ([note XVII.7.D](#)). Like source 34, source 36 counts externally well-founded orders over an arbitrary transitive model, with no  $\beta$ -hypothesis. New to this report: the proper-carrier spectrum  $[\kappa, \mathfrak{H}(M))$  and the parameter-preserving transfer of every internally proper presentation to the carrier  $\text{Ord}^M$ , which is [proposition XVII.2.4](#) carried out inside  $M$ .

### XVII.6.5 Closure and parameter budgets

**Proposition XVII.6.11** (Closure and cofinality of horizons). *The spectrum  $\text{Spec}(M)$  is closed under ordinary ordinal addition, multiplication, and exponentiation, and under  $\alpha \mapsto \varepsilon_\alpha$ . Consequently*

$$\varepsilon_{\mathfrak{H}(M)} = \mathfrak{H}(M).$$

*Let  $\mathfrak{H}_0(M)$  be the horizon for parameter-free presentations and  $\mathfrak{H}_p(M)$  the horizon for presentations definable from one fixed finite tuple  $p$ . Then*

$$\text{cf}(\mathfrak{H}_0(M)) = \text{cf}(\mathfrak{H}_p(M)) = \omega, \quad \varepsilon_{\mathfrak{H}_0(M)} = \mathfrak{H}_0(M), \quad \varepsilon_{\mathfrak{H}_p(M)} = \mathfrak{H}_p(M).$$

*Furthermore,*

$$\zeta_{\kappa+1} < \mathfrak{H}_0(M) \leq \mathfrak{H}_p(M) \leq \mathfrak{H}(M) < |\kappa|^+.$$

*Proof.* Given two definable presentations, combine their finite tuples of parameters and apply the explicit sums, products, and finite-support powers of the preceding section. External transitivity ensures that all finite codes occur in  $M$ , so these constructions have the ordinary ordinal sum, product, and power as their external types. The conventional cases with base 0 or 1 use the empty or singleton presentations. [Theorem XVII.6.4](#) similarly gives a presentation of type  $\varepsilon_\alpha$  from one of type  $\alpha$ .

Write  $\mathfrak{H} = \mathfrak{H}(M)$ . Successor closure makes  $\mathfrak{H}$  a limit ordinal, and realized types are cofinal in  $\mathfrak{H}$ . Normality of epsilon enumeration gives

$$\varepsilon_{\mathfrak{H}} = \sup_{\alpha \in \text{Spec}(M)} \varepsilon_\alpha \leq \mathfrak{H} \leq \varepsilon_{\mathfrak{H}}.$$

The middle inequality uses that each epsilon value is again realized.

For a fixed parameter tuple there are only countably many formulas. Their realized types are cofinal in the corresponding horizon and have no maximum, because successor construction preserves that tuple. The horizon therefore has cofinality exactly  $\omega$ . The epsilon construction also preserves the tuple, so the same continuity argument applies. No downward-closure assertion for this restricted spectrum is needed. Finally  $W + 1$ , with  $W$  from Theorem XVII.6.7, is parameter-free and has type  $\zeta_{\kappa+1} + 1$ . The remaining inequalities follow by inclusion of the permitted definitions and Proposition XVII.6.10.  $\square$

The same epsilon-closure argument applies when a fixed finite list of class predicates is named in the language: it is enough that the relevant definitions and finite coding are available. The next section exploits this observation for a named global enumeration. For unrestricted set parameters over an arbitrary  $M$ , the elementary cardinality argument alone gives  $\text{cf}(\mathfrak{H}(M)) \leq |\kappa|$ , not  $\text{cf}(\mathfrak{H}(M)) = \omega$ .

[merge] (4 October 2026.) Proposition XVII.6.11 is new against Part XVI in two respects. First,  $\varepsilon_{\mathfrak{H}} = \mathfrak{H}$  is stronger than the closure properties proved there for the ceilings over  $V_\kappa$ : source 32's  $\kappa^{\delta_A} = \delta_A$  (theorem XVI.8.9), source 33's  $\omega^{\delta_G} = \kappa^{\delta_G} = \delta_G$  (corollary XVI.8.17), and their extension to transitive  $\beta$ -models in the [merge] paragraph before corollary XVI.8.17. An epsilon number  $\delta > \kappa$  need not satisfy  $\varepsilon_\delta = \delta$  (for example  $\varepsilon_{\kappa+1}$ ), while  $\varepsilon_\delta = \delta > \kappa$  gives  $\omega^\delta = \kappa^\delta = \delta$  by the computation in the proof of theorem XVII.6.6. Second, it holds for every transitive  $M \models \text{ZFC}$ , with no  $\beta$ -hypothesis and no inaccessibility, and it adds the lower bound  $\zeta_{\kappa+1} < \mathfrak{H}_0(M)$  through the parameter-free order of theorem XVII.6.7. It proves source 32's remark after corollary XVI.8.11 that “closure under hereditary finite term formation gives further necessary restrictions” (also in source 32's question research question 113.284), in this precise form. The cofinality  $\text{cf}(\mathfrak{H}_0(M)) = \omega$  is source 34's statement on  $\mathcal{S}_0^L$  in proposition XVI.8.2. Dated notes at research questions 113.284 and 113.285 record the advance.

## XVII.6.6 Full classes and the admissible upper bound

**Proposition XVII.6.12** (The full-class calibration). *Let  $\kappa$  be inaccessible in the ambient universe. In the full class realization*

$$(V_\kappa, \mathcal{P}(V_\kappa)),$$

*the external order types of internally proper class well-orders are exactly  $[\kappa, \kappa^+)$ .*

*Proof.* Here  $|V_\kappa| = \kappa$ . Regularity ensures that a class function on an internal set has a set-sized, rank-bounded image in  $V_\kappa$ ; all subclasses are available. Thus the usual class-theoretic arguments apply, including the initial-Ord argument of Theorem XVII.6.9. A proper class well-order has type at least  $\kappa$  and cardinality at most  $\kappa$ , hence type below  $\kappa^+$ .

Conversely, if  $\kappa \leq \alpha < \kappa^+$ , choose an external bijection  $V_\kappa \rightarrow \alpha$ . Pulling back the ordinal order gives a relation on  $V_\kappa$ . Its ordered-pair codes belong to  $V_\kappa$ , so the relation is an admitted class in the full realization. Its carrier is proper and its type is exactly  $\alpha$ .  $\square$

This cutoff is an external ordinal. It is not a new member of  $V_\kappa$  or a set of all its class order types. The comparison with  $\mathfrak{H}(V_\kappa) < \kappa^+$  also shows that definable classes and all classes have different spectra even over the same set universe.

*Note XVII.6.C* ([merge]; the full-class spectrum). Proposition XVII.6.12 is source 12's theorem 21.1 (iv) (Part V; at every limit height, source 31's theorem XV.9.3) and source 34's theorem XVI.8.1, proved again by sources 35, 32 and 33 (notes XVI.8.5, XVI.8.8 and XVI.8.15); the proof is the same.

There is a finer historical bound. If  $A$  is an admissible transitive set containing  $M$  as an element, then

$$\mathfrak{H}(M) \leq \text{Ord} \cap A. \quad (\text{S36.6.2})$$

Indeed, satisfaction for the *set structure*  $M$  is available in  $A$  by admissible recursion. Each specified definable carrier and relation is therefore an element of  $A$ . An externally well-founded one has its ordinal collapse in  $A$ , by the well-founded recursion theorem for admissible sets. Each individual type is thus below the height of  $A$ ; taking the external supremum proves (S36.6.2). Applying this to the least admissible set above  $M$  gives the bound discussed by Blass [100].

Sharpness requires care. The cited discussions distinguish closure conditions giving a strict bound from examples giving equality; Taranovsky supplies equality examples in [101]. We do not claim a new resolution of that earlier existence question. Nor do we identify  $\mathfrak{H}(M)$  with a supremum over arbitrary computable presentations of  $M$ , whose formulation requires a precise choice of quantifiers and coding. The results proved here use explicit class presentations, ordinary external order types, and stated parameter budgets throughout.

[merge] (4 October 2026.) The admissible bound (S36.6.2) rests on the theorem that a well-founded relation which is an element of an admissible set has its rank below the height of that set; source 36 sketches it and credits Blass. With proposition XVII.8.1 (the unrolling height  $\kappa^+$  of the full model) it is the first comparison of a definability cutoff with admissible and unrolling heights that source 34's agenda item research question 113.283 asks for; the identification of  $\mathfrak{H}(M)$  stays open (source 36's research question 113.302). The MathOverflow discussions cited here were not checked by this write.

## XVII.7 Uniform notation systems and definability horizons

The preceding constructions supply long, explicit orders. We now ask how their lengths compare with *all* presentations available in a specified language. There are two complementary answers. Internally, a uniform family can always be surpassed by another class well-order. Externally, over a fixed set universe, definable presentations have an exact ordinal cutoff. At an inaccessible-height universe with a named global enumeration, this cutoff has countable cofinality, and allowing arbitrary set parameters does not increase the supremum already approached by parameter-free presentations.

The dependence on the available classes is a central feature of second-order set theory and class-theoretic potentialism [35, 84]. Here we isolate it in explicit constructions and prove the resulting bounds. The arguments do not require a converse to the known implication from elementary transfinite recursion to comparison of arbitrary class well-orders.

### XVII.7.1 The obstruction to a uniform universal notation system

An order embedding throughout this subsection is simply a strictly increasing injection; its image need not be an initial segment. This weaker notion makes the obstruction stronger.

**Lemma XVII.7.1** (A well-order cannot absorb an appended point). *In GB, if  $A$  is a class well-order, there is no order embedding  $A + 1 \rightarrow A$ .*

*Proof.* First observe that every increasing class map  $f : A \rightarrow A$  satisfies  $a \leq_A f(a)$  for every  $a \in A$ . Otherwise the class of counterexamples has a least member  $a$ . Put  $b = f(a) <_A a$ . Leastness gives  $b \leq_A f(b)$ , whereas monotonicity gives

$$f(b) <_A f(a) = b,$$

a contradiction.

Now suppose  $f : A + 1 \rightarrow A$  were an embedding, and let  $*$  be the appended point. Its image  $b = f(*)$  belongs to  $A$ . Applied to the restriction of  $f$  to  $A$ , the observation gives  $b \leq_A f(b)$ . But  $b <_{A+1} *$  gives  $f(b) <_A f(*) = b$ . These inequalities contradict each other. The same argument includes the empty case, in which  $f(*) \in A$  is already impossible.  $\square$

*Note XVII.7.A* ([merge]; the successor obstruction). [Lemma XVII.7.1](#) is source 34's [lemma XVI.3.2](#), with the same proof (an increasing self-map is inflationary), as are source 35's [lemma XVI.2.5](#) and [note XVI.7.7](#), source 32's [note XVI.2.10](#) and source 33's [notes XVI.2.15](#) and [XVI.2.16](#).

**Theorem XVII.7.2** (Uniform diagonal obstruction). *Work in GB. Let  $I$  be a class well-order, and let  $(A_i)_{i \in I}$  be a uniformly class-coded family of class well-orders. Then*

$$\mathcal{D} = \sum_{i \in I} (A_i + 1) \tag{S36.7.1}$$

*is a class well-order which does not order-embed into any  $A_i$ . Consequently, in GBC, no uniformly class-coded family indexed by an arbitrary class is cofinal in all class well-orders under order embeddability.*

*Proof.* Uniform coding means that one class specifies all pairs  $(i, x)$  with  $x \in A_i$ , and another specifies all triples  $(i, x, y)$  satisfying  $x <_{A_i} y$ . Thus tagged pairs and elementary comprehension construct  $\mathcal{D}$ . To find the least element of a nonempty subclass of  $\mathcal{D}$ , first find the least index at which it meets a block, and then its least element in that block. Hence  $\mathcal{D}$  is well-ordered.

If  $e : \mathcal{D} \rightarrow A_i$  were an embedding, its restriction to the  $i$ -th block would embed  $A_i + 1$  into  $A_i$ , contradicting [Lemma XVII.7.1](#).

For the last assertion, global choice places any class of indices in a set-like class well-order: restrict a global enumeration of the universe to that class. Apply the first assertion using this index order. If the family were cofinal, some member would have to receive an embedding of  $\mathcal{D}$ , which has just been excluded.  $\square$

The theorem addresses a precise form of notation system. Suppose the valid notations form an available class  $N$  of sets, and one available class relation uniformly evaluates their carriers and orders. If every evaluation is a well-order, the represented orders cannot be cofinal in all class well-orders. Neither quotienting by isomorphism nor allowing several notations for one order avoids the argument.

The hypotheses also identify the scope of the conclusion. An external enumeration of formulas is not automatically a class evaluator for their meanings. If proposed notations include ill-founded presentations, a uniform class of the valid codes is an additional requirement. Collections of class orders formed in a stronger surrounding universe are different objects from the same-level coded families considered here. Thus the obstruction rules out a universal evaluator at one level, while leaving systematic restricted calculi and extensions of the ambient language entirely available.

*Note XVII.7.B* ([merge]; the uniform-family diagonal). [Theorem XVII.7.2](#) is source 34's [theorem XVI.7.2](#) and [corollary XVI.7.3](#) (over GB, and GBC for the catalogue clause), with the same proof; it is also source 35's [note XVI.7.8](#) and [corollary XVI.7.9](#), source 32's [notes XVI.7.14](#) and [XVI.7.16](#) and source 33's [notes XVI.7.17](#) and [XVI.7.18](#), so it is now proved five times independently. Source 34 adds that  $\mathcal{D}$  is proper when  $I$  is. The earlier diagonal theorems of this report work at the level of relations ([theorems 19.37](#) and [19.38](#)); see the [merge] paragraph after [corollary XVI.7.6](#).

### XVII.7.2 An inaccessible-height universe with a named enumeration

For the remainder of this section, work in an external universe satisfying ZFC. Fix a strongly inaccessible cardinal  $\kappa$ , put  $M = V_\kappa$ , and let  $G$  be a predicate coding a bijection

$$G : \kappa \longrightarrow V_\kappa.$$

The graph of this bijection is coded by a subset of  $M$ . In the structure  $(M, \in, G)$ , its domain is the internal proper class  $\text{Ord}^M$ . Accordingly,  $\kappa$  is an external ordinal, not a set of  $M$ .

**Definition XVII.7.3.** Let  $\text{Spec}_G$  be the set of external ordinal order types of externally well-founded linear orders whose domains and relations are first-order definable in  $(M, \in, G)$ , allowing finite tuples of set parameters from  $M$ . Let  $\text{Spec}_G^0$  impose the additional requirement that no set parameters occur. Define the *definability horizon*

$$\mathfrak{H}_G = \sup \text{Spec}_G.$$

The word *parameter-free* here always refers to the expanded language with the named predicate  $G$ .

These are legitimate external sets of ordinals: there is a set of formulas and parameter tuples, and each interpreted carrier is a subset of the set  $M$ . We have not formed a class, inside  $M$ , whose members are proper classes or their isomorphism types.

**Lemma XVII.7.4** (Closure and correctness of the ambient model). *The structure  $(M, \text{Def}(M; G))$  satisfies GBC, and every class relation on  $M$  is externally well-founded if and only if it has no descending  $\omega$ -sequence coded by a set of  $M$ .*

*Proof.* Strong inaccessibility gives  $|V_\kappa| = \kappa$ , and if  $a \in V_\kappa$ , then  $|a| < \kappa$ . Every subset of  $a$  belongs to  $V_\kappa$ , so separation remains valid with  $G$  in the language. The image of  $a$  under any class function has fewer than  $\kappa$  members. Regularity bounds their ranks below  $\kappa$ , so that image also belongs to  $V_\kappa$ . This proves Class Replacement. Definable classes are closed under elementary comprehension, and  $G$  supplies global choice.

Every external countable sequence of elements of  $V_\kappa$  is a set in  $V_\kappa$ : regularity bounds the ranks of its entries below  $\kappa$ , and coding the sequence still gives rank below  $\kappa$ . In the external universe, an ill-founded relation on a set admits a descending  $\omega$ -sequence by dependent choice. Such a sequence for a relation on  $M$  therefore belongs to  $M$ . Conversely, a sequence in the transitive structure  $M$  witnessing descent witnesses actual external descent.  $\square$

The last assertion is what will make a definable validity filter sound. Transitivity alone does not suffice for this purpose: a countable transitive model can omit an external descending sequence. Our proofs below use the stated inaccessible-height hypotheses rather than silently treating an internal well-foundedness assertion as an external one.

*Note XVII.7.C* ([merge]; the inaccessible-rank model). [Lemma XVII.7.4](#) is source 32's [lemma XVI.8.7](#) (for  $\text{Def}(V_\kappa; \in, G, A)$  and for the full model), source 33's [note XVI.8.14](#) and source 34's  $\beta$ -model remark after [theorem XVI.8.1](#), with the same proof. Source 36's named predicate  $G$ , a bijection  $\kappa \rightarrow V_\kappa$ , is source 32's  $G$  and source 33's set-like global well-order  $G$  (the order induced by a bijection with  $\text{Ord}^M$ ).

**Theorem XVII.7.5** (The definable horizon). *Under these hypotheses,*

$$\text{Spec}_G = [0, \mathfrak{H}_G), \quad \kappa < \mathfrak{H}_G < \kappa^+, \quad \varepsilon_{\mathfrak{H}_G} = \mathfrak{H}_G. \quad (\text{S36.7.2})$$

Moreover,

$$\text{cf}(\mathfrak{H}_G) = \omega \quad \text{and} \quad \sup \text{Spec}_G^0 = \mathfrak{H}_G. \quad (\text{S36.7.3})$$

All ordinals and cofinalities in these displays are external.

We first verify (S36.7.2); the following subsections prove the more distinctive assertions (S36.7.3).

*Proof of the interval, bounds, and fixed-point assertion.* The parameter-preserving arguments of Theorem XVII.6.9 apply to the expanded language. In particular, an initial segment is defined using its endpoint as an additional set parameter, and appending a point shows that the spectrum has no maximum. Thus it is exactly  $[0, \mathfrak{H}_G)$ .

There are  $\kappa$  possible formula-and-parameter tuples. Every carrier has size at most  $\kappa$ , so every represented type is below the external successor cardinal  $\kappa^+$ . Its regularity implies  $\mathfrak{H}_G < \kappa^+$ . The definable presentation  $\text{Ord}^M + 1$  has type  $\kappa + 1$ , giving the strict lower bound.

The epsilon-term construction of Theorem XVII.6.4 preserves the allowed predicates and parameters. Therefore  $\alpha < \mathfrak{H}_G$  implies  $\varepsilon_\alpha < \mathfrak{H}_G$ . Since  $\mathfrak{H}_G$  is a limit, continuity of epsilon enumeration gives

$$\varepsilon_{\mathfrak{H}_G} = \sup_{\alpha < \mathfrak{H}_G} \varepsilon_\alpha \leq \mathfrak{H}_G.$$

The reverse inequality follows from  $\alpha \leq \varepsilon_\alpha$ , proving equality. The same constructions also give closure of  $[0, \mathfrak{H}_G)$  under ordinal sums, products, and powers. In particular  $\omega^{\mathfrak{H}_G} = \mathfrak{H}_G$ , and finite sums of ordinals below  $\mathfrak{H}_G$  remain below it.  $\square$

*Note XVII.7.D* ([merge]; the  $V_\kappa$  horizon theorem is a theorem of sources 32–34). Theorem XVII.7.5 is, apart from the clause  $\varepsilon_{\mathfrak{H}_G} = \mathfrak{H}_G$ , the definability-ceiling theorem that sources 32, 33 and 34 proved independently on 4 October 2026 and that Part XVI prints: source 32's theorem XVI.8.9 ( $S_A = [0, \delta_A)$ ,  $\kappa < \delta_A < \kappa^+$ ,  $\text{cf}(\delta_A) = \omega$ ,  $\kappa^{\delta_A} = \delta_A$ , for the language  $\{\in, G, A\}$ ; with  $A$  trivial,  $\delta_A = \mathfrak{H}_G$ ), source 33's note XVI.8.16 ( $\delta_G^0 = \delta_G$ ,  $\kappa < \delta_G < \kappa^+$ ,  $\text{cf}(\delta_G) = \omega$ ;  $\delta_G = \mathfrak{H}_G$  and  $\delta_G^0 = \sup \text{Spec}_G^0$ ) and source 34's proposition XVI.8.2, theorem XVI.8.3, and corollary XVI.8.4 ( $\Theta_L$  for  $L = \{\in, G\}$ , in every transitive  $\beta$ -model of GBC with a named global well-order). Source 36's is the fourth independent proof at  $V_\kappa$ , and source 35's theorem XVI.8.6 is the pure-language companion. Its route to the cofinality is source 33's: the bounded-complexity diagonals  $D_n$  (proposition XVII.7.6; theorem XVI.7.20); source 34 bounds each formula pair by its own parameter-free sum, source 32 uses diagonals of finite lists of formula pairs. New against Part XVI is  $\varepsilon_{\mathfrak{H}_G} = \mathfrak{H}_G$ , obtained from the epsilon-term functor, which strengthens source 32's  $\kappa^{\delta_A} = \delta_A$  and source 33's  $\omega^{\delta_G} = \delta_G$  as recorded after proposition XVII.6.11. Source 36's novelty sentences (Section XVII.1.5 and its title page) carry this credit in dated notes.

### XVII.7.3 A sound filter at every fixed formula complexity

Fix a standard natural number  $n$ , externally. Choose a nested syntactic complexity convention for first-order formulas, for example normalized Lévy complexity allowing both  $\Sigma_n$  and  $\Pi_n$  formulas. Every formula belongs to some finite level. At this one fixed level there is a first-order partial satisfaction formula  $\text{Sat}_n$  for  $(M, \in, G)$ . The subscript indexes a schema of formulas; no full uniform truth predicate is being assumed.

For completeness, partial truth here can be obtained by ordinary syntactic recursion at the metatheoretic level. Truth for bounded formulas is evaluated in a transitive set containing the parameters, with  $G$  restricted to that set. The restriction exists by amenability, and bounded truth is absolute between this set structure and  $M$ . Its satisfaction relation is a set constructed by ordinary set-valued recursion. For a normalized formula with a fixed finite number of unbounded quantifier

blocks, place the corresponding quantifiers over  $M$  in front of this bounded evaluation. Finite tuples encode a block containing several variables. Combining the two possible initial quantifier polarities yields the required  $\text{Sat}_n$ .

This construction is effective for each standard  $n$ , so the code of its output formula can be generated from  $n$ . It does not give one formula which correctly evaluates all levels at once: the unbounded quantifiers used at successive levels occur in the output formulas themselves. This distinction will be used both in the complexity hierarchy and in the truth-adjunction argument below.

For explicit coding, represent a class presentation by a unary predicate: entries  $\langle 0, x \rangle$  mark its domain, and entries  $\langle 1, x, y \rangle$  mark its strict order. An index  $u \in M$  codes a formula together with a finite parameter tuple. Partial satisfaction gives uniform candidate classes

$$\widehat{D}_{n,u}, \quad \widehat{R}_{n,u} \subseteq \widehat{D}_{n,u}^2.$$

Malformed syntactic codes are assigned empty candidates. Every presentation of the chosen complexity, with every allowed parameter tuple, occurs among these candidates.

Define  $\text{Valid}_n(u)$  to say that the candidate is a strict linear order and that

$$\neg \exists f \left[ f \text{ is a function with domain } \omega, \quad \text{ran}(f) \subseteq \widehat{D}_{n,u}, \right. \\ \left. \forall k \in \omega \quad f(k+1) \widehat{R}_{n,u} f(k) \right]. \quad (\text{S36.7.4})$$

All quantified objects in this formula are sets of  $M$ . Occurrences of the candidate predicates are replaced by the fixed formula  $\text{Sat}_n$ . Thus  $\text{Valid}_n$  is first-order in  $\{\in, G\}$ , although usually of greater complexity than the formulas being tested.

By Lemma XVII.7.4, the filter accepts precisely the externally well-founded candidates. Put

$$A_{n,u} = \begin{cases} (\widehat{D}_{n,u}, \widehat{R}_{n,u}), & \text{Valid}_n(u), \\ 0, & \text{otherwise.} \end{cases}$$

This is one uniformly definable family of genuine well-orders for the fixed  $n$ . Invalid formulas cause no problem because their entire block has been replaced by the empty order.

**Proposition XVII.7.6** (Bounded-complexity domination). *For each standard  $n$ , there is a parameter-free  $\{\in, G\}$ -definable class well-order*

$$D_n = \sum_{\xi \in \text{Ord}^M} (A_{n,G(\xi)} + 1) \quad (\text{S36.7.5})$$

whose external type  $\delta_n$  is strictly larger than every type presented at complexity level  $n$ , even when arbitrary finite set parameters are allowed in those presentations. Nevertheless  $\delta_n < \mathfrak{H}_G$ .

*Proof.* The preceding filter and the named enumeration  $G$  make the displayed sum a first-order definable presentation. Its index order and all its blocks are externally well-founded, so the sum is a well-order. A given level- $n$  presentation with its parameter tuple has some code  $u \in M$ , and  $u = G(\xi)$  for a unique  $\xi < \kappa$ . If its type is  $\alpha$ , the corresponding block has type  $\alpha + 1$ . Consequently  $\alpha < \delta_n$ , either by ordinary external ordinal comparison or by the obstruction in Theorem XVII.7.2.

The definition of  $D_n$  uses no set parameter: the standard  $n$  is compiled into the chosen partial satisfaction formula, and the remaining coding conventions are fixed. Thus  $\delta_n \in \text{Spec}_G^0 \subseteq \text{Spec}_G = [0, \mathfrak{H}_G)$ .  $\square$

This proposition explains why bounding the *number of set parameters* does not capture the decisive resource. Even a single fixed formula can range through arbitrarily many parameter values. Partial truth lets one collect all those values at a specified formula complexity; a modest increase in complexity then constructs an order exceeding all their types.

*Note XVII.7.E* ([merge]; the bounded-complexity diagonal is a theorem of sources 33–35). [Proposition XVII.7.6](#) is source 33’s [theorem XVI.7.20](#), by the same construction: a partial satisfaction formula for one fixed level (source 33’s [lemma XVI.7.19](#)), a first-order validity filter that is sound because the model is correct about well-foundedness, invalid candidates replaced by the empty order, and the tagged sum along  $G$ , with no set parameter. It is also source 34’s [corollary XVI.7.6](#) (internally, in GBC with named predicates) and source 35’s [note XVI.7.13](#); source 35’s [theorem XVI.7.11](#) is the pure-language form for orders on Ord with ordinal parameters. Source 33 states the domination by embeddings; source 36 by external order types, which at  $V_\kappa$  is the same by [lemma XVII.7.4](#).

#### XVII.7.4 Countable cofinality and the role of parameter-free syntax

Let

$$h_n = \sup\{\alpha + 1 : \alpha \text{ has a level-}n \text{ presentation with set parameters}\}. \quad (\text{S36.7.6})$$

The levels are nested, so  $h_n$  is nondecreasing. Every first-order definition has finite complexity, giving

$$\sup_{n < \omega} h_n = \mathfrak{H}_G.$$

[Proposition XVII.7.6](#) gives the sharper inequalities

$$h_n \leq \delta_n < \mathfrak{H}_G \quad (n < \omega). \quad (\text{S36.7.7})$$

Hence  $(\delta_n)_{n < \omega}$  is cofinal in  $\mathfrak{H}_G$ . Because  $\mathfrak{H}_G$  is a nonzero limit ordinal, this proves  $\text{cf}(\mathfrak{H}_G) = \omega$ . Since each  $\delta_n$  belongs to  $\text{Spec}_G^0$ , it simultaneously proves  $\sup \text{Spec}_G^0 = \mathfrak{H}_G$ , completing [Theorem XVII.7.5](#).

The parameter-free spectrum itself is not an interval. It has only countably many members externally, while it contains the type  $\kappa$  of  $\text{Ord}^M$ . It therefore omits many smaller external ordinals. Set parameters fill these gaps by naming endpoints; they do not raise the supremum beyond the cofinal parameter-free sequence just constructed.

**Corollary XVII.7.7** (An effective strict complexity hierarchy). *There is an effective function  $f : \omega \rightarrow \omega$ , with  $f(n) > n$ , such that*

$$h_n < h_{f(n)}.$$

*Thus an effective sequence of increasing finite complexity levels has strictly increasing spectrum bounds cofinal in  $\mathfrak{H}_G$ .*

*Proof.* The construction of the partial satisfaction formula, the validity test, and the tagged sum is an effective transformation of syntax. Read off a finite complexity bound for the resulting formula defining  $D_n$ , and increase it if necessary to obtain  $f(n) > n$ . Then  $\delta_n$  occurs at level  $f(n)$ , so

$$h_n \leq \delta_n < \delta_n + 1 \leq h_{f(n)}.$$

Starting at any level and iterating  $f$  gives a strictly increasing, unbounded sequence of natural-number levels, hence a cofinal sequence of their bounds.  $\square$

This statement avoids attaching significance to a numerical syntax overhead. With a fixed conventional prenex coding, the construction uses bounded truth followed by fixed formula templates, so one can audit a finite shift bound. The effective function formulation is enough for every mathematical conclusion above and is independent of such implementation choices.

[merge] [Corollary XVII.7.7](#) is new to this report in this form. Source 35's [corollary XVI.7.12](#) and [theorem XVI.7.11](#) separate definability levels for orders on  $\text{Ord}$  in the pure language, and source 35 claims no separation of two consecutive levels; source 36 claims none either, since  $f$  is effective but not computed. The height  $h_n$  is a supremum of  $\alpha + 1$ , which gives the strict inequality used in the proof (as the Hilbert's-tenth review notes); it is not source 20's height function  $h_\kappa$  of [corollary 108.3](#).

**Proposition XVII.7.8** (No uniform evaluator for the cofinal schema). *The sequence of definitions  $D_n$  can be generated effectively as syntax, but no first-order formula over  $(M, \in, G)$ , even with finitely many set parameters, uniformly evaluates presentations of all the  $D_n$ .*

*Proof.* Such an evaluator would make  $\sum_{n < \omega} (D_n + 1)$  a single definable class well-order. Its external type is at least  $\sup_n \delta_n = \mathfrak{H}_G$ , because it contains a copy of every summand. This contradicts  $\text{Spec}_G = [0, \mathfrak{H}_G)$ .  $\square$

There is therefore no conflict between the external countable cofinality and the internal diagonal obstruction. The external sequence lists definitions and their interpreted types. The class universe  $\text{Def}(M; G)$  does not contain a uniform semantic evaluation of that sequence. In particular, the countable cofinality of  $\mathfrak{H}_G$  does not supply an internal set sequence of ordinals approaching  $\text{Ord}^M$ : the entries  $\delta_n$  are external types beyond the internal ordinal range.

*Note XVII.7.F* ([merge]; no uniform evaluator). [Proposition XVII.7.8](#) is source 32's [corollary XVI.8.13](#), source 33's [corollary XVI.7.22](#) and the subsection of source 34 after [corollary XVI.8.4](#) (“Why the cofinal family does not create a largest notation”), with the same argument; the paragraph after it is source 33's [remark XVI.8.18](#).

### XVII.7.5 Truth makes the old horizon presentable

Let  $T$  be a full first-order satisfaction predicate for the structure  $(M, \in, G)$ , including assignments of finite tuples from  $M$ . It exists as an external subset of  $M$ , and hence among the full classes. Write  $\mathfrak{H}_{G,T}$  for the horizon obtained by allowing  $T$  as an additional named predicate. All the preceding arguments apply to this expanded language:  $G$  still supplies the enumeration, and the ambient closure properties are unchanged.

**Theorem XVII.7.9** (Truth promotion). *There is a parameter-free  $\{\in, G, T\}$ -definable class well-order of external type exactly  $\mathfrak{H}_G$ . Consequently*

$$\kappa < \mathfrak{H}_G < \mathfrak{H}_{G,T} < \kappa^+. \quad (\text{S36.7.8})$$

*Proof.* Choose the partial satisfaction formulas effectively, so that there is a recursive map  $n \mapsto d(n)$  giving the code of the formula defining the tagged presentation  $D_n$ . The natural numbers of  $M = V_\kappa$  are standard. Thus this syntactic map has its usual arithmetical definition inside  $M$ , and  $T$  evaluates the formula with code  $d(n)$  on any given assignment. The entire family  $(D_n)_{n < \omega}$  is now uniformly first-order definable using the predicate  $T$ .

Form

$$E_G = \sum_{n < \omega} (D_n + 1). \quad (\text{S36.7.9})$$

Its external type is

$$\lambda = \sup_{m < \omega} \sum_{n < m} (\delta_n + 1).$$

Every finite partial sum is below  $\mathfrak{H}_G$ , by closure of  $\text{Spec}_G$  under successor and finite addition. Hence  $\lambda \leq \mathfrak{H}_G$ . Conversely the sum contains every  $D_n$ , so  $\lambda \geq \sup_n \delta_n = \mathfrak{H}_G$ . Therefore  $\lambda = \mathfrak{H}_G$ .

The definition uses only the named predicates  $G, T$ ; no set parameter is required. It follows that  $\mathfrak{H}_G \in \text{Spec}_{G,T}$ , and the initial-segment description of that spectrum gives  $\mathfrak{H}_G < \mathfrak{H}_{G,T}$ . Its upper bound is the same cardinal counting argument used in Theorem XVII.7.5.  $\square$

This is a precise way in which additional definitional resources extend length. A truth predicate converts the former cutoff into one presented order, after which successor and the other constructors continue beyond it. The theorem also gives another proof that such a full  $T$  is not definable from  $G$  and finitely many set parameters: otherwise the two horizons would coincide.

*Note XVII.7.G* ([merge]; truth promotion is source 32's exact truth presentation). Theorem XVII.7.9 is source 32's theorem XVI.8.12, proved independently on the same day: a full satisfaction predicate makes the diagonal family uniform, and the  $\omega$ -sum (S36.7.9) (source 32's  $L$ , (S32.17)) has type exactly the old ceiling. Source 32's  $T_A$  is the truth predicate for  $(V_\kappa, \in, G, A)$ , which is source 36's  $T$  when  $A$  is trivial; its diagonals are those of finite lists of formula pairs, source 36's those of the complexity levels. Source 33's theorem XVI.8.19 gives the strict jump with  $\text{cf}(\delta_{G,T}) = \omega$  but not the exact presentation, and source 34's theorem XVI.7.4 gives, internally and from an assumed full satisfaction class, an order dominating every definable one. Source 36's order  $E_G$  is a sum of diagonal orders; it is not a stage equivalence  $E_i$  of Section XVI.5. Source 36's closing remark, that  $T$  is not definable from  $G$  with set parameters, is also made by source 32. The size of the jump stays open (research question 113.298).

### XVII.7.6 The horizons are unbounded when the enumeration varies

The upper bound  $\kappa^+$  is independent of  $G$ , but no smaller external ordinal bounds all the  $\mathfrak{H}_G$ . The following coding argument shows this without any appeal to class recursion.

**Lemma XVII.7.10** (Encoding a predicate by adjacent swaps). *For every external  $A \subseteq \kappa$ , there is a bijection  $G_A : \kappa \rightarrow V_\kappa$  from which  $A$  is first-order definable without set parameters.*

*Proof.* For each  $\xi < \kappa$ , reserve input positions  $4 \cdot \xi, 4 \cdot \xi + 1$  and output ordinals  $2 \cdot \xi, 2 \cdot \xi + 1$ . Here the finite factor is on the *left* in ordinal multiplication. Define

|                |                    |                        |
|----------------|--------------------|------------------------|
|                | $G_A(4 \cdot \xi)$ | $G_A(4 \cdot \xi + 1)$ |
| $\xi \notin A$ | $2 \cdot \xi$      | $2 \cdot \xi + 1$      |
| $\xi \in A$    | $2 \cdot \xi + 1$  | $2 \cdot \xi$          |

Ordinal division by a positive finite left factor uniquely partitions  $\kappa$  into these finite blocks. Thus the specified positions map bijectively onto  $\text{Ord} \cap V_\kappa = \kappa$ .

The remaining positions  $\{4 \cdot \xi + 2, 4 \cdot \xi + 3 : \xi < \kappa\}$  have cardinality  $\kappa$ . So does  $V_\kappa \setminus \text{Ord}$ : for example,  $\xi \mapsto \{\xi\}$ , for  $0 < \xi < \kappa$ , gives  $\kappa$  distinct nonordinals. Fill the remaining positions by any external bijection onto this complement. This completes  $G_A$  to the required bijection.

The decoding formula is simply

$$\xi \in A \iff G_A(4 \cdot \xi) = 2 \cdot \xi + 1.$$

All ordinal operations appearing here are definable in  $M$ , and no additional parameter occurs.  $\square$

**Theorem XVII.7.11** (Unbounded variation of the horizon). *As  $G$  ranges over all external bijections  $\kappa \rightarrow V_\kappa$ ,*

$$\sup_G \mathfrak{H}_G = \kappa^+.$$

*Indeed, every  $\alpha$  with  $\kappa \leq \alpha < \kappa^+$  is the type of a parameter-free  $G$ -definable class well-order for some such  $G$ .*

*Proof.* Fix  $\alpha$  in the stated interval. Its cardinality is  $\kappa$ , so there is an external well-order  $R$  on  $\kappa$  of type  $\alpha$ . Choose the standard parameter-free ordinal pairing  $\pi : \text{Ord}^2 \rightarrow \text{Ord}$ , obtained by ordering pairs first by their maximum coordinate and then lexicographically, and assigning to each pair the type of its predecessor set. Its restriction maps  $\kappa^2$  bijectively onto  $\kappa$ . To check this last point, predecessor sets of pairs below  $\kappa$  have cardinality below  $\kappa$ , while a pair with a coordinate at least  $\kappa$  has at least  $\kappa$  predecessors. The same pairing is computed correctly in the transitive structure  $V_\kappa$ .

Encode  $R$  by

$$A = \{\pi(\xi, \eta) : \xi R \eta\} \subseteq \kappa,$$

and apply Lemma XVII.7.10. In the language with  $G_A$ , the carrier  $\text{Ord}^M$  and the relation

$$\xi R \eta \iff G_A(4 \cdot \pi(\xi, \eta)) = 2 \cdot \pi(\xi, \eta) + 1$$

are parameter-free definable. Hence  $\alpha \in \text{Spec}_{G_A}^0$ , so  $\alpha < \mathfrak{H}_{G_A}$ . Such  $\alpha$ 's are cofinal in  $\kappa^+$ , and every individual  $\mathfrak{H}_G$  is below  $\kappa^+$  by Theorem XVII.7.5.  $\square$

Thus the fixed-point and countable-cofinality restrictions on an individual horizon coexist with an unbounded range of possible horizons. A named global enumeration need not be mathematically neutral: its ordering of the universe can encode substantial additional information.

[merge] (4 October 2026.) Lemma XVII.7.10 and theorem XVII.7.11 are new to this report. Source 32's corollary XVI.8.11 proves  $\sup_A \delta_A = \kappa^+$  by keeping  $G$  fixed and adding a predicate  $A$  that codes a well-order of the required type; source 36 varies the named enumeration itself, with no further predicate and no set parameter, by coding any  $A \subseteq \kappa$  into  $G$  through adjacent swaps. This answers source 33's research question research question 113.286, which asks how much  $\delta_G$  can vary as  $G$  ranges over set-like global well-orders of one  $V_\kappa$  and what information such a  $G$  can carry:  $\delta_G = \mathfrak{H}_G$  is unbounded in  $\kappa^+$ , every subset of  $\kappa$  can be coded into  $G$ , and every  $\alpha \in [\kappa, \kappa^+)$  is the type of a parameter-free  $G$ -definable order for some  $G$ ; which values  $\mathfrak{H}_G$  itself takes stays open (research question 113.295). The  $G$  here is a bijection  $\kappa \rightarrow V_\kappa$ , which induces a set-like global well-order of type  $\text{Ord}$  as source 33 requires. The dated note at research question 113.286 records this.

### XVII.7.7 Comparison with the full-class cutoff

Proposition XVII.6.12 gives the exact full-class spectrum of proper carriers,  $[\kappa, \kappa^+)$ . Including set carriers adds precisely the types below  $\kappa$ , so the spectrum of all class presentations is  $\text{Spec}_{\text{full}} = [0, \kappa^+)$ .

The set universe has remained  $V_\kappa$  throughout. With definable classes and a fixed  $G$ , the exact cutoff is  $\mathfrak{H}_G < \kappa^+$ ; adding truth presents that old cutoff and strictly raises it; allowing all classes reaches every type below  $\kappa^+$ . None of these cutoffs is itself an ordinal of  $V_\kappa$ . They are external measurements of the lengths carried by its class presentations, which is the distinction needed to speak rigorously about how far those presentations stretch beyond  $\text{Ord}^M$ .

## XVII.8 Rigorous formalization choices

Different formalizations answer different questions. A useful foundation must specify what its classes are, which maps are available, and whether a claimed well-order is internal or externally well-founded. Increasing the number of sorts or the universe level changes what counts as a set; it does not create a contradiction with the original set–class boundary.

### XVII.8.1 First-order ZFC and formula schemas

For a fixed first-order definition, ZFC is often sufficient. A presentation consists of formulas  $D(x, p)$  and  $R(x, y, p)$ . A construction such as sum, product, or finite-support power produces new formulas effectively from these particular inputs. A proof that every set subset of the defined order has a least element is an ordinary first-order proof. Instances involving another definable subclass are obtained by substituting its defining formula.

This framework is suitable for an executable library of individual constructions. It does not contain one object that is the collection of all proper-class order types. A natural number coding a formula is a set, but its semantic interpretation over the entire universe is not uniformly first-order definable. Formula syntax, semantic truth, and proof certificates must be represented separately.

Set parameters must also be part of the specification. A definition using an arbitrary set parameter is different from a parameter-free definition, and a named class predicate is a stronger resource than either. If a predicate is added to the first-order language, Separation and Replacement in that expanded language must be justified. At the inaccessible-height models used in the horizon theorem, this justification was explicit.

### XVII.8.2 GB, NBG, and admitted class maps

A two-sorted class theory is the most economical setting for the elementary calculus. Its objects are sets and classes; members of classes are sets. A function between class carriers is represented by a class graph of set-coded pairs. These data support all the constructions in the arithmetic and epsilon sections.

The notations GB, NBG, and GBC occur with different choice conventions in the literature. Here GB includes Power Set and Class Replacement, but does not include Choice by abbreviation. GBC adds Global Choice. This prevents a notation convention from silently strengthening a theorem.

There is an additional issue with order types. Two abstract class presentations can be externally isomorphic even when the isomorphism is not an admitted class in the chosen model. Accordingly, a formal interface should store an explicit comparison map when a theorem uses one. An external equality of order types is not automatically a usable internal class isomorphism.

The elementary constructors have a convenient implementation contract: the output domain, order, and each displayed isomorphism are given by a formula relative to the supplied input classes. They do not invoke an unspecified choice of representatives of class-isomorphism types.

### XVII.8.3 What elementary transfinite recursion adds

Elementary transfinite recursion concerns a family whose stages are *classes*. For a class well-order  $\Gamma$ , a typical instance asks for a class  $F$  satisfying

$$F_\gamma = \{x : \varphi(x, \gamma, F \upharpoonright \Gamma_{<\gamma}, A)\}, \quad \gamma \in D_\Gamma,$$

where  $\varphi$  has only set quantifiers and  $A$  is a fixed class parameter. The history supplied to a stage can itself be a proper class.

This is substantially different from evaluating a finite tree. Even an  $\omega$ -length class-valued recursion can assemble truth by formula depth; bare GBC does not supply a full first-order truth predicate. The explicit finite syntax used in this article avoids that extra requirement.

Over GBC, full ETR is equivalent to determinacy for clopen class games [22]. This connection helps locate class recursion within the broader landscape of principles for class constructions.

A useful established theorem is that  $\text{GBC} + \text{ETR}_\Gamma$  compares the fixed  $\Gamma$  with every class well-order [35, Lemma 3.17]. The recursion tries to map each point of  $\Gamma$  to the least target point not used earlier. If it never runs out of target points, it gives an initial embedding of  $\Gamma$ . If it does run out, its inverse on the completed domain gives an initial embedding in the other direction. Thus full ETR implies class-well-order comparability.

The known implication chain includes

$\text{ETR} \implies \text{continuous rankings} \implies \text{initial comparability} \implies \text{weak embeddability comparability}.$

The question of converses is explicitly posed by Hamkins and Woodin [27, Question 7]. We do not identify these principles here. The more specific principle  $\text{ETR}_{\text{Ord}}$  is the exact strength of the class forcing theorem [24]; having recursion at that length should not be silently treated as recursion along every longer class well-order.

[merge] Hamkins and Woodin’s Question 7 is source 29’s [research question 113.219](#) and the second theme of [section 113.28](#); over GB, comparability CWO is equivalent to canonical histories and to source 35’s FPE (theorems XVI.5.8 and XVI.6.21 and corollary XVI.6.19). Source 36 asks it again as its tenth question ([research question 113.304](#)).

| Framework                 | Appropriate role                                                                                                                |
|---------------------------|---------------------------------------------------------------------------------------------------------------------------------|
| Fixed ZFC formulas        | Individual definable carriers, finite syntax, and formula-by-formula theorems.                                                  |
| GB                        | Elementary class arithmetic, set localization, explicit class isomorphisms, and the finite-term systems of this article.        |
| GBC                       | The same constructions with a supplied global enumeration for uniform indexing of arbitrary set codes.                          |
| GBC +ETR                  | General elementary class-valued recursion and comparison of arbitrary class well-orders.                                        |
| KM                        | Impredicative comprehension and stronger class constructions; still no ordinary class with arbitrary proper classes as members. |
| KM + Class Collection     | The stronger unrolling theorem described next.                                                                                  |
| External transitive model | Ordinary ordinal measurements of class presentations, with external well-foundedness explicitly checked.                        |
| Higher type universe      | Set-sized implementations of lower-universe class presentations and their order types.                                          |

## XVII.8.4 Unrolling and a concrete larger universe

Unrolling treats suitable well-founded extensional class relations as membership codes for new objects. This is a principled way for a proper class of one universe to become a set in another.

The strong classical result uses KM together with Class Collection. In this statement, KM has ZFC, including Choice, as its set theory, following the convention of the cited source. As stated in the modern account of Freire and Williams [96, Theorem 2.1.1], this theory is bi-interpretable with ZFC without Power Set, with Collection in the weak-set-theory axiomatization, Choice expressed as the assertion that every set can be well-ordered, and a largest cardinal that is inaccessible. The Class Collection hypothesis and the Collection convention in the first-order theory are material; simply deleting Power Set from a Replacement-only axiom list does not specify the same theory.

For the full rank model, the construction has a particularly transparent external description.

**Proposition XVII.8.1** (The full unrolling at an inaccessible height). *Let  $\kappa$  be strongly inaccessible. The externally interpreted unrolling of  $(V_\kappa, \mathcal{P}(V_\kappa))$  is  $H_{\kappa^+}$ , the sets whose transitive closures have cardinal at most  $\kappa$ . Its ordinal height is  $\kappa^+$ .*

*Proof.* A class membership code has its nodes in  $V_\kappa$ , so it has at most  $\kappa$  nodes externally. A well-founded extensional code has its ordinary external Mostowski collapse. The transitive closure of the object represented by its designated root has cardinal at most  $\kappa$ ; hence the object belongs to  $H_{\kappa^+}$ .

Conversely, if  $x \in H_{\kappa^+}$ , the membership relation on the transitive closure of  $\{x\}$  has at most  $\kappa$  nodes. Transport it to a subset of  $V_\kappa$ , designating the node corresponding to  $x$ . All the resulting relations are available in the full class collection. The external collapse recovers  $x$ . The usual identification of isomorphic codes therefore gives exactly  $H_{\kappa^+}$ . Its ordinal members are precisely the ordinals below  $\kappa^+$ .  $\square$

This explains the full-class cutoff from another direction. A class well-order of external type  $\alpha$ , with  $\kappa \leq \alpha < \kappa^+$ , becomes an ordinary ordinal in the unrolled universe. It was never an ordinal set of the original  $V_\kappa$ . Power Set fails at  $\kappa$  in the unrolled universe: each subset of  $\kappa$  is present, but the collection of all of them is too large to be one of its sets.

[merge] Proposition XVII.8.1 is a standard computation, new to this report as a stated proposition; source 34 discusses unrolling without it (section XVI.10), and source 33 asks about unrolled order codes (research question 113.276). The account of Freire and Williams [96] is cited as source 36 states it and was not checked by this write.

### XVII.8.5 Universes and proof assistants

A universe hierarchy gives another rigorous implementation. In a Lean-style notation, the type of  $u$ -small ordinals lives one universe level higher:

$$\text{Ordinal}_u : \text{Type}_{u+1}.$$

Viewed from the next level, its natural well-order has an ordinary order type

$$\Omega_u = \text{otp}(\text{Ordinal}_u, <) \quad \text{in} \quad \text{Ordinal}_{u+1}.$$

The sums, products, finite-support powers, and finite trees can then be implemented as ordinary types at the larger level. Increasing a universe level makes the previously proper collection small relative to the new level. It does not provide a single type of ordinals containing every universe's ordinals.

[merge] Here  $\Omega_u$  is an ordinal of the next universe level, the order type of  $\text{Ordinal}_u$ ; it is not the presentation  $\Omega = (\text{Ord}, \in)$  of this Part (source 36 writes the latter in bold and  $\Omega_u$  in light face). Mathlib's corresponding declarations are discussed in Section XVI.10 (source 32's section XVI.10.7).

There are two distinct verification targets.

1. **External typed orders.** Implement the finite syntax and interpret it in a larger ordinal type. Prove that the comparator agrees with that interpretation. This gives genuine well-foundedness in the ambient proof assistant.
2. **Internal class theory.** Formalize a first-order set model  $M$ , a class realization  $\mathcal{X}$ , and the evaluation relation between them. Then prove the GB theorems about admitted presentations and admitted maps. Internal well-foundedness must use that interpretation, rather than being silently replaced by the proof assistant's external well-foundedness predicate.

The first target is considerably smaller and provides a practical first milestone. The second is required for the exact foundational-strength claims and the comparison of different class realizations.

The following proposed modules make the dependencies explicit. These are design targets, not assertions that corresponding files have already been added to ProveIt.

| Proposed module                     | Mathematical responsibility                                                                                    |
|-------------------------------------|----------------------------------------------------------------------------------------------------------------|
| <code>ClassOrderPresentation</code> | Carrier and relation data, set-likeness, admitted embeddings, and the set-subset well-foundedness formulation. |
| <code>FiniteSupportPower</code>     | Finite support representation, comparison, power laws, predecessor decomposition, and set-likeness criterion.  |
| <code>OmegaNormalForm</code>        | Hereditary syntax, validity, comparison, local radix semantics, tower cuts, addition, and multiplication.      |
| <code>EpsilonTerms</code>           | Epsilon atoms, mixed comparison, exact set semantics, and finite-support transfer to classes.                  |
| <code>DefinabilityHorizon</code>    | Transitive-model spectra, partial satisfaction, bounded-complexity diagonalization, and truth promotion.       |

ProveIt's existing ListCoding documentation reports a common hereditary Cantor-normal-form coding below  $\varepsilon_0$ , with Lean denotation theorems and separately scoped Rocq syntactic results [94]. That is a natural source of engineering patterns. Its current theorem statements are not automatically theorems about proper classes. Mathlib's general-base Cantor normal form is a directly relevant set-level component [99].

[merge] (4 October 2026.) None of the five proposed modules exists in the repository, and no statement of Part XVII is formalized (section 1.5). The ListCoding documentation is `Logi c/PeanoArithmetic/ListCoding/README.md`; it describes the hereditary codes below  $\varepsilon_0$ , the Lean denotation theorems and the separately scoped Rocq results as source 36 says. Mathlib's `Mathlib/SetTheory/Ordinal/CantorNormalForm.lean` is in the Mathlib version this repository pins. The formalization plans of Part XVI's sources (sections XVI.10 and XVI.10.9) propose comparable first milestones.

### XVII.8.6 A contract for systematic notations

A reusable class-order notation should state five items.

1. Its input signature: ordinal labels, set parameters, named class predicates, or supplied class orders.
2. The set codes representing its points, together with a normality test.
3. The comparison procedure and the hypotheses needed for well-foundedness.
4. Its semantic coverage: a precise initial segment or a family of presentations, not an unspecified claim to represent every long ordinal.
5. Its map discipline: which isomorphisms, embeddings, or normalization functions are explicitly definable from the inputs.

Our  $A^{[B]}$ ,  $E$ , and  $\text{Ep}(B)$  satisfy this contract. The polynomial display for a point of  $A^{[B]}$  denotes its predecessor presentation. The whole notation class is a separate object. A proposed Veblen or collapsing-function extension should follow the same contract before its printed expressions are used as if they were established class ordinal arithmetic.

## XVII.9 Further research questions and topics

[merge] Source 36's introduction to its questions and its ten research questions (its lines 2519–2635) are printed with the other sources' questions in [section 113.30](#), each with its status after this write; the questions of this report that it answers or advances are in [section 113.31](#). Its closing subsection follows.

### XVII.9.1 A concrete next formalization project

A manageable first project is to formalize the hereditary term comparator, its local radix theorem, and root decomposition. The next stage adds the epsilon grammar and support transfer. These results would certify a long, explicit class-notation family without first formalizing all of KM or settling general class comparison.

The horizon theorem is a separate model-theoretic project. Its first formal milestone should be the external theorem for  $V_\kappa$  with a named  $G$ : downward closure of the spectrum, the cardinal bound, the sound partial-truth filter, and the diagonal sequence. This keeps the genuine semantic difficulty visible instead of burying it in a notation parser.

## XVII.10 Proof status, source audit, and reproducibility

### XVII.10.1 What was checked mathematically

The main statements were developed with separate reviews of class arithmetic, finite syntax, external spectra, and the bounded-complexity argument. A further independent review checked the inaccessible-height horizon theorem, truth promotion, and the epsilon and zeta extensions. The final article distinguishes assertions about admitted class maps from equalities of external ordinal order types.

Several hypotheses are especially important to the proofs:

- The choice-free localization argument is a GB argument with Power Set. It uses rank sets and Class Replacement.
- The ordinal labels in hereditary terms are leaves of a finite syntax tree. Recursion is not performed on their possibly infinite transitive closures.
- An arbitrary transitive model need not recognize external ill-foundedness of its class relations. Every  $\mathfrak{H}(M)$  spectrum in the article uses external well-foundedness.
- The bounded-complexity validity filter is externally sound at  $V_\kappa$  because  $\kappa$  is inaccessible. This hypothesis is not silently dropped.
- Parameter-free cofinality in the  $G$ -theorem means no *set* parameters in the language already naming  $G$ . It does not mean that every represented type has a parameter-free presentation.
- The diagonal formulas form an effective syntactic schema. Their interpretations are not supplied by one formula before truth is added.
- General class powers are constructed, but a complete power-normalization algorithm on hereditary point-cuts is not claimed.

These checks are conventional mathematical review, not external refereeing or proof-assistant certification. The code checks described next have a strictly finite scope.

### XVII.10.2 The executable notation demonstrator

The file `code/notation_demo.py` implements the natural-coefficient fragment of the hereditary  $\Omega$ -term syntax. Terms are immutable tuples of exponent–coefficient pairs. The empty tuple represents zero. The program validates normal forms, compares them, prints them, and builds the tower boundary terms. It does not silently sort malformed input.

Only positive natural numbers are implemented as coefficients. Infinite set-ordinal coefficients, general class-order presentations, and arbitrary class arithmetic are outside this program’s scope. A complete finite alphabet naming every set ordinal would be a different and impossible interpretation of the mathematical grammar.

The verification report records the following run:

| Check                                                    | Count or value |
|----------------------------------------------------------|----------------|
| Distinct bounded normal terms                            | 994            |
| Unordered pairs checked against an independent evaluator | 493,521        |
| Additional ordered pair comparisons                      | 2,000          |
| Reflexive comparisons                                    | 994            |
| Malformed inputs rejected                                | 16             |
| Tower boundaries checked structurally                    | 8              |
| Common finite base in the independent evaluator          | 7              |
| Largest integer produced by that evaluator               | 92 bits        |

For the independent check, the program substitutes one ordinary natural base 7, greater than every coefficient in the bounded sample, and evaluates each finite tree by exact integer exponentiation and addition. The evaluator calls neither the validator nor the structural comparator. All 994 values are distinct and their ordering agrees with the structural comparison. A size bound prevents the test from trying to evaluate enormous towers.

Substitution of a finite base is a comparison test, not the interpretation of  $\Omega$  as Ord. In particular, the finite tests do not establish class well-foundedness, which is proved separately in the article.

To run the examples and reproduce the recorded check:

```
python3 code/notation_demo.py --examples-only
python3 code/notation_demo.py --report code/verification.json
```

[merge] (4 October 2026.) The program is shipped as `code/36-horizons-notation_demo.py` and its report as `data/36-horizons-verification.json`; the commands above use the delivery names, and the second overwrites the recorded report in place, so it must be run on a copy ([appendix A.14](#)). On Windows the program needs `PYTHONUTF8=1` (or `py -X utf8`): with the default code page it stops with `UnicodeEncodeError` on the letter  $\Omega$ , and the report run then leaves a 0-byte file. Rerun on a copy with `PYTHONUTF8=1` on 5 October 2026 (Python 3.14.4): status passed, with the counts of the table above; the regenerated report equals the delivered one except for `python_version` and line endings. The program implements natural coefficients only; it is not a formalization, and the theorems of this Part do not depend on it.

### XVII.10.3 The ProveIt snapshot

The targeted repository audit used the main-branch commit

e1d2f3048b947801873a6e9ddc4e03736234b328,

whose recorded commit time is 4 October 2026, 23:34:43 UTC. The code-search index initially reported an older snapshot; selected documents were therefore fetched at the pinned commit.

The inspected materials were:

1. The repository README, establishing the organization and the distinction between formal developments and research reports.
2. The catalogue at `Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/README.md`. Its relevant entries describe the canonical ordinal block structure, finite normal forms from condensation, and the comparison-specific scope of certain conclusions.
3. The accompanying `29-birthdays-PROOF_STATUS.txt`, which explicitly separates the condensation/comparability result from an unproved converse to ETR.
4. `Logic/PeanoArithmetic/ListCoding/README.md`, particularly the documented hereditary ordinal codes below  $\varepsilon_0$  and the separate Lean and Rocq theorem scopes.

The approximately 3.3-MB consolidated surreal-well-orders LaTeX manuscript was not inspected end to end. The targeted audit used its detailed catalogue and proof-status documents; it is not an exhaustive duplicate search or an independent verification of that corpus. This limits claims about novelty relative to every repository passage. It does not affect the proofs in the present article, which are supplied independently.

No repository files were modified, and no Lean or Rocq build of ProveIt was performed. The package is an article and a finite notation demonstrator, with a proposed formalization route.

[merge] The commit `e1d2f3048` (4 October 2026, 16:34:43 PDT) is the pin of source 34; this report’s `article.tex` there is the text with Parts I–XV, unchanged until Part XVI was written. The older index commit `555ee36fb` also exists. The four inspected paths exist at the current revision, and their contents are as described; “the approximately 3.3-MB” manuscript is this report’s `article.tex`, 3,289,057 bytes at the pin. The source audit is shipped as `36-horizons-SOURCE_AUDIT.txt` ([appendix A.14](#)).

## XVII.10.4 How to rebuild the document

The main `beyond_ord.tex` in the final package is self-contained: the section source and bibliography are included in that one file. No external bibliography database or downloaded image is required. A standard TeX Live installation with the listed packages suffices.

To rebuild, run:

```
latexmk -pdf -interaction=nonstopmode -halt-on-error beyond_ord.tex
```

The accompanying `build.sh` performs the same build. The delivered PDF was compiled from this source and checked for unresolved references and layout defects. The separate `DOCUMENT_CHECKS.json` records the final page count, compilation diagnostics, and rendering review.

[merge] The manuscript `beyond_ord.tex`, its 40-page PDF and the delivery README are not shipped; they survive in the arrival commit’s archive ([appendix A.14](#)). `build.sh` is shipped as `code/36-horizons-build.sh` and builds a file that is not shipped; `DOCUMENT_CHECKS.json` is shipped as `data/36-horizons-DOCUMENT_CHECKS.json`, and its four SHA-256 values match the delivered files. This Part is built as part of this report.

### XVII.10.5 Research status in one table

| Item                                             | Status                                                                                           |
|--------------------------------------------------|--------------------------------------------------------------------------------------------------|
| Long class orders and basic arithmetic           | Established background, with explicit constructions and proofs supplied.                         |
| Hereditary $\Omega$ -terms and epsilon extension | Fully specified and proved here; epsilon syntax has stated classical prior art.                  |
| External spectra and the $G$ -horizon theorem    | Conventional proofs included; hypotheses and parameter regimes explicit.                         |
| Truth promotion and unbounded variation with $G$ | Proved by the displayed uniformization and coding constructions.                                 |
| Historical priority                              | Not established by the targeted source search.                                                   |
| General comparability versus ETR                 | Not resolved; cited literature and search limitation stated.                                     |
| Proof-assistant verification                     | A roadmap is given; no such certification is claimed for this article.                           |
| Finite software checks                           | Reproducible comparator checks only; no inference from finite testing to class well-foundedness. |

[merge] (4 October 2026.) The rows “External spectra and the  $G$ -horizon theorem” and “Truth promotion” concern theorems proved independently on the same day by sources 32–34 (notes XVII.7.D and XVII.7.G); “Historical priority: not established” applies to them in that sense too.

### XVII.11 What this Part answers

[merge] Dated notes, 4 October 2026, in the form of section XVI.12; the questions concerned carry dated notes of their own (sections 113.28 and 113.31).

- (a) *Source 33’s research question research question 113.286, how much the definability ceiling depends on the global-order predicate:* **answered**. The ceilings  $\delta_G = \mathfrak{H}_G$  are unbounded in  $\kappa^+$  as  $G$  varies over the bijections  $\kappa \rightarrow V_\kappa$ , every  $A \subseteq \kappa$  can be coded into some  $G$ , and every  $\alpha \in [\kappa, \kappa^+)$  is the type of a parameter-free  $G$ -definable order for some  $G$  (lemma XVII.7.10 and theorem XVII.7.11).
- (b) *Source 34’s agenda item research question 113.275, arithmetic of the hereditary notation:* **answered for addition and multiplication** (theorems XVII.5.1 and XVII.5.2); exponentiation open (research question 113.300).
- (c) *Source 32’s research question 113.284 and source 33’s research question 113.285, the definability ceiling:* advanced by the necessary conditions  $\varepsilon_\delta = \delta$  and  $\delta > \zeta_{\kappa+1}$ , for every transitive model (proposition XVII.6.11) and at  $V_\kappa$  with a named enumeration (theorem XVII.7.5).
- (d) *Source 34’s research question 113.272 and source 35’s research question 113.273, Veblen-style hierarchies of class-order constructors:* advanced by the finite-support transfer theorem and the epsilon-term functor (theorems XVII.6.2 and XVII.6.4).
- (e) *Source 34’s research question 113.283, comparison of the ceiling with admissible and unrolling heights:* advanced by (S36.6.2) and proposition XVII.8.1.
- (f) *Source 31’s research question 113.239:* advanced for external order types at every transitive height (section 113.31 (f)).
- (g) *Not settled:* Hamkins and Woodin’s Question 7, and source 36’s ten questions (section 113.30); its second question is answered in part by source 34’s theorem XVI.8.3.

[merge] *New against the repository* (checked against Parts I–XVI; source 36 claims no historical priority): normal-form addition and multiplication with the absorption  $D + \Omega^{[B]} \cong \Omega^{[B]}$  (theorems XVII.5.1 and XVII.5.2); the predecessor decomposition for an arbitrary base, the set-likeness criterion and  $a^{\Omega \cdot B} \cong \Omega^{[B]}$  (theorems XVII.3.5 and XVII.3.6 and corollary XVII.3.7); the second clause of proposition XVII.3.4; the carrier Ord without choice (proposition XVII.2.4); the finite-support transfer theorem (theorem XVII.6.2); the epsilon-term functor on class orders and its calibrations,  $\varepsilon_\kappa = \zeta_\kappa = \kappa$  at transitive heights, and the order of type  $\zeta_{\kappa+1}$  (theorems XVII.6.4, XVII.6.6 and XVII.6.7 and lemma XVII.6.5); the proper-carrier spectrum, the transfer to  $\text{Ord}^M$  and  $\varepsilon_{\mathfrak{H}(M)} = \mathfrak{H}(M)$  with  $\zeta_{\kappa+1} < \mathfrak{H}_0(M)$  (theorem XVII.6.9 and proposition XVII.6.11); the clause  $\varepsilon_{\mathfrak{H}_G} = \mathfrak{H}_G$  of theorem XVII.7.5; the effective hierarchy corollary XVII.7.7; the swap coding and the variation of  $G$  (lemma XVII.7.10 and theorem XVII.7.11); and the unrolling computation (proposition XVII.8.1). *Proved again* (credit Notes): set localization (source 34), the set-like boundary (sources 11 and 32–35), the power theorem and its laws (sources 29 and 32–35), the hereditary order, its fixed point, towers and leastness (sources 32–35), the calibration at cardinals (source 34), the parameter spectrum (source 34), the full-class spectrum (sources 12 and 32–35), the successor obstruction and uniform diagonal (sources 32–35), the inaccessible-rank model (sources 32–34), the  $V_\kappa$  horizon theorem (sources 32–34), the bounded-complexity diagonal (sources 33–35), the missing uniform evaluator (sources 32–34) and truth promotion (source 32). *Inherited and credited by source 36*: class arithmetic and long class orders (Barton and Williams), the epsilon-term syntax (Marcone and Montalbán), the admissible bound (Blass) and its equality examples (Taranovsky), the unrolling theorem for KM with Class Collection (Freire and Williams), and the comparison theorem GBC + ETR<sub>F</sub> (Williams).

[merge] *Review*. The Hilbert’s-tenth research tree reviewed the archive in a bounded intake (Computability/HilbertTenthProblem/Papers/research-wip/native-stream-queue/review\_beyond\_ord\_package\_d7cf7d554.md, commit 39bb02ece): it read 1,879 lines of the manuscript; checked the set-localization lemma, the ordinal initial segment and carrier reduction, the power calculus with its transport, continuity, predecessor and set-likeness results, the hereditary comparison, root decomposition, towers and the least fixed point through a supplied isomorphism, the normal-form addition and multiplication, and the transfer theorem; read the uniform diagonal and the setting, validity filter and complexity hierarchy of the horizon theorem; and found no defect. It records that the arithmetic procedures keep ordinal-label primitives and that the demonstrator’s interface has no addition or multiplication. It did not read the proofs of the epsilon interpretation, the epsilon and zeta calibrations, the general spectrum theorem, truth promotion, the variation of  $G$ , the admissible bound or the unrolling proposition, and it ran no delivered program. The placement check (6571ee1af) read the main proofs, recomputed the three worked products and found no false statement. A later bounded publication review at a21a42d8c, recorded in review\_horizons\_write\_a21a42d8c.md in the same research tree, reads the whole 557-line guide diff and 1,698 selected article lines. It authenticates the source archive, all five ancillary placements and all 70 source-label routes. The selected arithmetic proofs, the initial-embedding leastness of note XVII.4.B, and the fixed-standard-complexity syntax hierarchy pass within their hypotheses. Three editorial arithmetic summaries are corrected below. This review does not certify the epsilon interpretation, the epsilon/zeta calibrations, general transitive-model spectrum, truth promotion, variation of  $G$ , admissible bound or unrolling proof; downstream uses retain those dependencies. No supplied program was run and no paid fixed-arity integer compiler follows from the ordinal-relative arithmetic.

**Review remark H1 (multiplication scope).** The guide originally extended “addition and multiplication” to every  $\Omega^{[B]}$ ; the notation table said “points of  $\mathbf{E}$  or  $\Omega^{[B]}$ ”, and this Part’s introduction made the same extension. For  $B = 2$ , the point-cut  $\Omega$  belongs to  $\Omega^{[2]}$ , but its product with itself is the whole order  $\Omega^2 = \Omega^{[2]}$ , which cannot be a proper initial point-cut of itself. Only the addition rule is asserted on every such power; both operations are defined on  $\mathbf{E}$ . The printed theorems retain that scope.

**Review remark H2 (set-likeness hypotheses).** The guide omitted “ $A$  has at least two elements and  $B$  is nonempty” from [theorem XVII.3.6](#). For  $A = 1$ ,  $B = \text{Ord} + 1$ , the power is the set-like singleton, but neither stated alternative holds. Independently,  $A = \text{Ord}$ ,  $B = 0$  again gives the set-like singleton without either alternative. Both restrictions are now explicit in the guide; the theorem is unchanged.

**Review remark H3 (set-base collapse).** The guide stated  $a^{[\Omega \cdot B]} \cong \Omega^{[B]}$  without the assumption that  $a$  is a set ordinal at least two. Taking  $a = 1$  and  $B = 1$  would assert  $1 \cong \text{Ord}$ . The guide now repeats the premise of [corollary XVII.3.7](#); its proof is unchanged.

# Questions, conclusions and status

## 113 Research questions

[merge] The four sources' questions are printed per source in the following subsections, as proposed continuations, not as a census of open problems. The index below groups the duplicates, credits every source that asks them, and records the status after the merge (dated 2 October 2026). Questions of source 09 and source 08 are numbered by the order of their subsections and paragraphs in [sections 113.3](#) and [113.4](#). [merge] (3 October 2026.) The status column below carries dated updates for the batch-81 addition; the questions of sources 13–18 have their own index in [section 113.5](#). [merge] (3 October 2026, batch 83.) Entries marked *batch 83*: give the status after Parts X–XIV, with the item of [section 113.25](#) that records it; the questions of sources 19–30 are indexed in [section 113.12](#).

| Topic                                                   | Asked by                                                                                                        | Status                                                                                                                                                                                                                                                                                                                                                                                                                                          |

### 113.1 Source 11's research questions and topics

The questions below are proposed extensions of the present development. Except where a source is explicitly named, they are not asserted to be established open problems in the literature. Several ask for a stronger classification than the proved results supply.

#### 113.1.1 A precise description of the represented cuts

Fix the dense ordinary class  $\mathcal{P}_{\text{bd}} \cong \mathbf{No}$ . Every set-like global enumeration determines a lower cut of  $\mathcal{P}_{\text{bd}}$ , and so does every injective nonexhaustive Ord-word. The omitted-range example shows that the first collection does not fill every cut generated by the second.

**Research question 113.1.** Characterize, using the prefix tree and its numerical labels, exactly which class cuts of  $\mathcal{P}_{\text{bd}}$  arise from injective Ord-words, and which of these words are exhaustive.

A useful first target is a necessary-and-sufficient compatibility condition on the intersections of a cut with prefix cylinders. The challenge is to separate missing labels, impossible repeated labels, and cuts that escape every coherent branch. This should first be stated for a fixed uniform class cut, before quantifying over an entire hyperclass of cuts.

#### 113.1.2 The embedding relationship between the two global orders

The set-like fragment and binary class words are equimorphic, while the unrestricted order has additional convex fibers. Theorem [20.1](#) rules out a reverse embedding in the full universe interpretation. Theorem [20.2](#) also rules out a definable uniform reverse embedding in  $\mathbf{KM} + \mathbf{GC}$ .

**Research question 113.2.** What is the weakest comprehension scheme over GBC that proves the uniform nonembedding result? Can the inverse-evaluation step be replaced by an elementary argument, or is a genuine strengthening necessary?

A precise project should specify the syntactic complexity of the proposed transformation and of the comprehension used to invert its code assignment. In the bounded setting one can instead

compare the density and cellularity of all well-orders of  $\mathbf{No}_{<\kappa}$  with their minimum-length stratum, especially when  $\kappa$  is not inaccessible. The full-universe case is already settled above; the remaining questions concern strength and wider hypotheses.

### 113.1.3 Iterated residual decomposition

One extraction of the canonical initial Ord-part requires only elementary class comprehension. A residual proper class has another such part, suggesting a hierarchy of successive blocks.

**Research question 113.3.** What is the exact recursion strength needed to organize iterated residual decompositions uniformly, and what class order types can occur as their block-index orders?

An initial project could analyze finitely many blocks and specified set-length constructions, recording where the recursion state becomes a class. The general case should be compared with known ETR results on class well-order comparability, rather than assumed to follow from the one-step theorem.

### 113.1.4 Recovering the prefix structure from the bare order

The definitions exhibit a labeled tree of prefixes. An automorphism of the bare lexicographic order need not obviously preserve its displayed labels or cylinders.

**Research question 113.4.** Which prefix cones, canonical-core fibers, and finite permutation blocks are definable from the linear order alone? What extra predicates make the reconstruction unique?

Adjacency directly detects finite stretches, but a singleton fiber can be exhaustive or can omit one label. Thus local block size alone cannot recover set-likeness. An analysis of the automorphism group may clarify what the order remembers about the original enumeration.

### 113.1.5 The bounded-support choice of baseline

Every baseline enumeration gives an ordinary class  $\mathcal{P}_{\text{bd}}$  abstractly isomorphic to  $\mathbf{No}$ . If two baselines differ on a proper class of positions, their bounded-support subfamilies can be disjoint.

**Research question 113.5.** How do the two dense classes sit inside the same  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$ , and when does an automorphism of that higher-order order carry one onto the other?

The abstract isomorphism of the two dense orders does not automatically extend to all global enumerations. The represented-cut problem is likely relevant. A restricted first case is a baseline change obtained by an order automorphism of the numerical surreal line.

### 113.1.6 Sharper birthday bounds and minimal codes

The explicit code gives a usable bound

$$\text{bd}(E(f)) = \sum_{i < \text{dom } f} (1 + 2 \cdot \text{bd}(f(i)) + 2).$$

It is designed for a transparent proof, not asserted to be optimal.

**Research question 113.6.** Which birthday bounds are optimal for uniform embeddings of injective surreal words? Can shorter prefix-free coefficient codes preserve useful simplicity relations?

Regular cutoffs permit same-stage compression; singular cutoffs show why a cardinal bound alone is insufficient. A sharpened result should specify whether it preserves only numerical order, prefix extension, simplicity, or all of these.

### 113.1.7 Saturation of more general bounded alphabets

If  $X$  is an  $\eta_\kappa$  order of cardinality  $\kappa$ , its minimal-length permutation order inherits  $\eta_\kappa$ . Birthday fragments often have cardinality  $2^{<\kappa}$ , which may exceed  $\kappa$ .

**Research question 113.7.** Determine the exact cut spectrum and point characters of  $\mathcal{W}_\lambda(\mathbf{No}_{<\kappa})$ , where  $\lambda = 2^{<\kappa}$ , without assuming  $2^{<\kappa} = \kappa$ .

The issue combines the size of a used prefix with the number and birthdays of possible numerical separators. The real-alphabet formulas in the precursor report cannot settle this case by substitution.

### 113.1.8 Class extensions and available global orders

Two models may have the same sets and hence the same individual surreal numbers, but different available classes and different global well-orders.

**Research question 113.8.** Which features of the lexicographic theory are invariant under extensions of the class part, and how does the represented-cut collection change?

Uniform formulas such as first divergence remain the same for the existing relations. Existence of additional enumerations changes the larger totality. This offers a way to distinguish properties of the labeled surreal order from properties of the surrounding class theory.

### 113.1.9 A verified first milestone for ProveIt

**Research question 113.9.** Can the explicit word compression and the direct predecessor comparison be formalized first, with a small, reusable interface independent of surreal arithmetic?

These are concrete, finite-dependency targets: ordinal concatenation, numerical first difference, injectivity, and well-order predecessor sets. The next milestone is the general successor-cardinal obstruction, followed by bounded-support completion and the small-family interpolation theorem. This ordering keeps the central algorithms separate from a formalization of an entire higher-order set theory.

### 113.1.10 Uniform mathematical constructions indexed by well-orders

The Kanovei–Shelah method suggests using a definable linear order of codes to index constructions without selecting one privileged code. The surreal setting raises additional smallness conditions.

**Research question 113.10.** Which finite-support or bounded-support constructions can be indexed by a uniform class family of global well-orders, and which require a genuine higher-order index object?

A first investigation should specify its support sets, evaluation maps, and quantifier domains before adding algebra or model theory. The diagonal theorem prevents an exhaustive class-code shortcut, but leaves many useful uniform families available.

[merge] Status of source 11’s questions after the merge: all remain open. Source 12’s dichotomy (theorem 8.3) computes the binary coding length of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  in every case, but not the cut spectrum or the point characters that research question 113.7 asks for.

[merge] Dated note, 3 October 2026 (batch 81). Research questions 113.1 and 113.7 are answered (sections 33 and 50); research questions 113.2 to 113.5 and 113.8 are answered in part (sections 50 and 60); research questions 113.6, 113.9 and 113.10 stay open, the explicit codes and support bounds of sources 13–17 bearing on research question 113.6 (sections 39 and 50).

### 113.2 Source 12’s research questions and prioritized program

The following are proposed continuations. Except where an older question is explicitly attributed, they are not claimed to be recognized open problems in the literature.

**Research question 113.11** (All fixed enumeration types). Determine  $\ell_2(\mathcal{W}_\alpha(\mathbf{No}_{<\kappa}))$  for every ordinal  $\alpha$  of cardinality  $2^{<\kappa}$ , not only the minimal type. Can the answer be expressed by a precise ordinal-sum invariant of admissible entry-code lengths, together with the finite terminal permutation factor?

The singular theorem identifies the first obstruction that any such formula must capture. A useful initial target is  $\alpha = \mu \cdot 2$  and then  $\mu \cdot \gamma + n$  for finite  $n$ .

**Research question 113.12** (Noncardinal birthday bounds). For an arbitrary infinite ordinal  $\theta$ , classify the minimal permutation order of  $\mathbf{No}_{<\theta}$ . Which features of the ordinal tail of  $\theta$ , beyond  $|\theta|$  and  $|\mathbf{No}_{<\theta}|$ , survive in its coding rank and local character?

The cone argument for an initial cardinal relies on closure under  $i + 1 + \alpha$  below the cutoff. At a noncardinal cutoff that closure can fail and should be replaced by a stratified family of cones.

**Research question 113.13** (Isomorphism, not merely equimorphism). Classify the order topology and isomorphism invariants of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$ . At regular cutoffs, and at singular strong limits, what are its density, cellularity, cut-character spectra, and degrees of homogeneity? Which distinguish it from other orders of the same binary rank?

The binary cube itself cannot be the literal answer: it has endpoints and adjacent pairs, while the surreal permutation order has different local behavior. A dense suborder equimorphic with a cube can retain substantial information not measured by rank.

**Research question 113.14** (The hierarchy of proper-class blocks). Study the subpredicates of  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  with types  $\text{Ord} \cdot \gamma + \alpha$  for fixed set ordinals  $\gamma, \alpha$ . Give explicit, size-safe embedding and nonembedding theorems between these subpredicates and the set-like order.

The inaccessible-model calculation provides concrete bounded targets and shows that the full order is strictly more complex than the set-like order there. Extending binary fusion to uniform transformations on class predicates may require stronger comprehension; that dependence should be proved, not assumed away.

*Remark 113.15* (Source 12’s question “The exact weak-choice strength”, answered). *Source 12’s text*: Remove set-level AC from the base theory in [theorem 13.2](#). What principle is equivalent to a class well-order of the sign-sequence surreals then? Compare it with coherent well-ordering of power sets of ordinals and with uniform ordinal presentations of transitive closures.

[merge] *Answered* (2 October 2026). Source 11’s [theorem 13.1](#) proves the equivalence over GB with no set-level choice: a class well-order of the sign-sequence surreals is equivalent to global choice. Its proof is precisely a uniform well-ordering of the power sets  $V_{\beta+1}$ , obtained by set-valued recursion from the given well-order on the sign sequences of each length  $\theta$ ; see [remark 13.4](#). (Corrected on 3 October 2026 after the Hilbert’s-tenth review [review\\_surreal\\_synthesis\\_0be9b9134.md](#): “uniform” replaces “coherent”, since these orders need not extend one another; [remark 13.4](#) gives a finite example.)

This is separate from the question whether surreal universality for class linear orders itself implies global choice, raised by Hamkins [21]. The present equivalence concerns a well-order of all surreal labels and does not settle that universality question.

**Research question 113.16** (Elementary common-prefix theory). Formalize [theorem 14.7](#) over a precisely chosen weak class theory. How little comprehension and class well-foundedness are needed? Can one characterize the same relation directly by a formula avoiding explicit mention of the common-prefix class?

The definition already expands to elementary quantifiers. A mechanized proof would make the separation from abstract class comparability particularly transparent and yield a reusable theorem for other carriers.

**Research question 113.17** (Automorphisms and finite condensation). Determine natural automorphism groups of the full lexicographic order, and of the order after collapsing finite residual blocks. Which operations arise from numerical automorphisms or permutations of the underlying surreal carrier, and which genuinely act on enumeration structure?

Finite-tail blocks are now characterized intrinsically by adjacency. That makes condensation a plausible first invariant, but no complete classification of its quotient is claimed here.

**Research question 113.18** (Dependence on the class realization). Fix a transitive set universe  $M$  and vary its admissible class collection  $\mathcal{X}$ . Which external order invariants of the admitted global well-orders detect this change? Can the order reconstruct useful information about available truth predicates or class choice functions?

The diagonal obstruction persists internally, while external cardinality can vary. This makes the distinction between full and Henkin semantics a source of mathematical questions rather than merely a formal warning.

**Research question 113.19** (Compatibility between birthday cutoffs). Construct and analyze coherent embeddings from the well-order spaces at smaller birthday cutoffs into those at larger cutoffs. Which choices of reserve labels and tail enumerations are functorial, and which preserve finite condensation, coding ranks, or canonical cylinders?

Naively extending every enumeration by an arbitrary tail can change minimal length, and fixed choices need not be compatible across three cutoffs. A coherence theorem would make universe-lifting arguments much more useful in a proof assistant.

[merge] Status of source 12's questions after the merge: [remark 113.15](#) is answered (it is printed above as a remark). [Research question 113.11](#) continues the reals report's question "Other ground orders" for the surreal cutoffs, whose minimal type [theorem 8.3](#) settles. The others remain open.

[merge] Dated note, 3 October 2026 (batch 81). [Research question 113.11](#) is answered for the types  $\mu \cdot \gamma + n$ , and [research question 113.13](#) except for the isomorphism type and homogeneity ([section 33](#)); [research questions 113.14](#), [113.17](#) and [113.18](#) are answered in part ([sections 50](#) and [60](#)); [research questions 113.12](#), [113.16](#) and [113.19](#) stay open, and sources 13–18 ask them again ([section 113.5](#)).

### 113.3 Source 09's research directions

The following are proposed problems emerging from the development, not a claim that all are already catalogued open problems. Each is stated with a foundational level so that its intended meaning is clear.

### 113.3.1 Formal proof of the surreal core theorem

**Framework:** universe-indexed Lean with explicit smallness and a baseline parameter. Complete the prefix-extension and interpolation modules, then prove the back-and-forth isomorphism. The difficult part is expected to be the bookkeeping of small histories and variable ordinal prefixes, not the finite first-disagreement arguments. A useful first milestone is the inaccessible or regular-cardinal set-sized version, parameterized by an abstract saturated alphabet.

### 113.3.2 Exact axiomatic strength of the global conclusions

**Framework:** GB with ordinary set choice but without global choice. [Proposition 13.7](#) settles the baseline question: a set-like global well-order of **No** is equivalent to global choice. Determine the exact strength of alternative universality and homogeneity assertions that do not already assume such a baseline. In particular, which conclusions can be stated and proved for individually definable class orders without supplying a single uniform global enumeration? Distinguish uniform existence assertions from a schema treating one fixed definition at a time; the latter is not automatically a uniform class construction.

### 113.3.3 Which cuts of the core represent exhaustive branches?

**Framework:** class cut parameters over  $\mathcal{P}_s(b)$  or an explicitly higher-sorted completion. Every global enumeration determines a cut in the dense core, and density makes this representation injective. Characterize its image intrinsically. The missing-branch construction shows that injectivity of a class word is insufficient: exhaustiveness must be detected. A promising formulation separates coherence of set prefixes, realizability of each next-coordinate cut, and eventual coverage of every surreal value.

### 113.3.4 Automorphisms beyond set-sized partial maps

**Framework:** GBC for the core; higher-sort or universe-bounded versions for the full comparison object. Set-sized partial isomorphisms extend in the core, but proper-class partial maps need not. Classify which preserve enough prefix or support structure to extend. Also distinguish automorphisms of the bare order from those preserving the preferred filtration by support bounds. These are different classification problems even though the bare core is always **No**.

### 113.3.5 Non-set-like well-order relations

**Framework:** GBC or GBC + ETR, with a fixed relation-code coordinate order. Study the alternative binary comparison of all global well-order relations. Which order properties depend on the coordinate enumeration? Does it contain a natural set-coded dense core, and when are its cuts represented by actual class well-orders? No conclusion about that different comparison follows merely from the enumeration results proved here.

### 113.3.6 Sharp birthday and support bounds

**Framework:** ZFC on bounded fragments. Given bounds on the birthdays and first-disagreement coordinates of a set family, determine optimal bounds for an interpolating prefix and its supported completion. The present proof bounds the forced prefix length by  $\sup\{\Delta(E_i, F_j) + 1 : i \in I, j \in J\} + 1$  and uses an oversized cardinal for support. That bound is safe but not generally minimal. This direction could yield concrete complexity estimates for symbolic surreal order calculations.

### 113.3.7 What survives away from inaccessible truncations?

**Framework:** ZFC with specified cardinal arithmetic. Replace the inaccessible  $\kappa$  by a regular cardinal and a set alphabet with appropriate cut saturation. Separate the roles of regularity,  $\kappa^{<\kappa} = \kappa$ , and closure under the required cut constructor. At singular cardinals, the first-disagreement bound can reach the ambient length even for relatively small families; identify the resulting interpolation spectrum and construct sharp counterexamples.

### 113.3.8 Other termination conventions for set words

**Framework:** GBC or bounded ZFC. Our dictionary order makes proper prefixes smaller and therefore creates the limit-prefix suprema of [note 11.4](#). Study a distinguished internal termination value, restricted alphabets, or prefix-free codes of set well-orders. Determine exactly which variants have the set-cut property and hence are isomorphic to **No**. The convention must be part of the statement, not an implicit analogy with surreal signs.

### 113.3.9 Uniform infinitary constructions indexed by redundant codes

**Framework:** bounded universes first. Kanovei–Shelah-style redundant indexing suggests avoiding a choice of one representative for each well-order or auxiliary object. Investigate constructions using the support core or bounded strata as indices, while checking that the resulting products, functions, and quotient relations remain at the declared level. The diagonal theorem forbids a uniform same-level list of all global enumerations, but does not preclude purpose-built redundant families adequate for a particular theorem.

[merge] Status of source 09's directions after the merge. Direction 2: the baseline question it already settles over  $\text{GB} + \text{AC}$  needs no set choice ([theorem 13.1](#)); the strength of the other universality and homogeneity assertions remains open. Direction 3 is source 11's [research question 113.1](#). Direction 5: source 08's [proposition 17.1](#) gives the equimorphism type of a relation-code order; the dense core and the representation of its cuts remain open. Direction 7: source 12's dichotomy treats coding lengths at singular cutoffs, not the interpolation spectrum the direction asks for. The others remain open.

[merge] Dated note, 3 October 2026 (batch 81). Direction 3 is answered ([section 50](#)), direction 7 for the minimal slice and direction 8 for unrestricted and injective words ([sections 33](#) and [39](#)); directions 4, 5 and 6 are answered in part ([sections 39](#) and [50](#)); directions 1, 2 and 9 stay open, with source 16's  $\Sigma_1^1$  bound bearing on direction 2 ([section 60](#)).

## 113.4 Source 08's research questions and topics

The following are directions not resolved by the present manuscript. They are not blanket assertions that no relevant answer exists in the literature. Each should begin with a targeted literature search and a precise choice of size level.

### 113.4.1 Set-sized enumeration orders

**1. Isomorphism classification beyond the common spectrum.** The ordinal spectrum and cardinality of  $\mathcal{W}(X)$  depend only on  $|X|$ , while its local cylinder structure remembers the numerical order of residual alphabets. Which additional invariants of  $X$  can be recovered from  $\mathcal{W}(X)$ ? Determine sufficient and necessary conditions for  $\mathcal{W}(X) \cong \mathcal{W}(Y)$ , rather than merely embeddings in both directions. Dense alphabets, well-orders, and mixed sums provide natural test cases.

**2. Exact invariants at regular cutoffs ([merge] partly answered; answered 3 October 2026; see the notes after this list).** For regular  $\kappa$  with  $2^{<\kappa} = \kappa$ , compute the density, cellularity, point characters, and cut cofinalities of  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$ . The binary equimorphism in (S08.6) does not by itself determine its order-topological isomorphism type. Investigate whether the support skeleton construction has a natural  $\kappa$ -sized dense realization inside this set order under weaker assumptions than strong inaccessibility.

**3. Singular birthdays and code lengths ([merge] answered in part; see the notes after this list).** At singular  $\kappa$ , exactly which cuts of size below  $\kappa$  fail to be realized in  $\mathbf{No}_{<\kappa}$  or in its fixed-length enumeration order? Determine the least binary coding lengths for these orders and how they depend on cofinality and cardinal arithmetic. The three specific uses of regularity in note 7.6 identify where a new argument is needed.

**4. Prescribed noninitial lengths.** For  $\alpha$  of cardinality  $\kappa$ , classify  $\mathcal{W}_\alpha(\mathbf{No}_{<\lambda})$ . Finite tails are understood through note 6.25, but noninitial limit lengths may preserve finer lexicographic complexity. Compare this problem with the fixed-type analysis proposed in the continuum manuscript [2], checking its hypotheses and proofs independently for nonseparable alphabets.

#### 113.4.2 The skeleton and the virtual ambient order

**5. Definable choices of the surreal isomorphism.** The back-and-forth isomorphism  $\mathcal{P}_s(b) \cong \mathbf{No}$  depends on witness choices. With a specified global well-order, can it be chosen to respect useful support or birthday bounds? What additional normalization gives uniqueness, if any? Distinguish definability from parameters, parameter-free definability, and invariance under a change of baseline.

**6. Automorphisms and extension from a skeleton.** An order automorphism  $\varphi$  of  $\mathbf{No}$  acts on  $\mathcal{W}_{\text{sl}}$  by  $e \mapsto \varphi \circ e$  and sends  $O_b$  onto  $O_{\varphi \circ b}$ . Which automorphisms of one skeleton extend to uniform automorphisms of the full virtual order? Can order alone recognize eventual-agreement orbits, or are these additional structure supplied by the coordinate presentation?

**7. Full virtual lexicographic products ([merge] answered 3 October 2026; see the notes after this list).** For an ordinary class carrier, every set-indexed lexicographic power of  $\mathbf{No}$  embeds into a skeleton. The *full virtual* product  $\mathcal{W}_{\text{sl}} \times_{\text{lex}} \mathcal{W}_{\text{sl}}$  is a different object. Does it admit a uniform order embedding into  $\mathcal{W}_{\text{sl}}$ ? More generally, determine an absorption spectrum for uniform virtual powers. Simply concatenating two Ord-long words has domain  $\text{Ord} + \text{Ord}$ , not a set-like Ord domain, so the set-sized concatenation argument is unavailable.

**8. Higher-size cuts and completion ([merge] answered 3 October 2026 for cuts of the core; see the notes after this list).** The set-cut theorem deliberately leaves out cuts specified by proper class families of enumeration codes or by higher collections of classes. Classify which such cuts are realized once a precise higher-type language is chosen. A proposed Dedekind completion must identify the type of its cut objects and cannot be treated as another ordinary class without a size proof.

**9. Classification of relation-code orders.** For two global coordinate enumerations  $q, q'$  of  $\mathbf{No}^2$ , the relation-code orders have the same binary equimorphism type. Are there useful hypotheses yielding an isomorphism? Determine which invariants are artifacts of the coordinate order and which reflect genuine properties of class well-orders.

### 113.4.3 Foundations and formalization

**10. Minimal axioms, stated theorem by theorem.** Separate the strength of a baseline  $\text{Ord} \cong \mathbf{No}$ , uniform prefix completion, orbit cut filling, and the global back-and-forth theorem. Over variants of GB with set Choice, which global selection principles are necessary for their uniform formulations? The present proofs establish sufficiency of GBC, not an exact reverse-mathematical classification.

**11. Comparison of non-set-like class well-orders ([merge] answered; see the note after this list).** Formulate an explicit alignment or comparison principle for arbitrary class well-orders and locate its recursion requirements. Which restricted domains, such as finite sums of  $\text{Ord}$  and set ordinals, admit direct elementary algorithms? A theorem about all class domains should not be extrapolated from these examples without proof.

**12. Dependence on the class collection.** For fixed  $M$  and  $\mathcal{C} \subseteq \mathcal{D}$ , compare the virtual orders of global enumerations in  $(M, \mathcal{C})$  and  $(M, \mathcal{D})$ . The same set-coded skeleton relative to a shared baseline remains available, but new class rows may appear. Study which higher-size cut properties, operator embeddings, and definability properties change.

**13. Quantitative and certified prefix extension.** Formalize the support bound in [note 19.8](#), the forced-prefix length in [note 19.13](#), and the birthday of its stopping entry. This would make the central theorem a sequence of explicit bounded lemmas rather than one monolithic existence proof. It is a strong first target for the repository's existing small-cut interface.

**14. Increasing-subset and alternate-termination orders ([merge] answered 3 October 2026 except one type; see the notes after this list).** Study lexicographic orders of numerically increasing set sequences, as opposed to arbitrary enumerations, and compare prefix-small, prefix-large, and centered-termination conventions. The limit-prefix counterexample shows that these choices affect local cofinalities even when the alphabet is  $\mathbf{No}$ .

**15. An order-theoretic interface for class nonstandard models.** Determine which part of a Kanovei–Shelah-style indexing construction can use a set-coded skeleton and which genuinely needs a larger collection. Keep the order embedding problem separate from the existence of a class ultrafilter, satisfaction relation, or transfer principle. A successful construction should include an explicit uniform-family and smallness audit at every step.

[merge] Status of source 08's questions after the merge, dated 2 October 2026. Question 11 is answered: the labelled comparisons of [theorem 14.2](#) and [theorem 14.7](#) compare arbitrary class well-orders of a labelled class with elementary comprehension, without ETR (see the note after [proposition 17.1](#)). Question 3 is answered in part: the least binary coding length of the fixed-length enumeration order at a singular cutoff is  $\kappa \cdot \kappa$  at a strong limit and  $2^{<\kappa}$  otherwise ([theorem 8.3](#)); which cuts of size below  $\kappa$  fail to be realized remains open. Question 2 is answered in part by [proposition 12.1](#) (the order is  $\eta_\kappa$ , and all its global and local cofinalities and coinitalities equal  $\kappa$ ). Question 4 is source 12's [research question 113.11](#). The others remain open.

[merge] Dated note, 3 October 2026 (batch 81). Questions 2 and 7 are answered ([sections 33](#) and [60](#)); question 3 also in its cut half, in character terms ([section 33](#)); question 8 for class cuts of the core ([section 50](#)); question 14 except the isomorphism type of the centered increasing order ([section 39](#)); questions 4, 6, 9, 12 and 13 in part ([sections 33](#), [39](#), [50](#) and [60](#)); questions 1, 5, 10 and 15 stay open.

### 113.5 The questions of sources 13–18: index and status (3 October 2026)

[merge] Sources 13–18 ask 74 questions (13, 13, 12, 11, 13 and 12), printed per source in the following subsections as proposed continuations, not as a census of open problems. Many repeat each other or a question above; the table groups them, names the earlier question each continues, and records the status after the whole batch-81 addition. A question answered by a sibling source is marked in its source’s subsection. The status of the questions of sources 11, 12, 09 and 08 after the addition is recorded in the dated notes after their subsections and in [sections 33, 39, 50 and 60](#).

| Topic                                                                           | Asked by                                                                                                                                                                                                                                                                                   | Status, 3 October 2026                                                                                                                                                                                                                                                                                                 |

### 113.6 Source 13: further research questions and proposed projects

These questions are proposed continuations of the present development, not a claim that each is a previously published open problem. The prefix-trace criterion, the first-failure classification, and the negative pure-order cylinder result settle the versions stated here; the questions below ask for stronger or different conclusions.

#### 113.6.1 Cuts, trees, and enriched structure

**Research question 113.20** (Minimal extra structure for recognizing branches). What is the weakest expansion of the pure core order  $\mathcal{P}_s(b) \cong \mathbf{No}$  that makes its branch traces recognizable? Is the family of all cylinders enough as an unranked family, or must one retain the prefix-length relation? Can a support filtration recover the necessary levels without explicitly naming prefixes?

[Theorem 47.12](#) shows that the pure order alone cannot canonically recover the original cylinder family. The positive target is therefore an enriched reconstruction theorem, not a repetition of the disproved pure-order assertion.

**Research question 113.21** (Automorphisms preserving a chosen core). Classify the uniform order automorphisms of  $\mathfrak{W}_{sl}$  that preserve the specific eventual-agreement core  $\mathcal{P}_s(b)$ . Which preserve its support filtration, and which preserve the set of exhaustive traces after an isomorphism between two cores? Does adding birthday or simplicity information force a substantial rigidity theorem?

The finite-block automorphisms need not preserve the baseline orbit. A useful initial project is to characterize tail alphabet transformations that do preserve it.

**Research question 113.22** (A normal form for class cuts). Can the branch/horizontal/limit-boundary trichotomy be organized into a canonical recursive notation for every available normalized cut? For horizontal cuts, how much of the next-label cut can be encoded by surreal simplicity data? What uniqueness survives when changes of prefix presentation are allowed?

A complete class-cut collection is not an ordinary class object in GBC. The first implementation should concern one supplied class cut or one uniform class-indexed family, before introducing a higher sort.

**Research question 113.23** (Sharp cutoff analogues). For a birthday fragment  $X_\kappa$ , determine which part of the first-failure classification survives when prefix extension can fail through exhaustion, complement-cardinality mismatch, or a missing label separator. Can these three obstructions be combined with the singular strong-limit transition into a practical classification of cut characters in fixed-length strata?

This asks for more than substituting  $X_\kappa$  into the global theorem; the hypotheses that must be replaced are explicitly identified in [Section 32.2](#).

### 113.6.2 Products, comprehension, and model dependence

**Research question 113.24** (The weakest uniform split obstruction). Over GBC, what additional comprehension principle suffices to rule out a fixed-formula uniform embedding  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} 2 \rightarrow \mathfrak{W}_{\text{sl}}$ ? Can the inverse-evaluator argument be reduced to a restricted existential-class comprehension schema? For more restrictive formulas defining the proposed embedding, is there an elementary diagonal argument avoiding that comprehension altogether?

[Theorem 55.4](#) gives a sufficient theory and identifies the point to optimize. It is not a proof that full KM is necessary.

**Research question 113.25** (A hierarchy beyond one split). In a full inaccessible universe, classify the mutual embeddability of  $\mathfrak{W}_{\text{sl}}^n$  for finite  $n \geq 2$ , of  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} K$  for various right factors  $K$ , and of iterated point-splittings. Which invariants distinguish these orders after the first dense-core obstruction has saturated at cardinality  $2^\kappa$ ?

All these orders can have the same cardinality, so a useful invariant must record more than the number of elements. Families of disjoint intervals, patterns of adjacent pairs, and iterated condensation are natural candidates.

**Research question 113.26** (Class realizations with intermediate behavior). For a fixed set model  $M$ , how do different collections of available classes  $\mathcal{C}$  affect the external density, cellularity, and product-embedding behavior of its enumeration order? Which intermediate behaviors lie between the externally countable rational case and the full inaccessible-universe obstruction?

A precise answer should state whether a map is arbitrary external, definable over the two-sorted model, or coded in an additional sort. Those are distinct classification problems.

**Research question 113.27** (Uniformity versus external isomorphism). For an externally countable model, can the complexity of an external isomorphism  $\mathfrak{W}_{\text{sl}} \cong \mathbb{Q}$  be measured relative to presentations of its set and class sorts? What information about the model is necessary to compute, define, or select such an isomorphism?

This connects the order-theoretic collapse to computability and model presentation without mistaking an external construction for a class available internally.

### 113.6.3 Termination, bounds, and residual orders

**Research question 113.28** (A classification of termination cuts). For a class alphabet order-isomorphic to **No**, characterize the placements of an extra terminal marker for which arbitrary set-word or injective set-word lexicography is set-cut saturated. What happens when the marker is placed immediately on one side of an existing label, rather than reserving that label? Can the answer be expressed in terms of the two characters of the marker cut?

The end-first and end-last failures and the reserved-central success are settled here. They need not exhaust all intermediate behavior.

**Research question 113.29** (Optimal birthday and support bounds). For prescribed bounds on input birthdays, word length, and baseline indices, sharpen the prefix-length and support-cardinality bounds in [Theorem 42.4](#). Is the explicit central-code birthday sum optimal within a useful class of prefix-free local codes? Which bounds are compatible with embeddings across birthday cutoffs?

The current support completion deliberately chooses a large cardinal to equalize complements. It proves existence, not optimality.

**Research question 113.30** (Iterating raw residual decomposition). The ordinal-head fiber theorem removes one set-like initial part. How far can residual decomposition be iterated with set-valued codes, and what class-recursion principles are needed when an iteration has class-valued stages? Is there a canonical rank or notation for a substantial family of raw class well-orders beyond the first head?

This is where ETR or a stronger scheme could become genuinely relevant. The elementary one-head construction alone does not justify an arbitrary iteration.

**Research question 113.31** (Relation-code dependence). For two set-like enumerations of pairs, determine which transformations relate their relation-bit orders on raw well-orders. When do the two induced orders become isomorphic, merely equimorphic, or distinct under definability restrictions? Which code orders can be characterized by simple invariants of the pair enumeration?

#### 113.6.4 A concrete formalization milestone

**Research question 113.32** (First checked extension). Formalize the split-order density lemma and the crossing-prefix uniqueness/reconstruction argument in a size-explicit abstract setting. Then instantiate the small-cut and fresh-value interfaces using `SignSequenceCut.lean`. Can the central-word saturation theorem be completed without introducing surreal field arithmetic?

The answer to the last design question should be positive at the mathematical level: the proof uses only order, the reserved marker, smallness, and fresh set-cut separators. Establishing this dependency boundary in Lean would be a useful substantial first checked result.

[merge] Status of source 13's questions, 3 October 2026. [Research question 113.28](#) is **answered** by source 16 ([theorems 36.1](#) and [36.2](#), transported along an isomorphism of the alphabet with **No**; [section 39](#) (c)). [Research question 113.22](#) is answered in part by source 14's unique-data trichotomy ([theorem 43.3](#)) and source 15's finer successor cases; [research question 113.23](#) in part, for the minimal slice, by source 17's gap spectrum ([theorem 30.11](#)). [Research question 113.21](#) bears on source 17's extension criterion ([theorem 47.5](#)), [research question 113.26](#) on source 18's countable models ([theorem 58.6](#)), [research question 113.29](#) on source 17's exact reserve ([theorem 49.7](#)), [research question 113.30](#) on the block decomposition ([note 52.1](#)), [research question 113.31](#) on source 15's endpoint transfer ([theorem 38.2](#)), and [research question 113.24](#) on source 16's  $\Sigma_1^1$  bound ([note 56.4](#)). The others remain open.

#### 113.7 Source 14: further research questions and priorities

The following are proposed continuations of the present work. They are not all established named open problems in the literature. In particular, the prefix-structured exhaustive-cut question and the support-cardinal threshold are now answered by the theorems above; the questions here state stronger or different targets rather than restating those results.

### 113.7.1 Cut recognition beyond the named prefix structure

**Research question 113.33** (The exhaustive-trace stabilizer). Characterize the subgroup of class order automorphisms of  $\mathcal{P}_s(b)$  that preserves the exhaustive-trace collection. How does it compare with the groups preserving all prefix cylinders, or all label incidences? Can it be generated by explicit transformations of enumeration structure?

[Theorem 47.2](#) classifies the bare-order cut orbits and [Corollary 47.3](#) proves that this stabilizer is proper. What remains is its structure, not the now-answered yes/no question whether every core automorphism preserves exhaustive representability.

**Research question 113.34** (Minimal enrichment for exhaustiveness). Can the coverage predicate be recovered from cylinder inclusion and numerical order of children without naming the label evaluation itself? What additional incidence relation records that the same surreal label appears at different possible coordinates?

Coherence is essentially a branch property of the cylinder tree, whereas exhaustiveness compares labels along that branch with the entire alphabet. Separating these logical resources should clarify exactly what the recognition theorem uses.

### 113.7.2 The support hierarchy beyond one saturation invariant

**Research question 113.35** (Isomorphism of support layers). For infinite cardinals  $\kappa, \lambda$  with  $\text{cf } \kappa = \text{cf } \lambda$ , when are  $\mathcal{P}_{<\kappa}(b)$  and  $\mathcal{P}_{<\lambda}(b)$  isomorphic as bare class linear orders? Does some cut invariant recover more than the cofinality of the support threshold?

[Theorem 49.3](#) separates layers with different cofinalities but leaves this equal-cofinality case untouched. Their shared embedded copy of **No** is too weak to decide it. The attained minimum support cost is an invariant of the *support-enriched* structure, not yet an invariant of its bare order.

**Research question 113.36** (Support ideals). Replace the cardinality condition by an ideal of permitted set supports. Under what closure and permutation-invariance hypotheses is saturation controlled by the ideal's additivity? Can a failure of union closure always be converted into a coherent prefix configuration forcing a support outside the ideal?

The compression lemma bounds cardinality, not membership in an arbitrary ideal: it can adjoin images of moved coordinates and a buffer. Therefore a general ideal theorem needs explicit closure under those operations. It would be incorrect simply to replace  $< \kappa$  by “belongs to the ideal” in the existing proof.

**Research question 113.37** (Optimal simultaneous support cost). Given a specific separated set family, characterize the least support cardinality of a separator by its forced-prefix tree, rather than only by the union of all input supports. Can the finite version be computed without enumerating all possible separator permutations?

The sharp examples attain the threshold, but many input supports contain coordinates irrelevant to their comparisons. The first-outside-support argument suggests an algorithmic pruning principle. Finite optimization and the transfinite cardinal minimum should be studied separately.

### 113.7.3 Raw tails, condensation, and alternative comparison orders

**Research question 113.38** (Iterated initial-branch quotients). After quotienting raw well-orders by their first Ord-long branch, can one iterate a similarly explicit trace construction to recover successive proper-class blocks? What can be proved for prescribed block patterns without assuming a canonical class ordinal for every well-order?

The trace-fiber theorem completely describes the first loss of information. Iterating it along class-valued histories may require stronger recursion principles. The exact point at which elementary comprehension ceases to suffice should be isolated as a theorem.

**Research question 113.39** (Automorphisms of raw trace fibers). Which automorphisms of the branch order extend to the unrestricted well-order order, and what compatibility conditions do the residual alphabets impose? Which automorphisms preserve finite residual blocks but fail to preserve the core-trace quotient?

The singleton omitted-label fiber shows that being a singleton is not enough to recognize the exhaustive suborder. Any extension theorem must also account for residual alphabets with more than one label.

**Research question 113.40** (Relation-code comparison). For a specified coordinate schedule on pairs of surreal labels, classify the class cuts represented by genuine well-order relations. Is there a useful analogue of crossing cylinders that detects transitivity, linearity, and well-foundedness from a coherent branch of relation bits?

Coherent binary bits always define a relation, but well-foundedness is a global constraint. The strong reconstruction phenomenon for exhaustive enumerations may not carry over. A schedule-independent theorem must explicitly quantify which coordinate changes it tolerates.

### 113.7.4 Birthday cutoffs and universe coherence

**Research question 113.41** (Exact local geometry of set slices). For  $\mu = 2^{<\kappa}$ , determine the complete cut-character spectrum of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$ , especially when  $\mu > \kappa$  and at singular cutoffs. Which parts of the crossing-cylinder proof survive when deleting a long used prefix can exhaust intervals of the alphabet?

This continues an unfilled target of the predecessor. The global proof uses the fact that deleting *any set* leaves plentiful fresh surreals; a fixed birthday fragment lacks that unrestricted property. The inherited binary equimorphism does not decide the local characters.

**Research question 113.42** (Coherent embeddings across cutoffs). Construct explicit embeddings between enumeration spaces for increasing birthday bounds that compose coherently. Which preserve the minimal allowed enumeration type, the prefix cylinders, or the relevant support filtration?

Appending an arbitrary tail preserves a first disagreement but may change the ordinal type. A functorial construction should record both the alphabet inclusion and the position schedule, rather than silently identify cardinally equivalent domains.

### 113.7.5 Class realizations and proof strength

**Research question 113.43** (Which new cuts can a class extension add?). For a fixed set model and old baseline, characterize the additional exhaustive trace cuts admitted by specified class extensions. Can the new-cut collection distinguish natural classes of realizations even when their old-cut realizability relations agree?

[Theorem 48.1](#) supplies a rigidity constraint: no old cut changes status. It does not classify the new parameters. The tail fibers also suggest studying extensions that add raw orders with an old trace but a new tail.

**Research question 113.44** (Axiomatic economy). What is the weakest class theory proving the crossing-chain trichotomy and its reconstruction theorem once a baseline and fresh-separator property are supplied? Can the proof of the support threshold be formalized in a set-only regular-cardinal model before passing to classes?

The existing proofs visibly use elementary comprehension and class Replacement, plus set Choice for extensions. Identifying which are essential is more informative than merely observing that a stronger class theory also proves the theorem.

**Research question 113.45** (First kernel-verified milestone). Can the common-prefix comparison and the support-compression lemma be formalized as small reusable Lean modules, then independently connected to the pinned surreal sign-sequence library?

These targets avoid the largest foundational infrastructure while capturing the most error-prone finite and cardinal bookkeeping. A useful deliverable would include separate tests for fixed-position preservation, complement cardinalities, and the distinction between strict right character and the character of a normalized cut complement.

[merge] Status of source 14's questions, 3 October 2026. [Research question 113.41](#) is **answered** by source 17 ([theorems 30.2](#) and [30.11](#), with source 18's multiplicities, [theorem 30.16](#)), at every cutoff, including  $\mu > \kappa$  and singular  $\kappa$ . [Research question 113.43](#) is answered in part by source 17's [theorem 48.4](#) (every proper same-set extension adds new represented cuts), [research question 113.38](#) in part by the block decomposition ([note 52.1](#)), and [research question 113.33](#) bears on source 17's extension criterion ([theorem 47.5](#)), which identifies the stabilizer of the represented-cut predicate abstractly. [Research question 113.42](#) is source 12's [research question 113.19](#). The others remain open.

## 113.8 Source 15: further research questions and a prioritized program

**Research question 113.46** (All fixed enumeration types). Write  $\alpha = \mu \cdot \gamma + \zeta$  with  $\zeta < \mu$  infinite. Classify the possible residual numerical suborders left after the long prefix, and use them to compute  $\mathcal{W}_\alpha(\mathbf{No}_{<\kappa})$ . The theorem here handles exactly finite  $\zeta$ . A useful first family is  $\zeta = \omega$ , followed by regular and singular infinite remainders.

**Research question 113.47** (Noncardinal birthday bounds). For an arbitrary ordinal  $\theta$ , determine the order structure of  $\mathbf{No}_{<\theta}$  and its permutation strata. The cone and ordinal absorption arguments for an initial cardinal need not survive unchanged. Identify which ordinal invariants of  $\theta$  replace the present regular/singular dichotomy.

**Research question 113.48** (The exact strength of arbitrary-input condensation). Does GB prove a uniform class coding all finite condensations of every class well-order? If not, determine a sharp sufficient and necessary principle. Then study longer histories with specified limit intersections. The explicit polynomial examples show that existence for particular long histories alone is insufficient to calibrate the general scheme.

**Research question 113.49** (Intrinsic information in the full raw order). Which prefix cones, first-block fibres, and finite residual blocks are definable from the bare lexicographic order of raw well-orders? [Theorem 47.10](#) shows that the abstract core does not determine its represented cuts.

Determine how much extra structure is needed for reconstruction, and whether the full raw order restores any of the lost distinctions.

**Research question 113.50** (Completion with residual data). Construct and characterize a stratified completion that contains all terminal cuts while recording the residual well-order fibres over persistent branches. Determine its universal property and its minimum required size level. Ordinary Dedekind completion alone loses the residual data.

**Research question 113.51** (Automorphism extension). Characterize those automorphisms of a bounded-support core that preserve persistent cuts, preserve exhaustive cuts, or extend to native global enumerations. Compare cores built from baselines differing on a proper class of positions. The abstract isomorphism of two cores does not decide their placement inside the surrounding order.

**Research question 113.52** (Finer topology of bounded slices). After the density, cellularity, and point-character calculations, classify the exact gap spectra, local bases, and isomorphism types of the bounded permutation spaces. Equimorphism with a binary product does not determine all these invariants. Study which distinctions survive when cardinal arithmetic makes displayed density values coincide.

**Research question 113.53** (Inverse ranks and prescribed relation scans). Classify the cuts and point characters of ordinal-rank lexicography beyond the points  $M_\lambda$ . For table lexicography, use endpoint transfer to characterize scans whose extremal linear-order table is well-founded or set-like. Then seek invariants beyond the three possible endpoint patterns.

**Research question 113.54** (Coherent restricted filtrations). The three-label theorem rules out monotonicity for every restriction. Which nested chains of carriers, or which restricted families of orders, admit a useful monotone restriction system? Can birthday cutoffs be linked by canonical order embeddings rather than by unrestricted deletion?

**Research question 113.55** (Naturally well-ordered supports). Characterize the image and omitted cuts of  $A \mapsto -\sum_{a \in A} \omega^{-a}$ . Compare shorter-first and longer-first orders on increasing set words, and develop a higher-level analogue that treats proper-class supports without calling the result a single surreal normal form.

**Research question 113.56** (Class-model dependence). For a fixed set universe  $M$ , study changes in the lexicographic theory as the class realization grows from  $\mathcal{C}$  to  $\mathcal{C}'$ . Which statements about existing orders are absolute, which require well-foundedness preservation, and which detect newly available cuts or enumerations? Keep full-class and Henkin interpretations separate.

**Research question 113.57** (First formal milestones). Formalize the set-prefix common-disagreement formula and the elementary set-interval quotient before the entire class theory. Next verify the binary scheduler and finite-fibre fusion; then the persistent-cut reconstruction with explicit smallness. These have concise interfaces and clear failure cases, making them useful independent additions to ProveIt.

The most concrete next mathematical projects are the smaller infinite-tail classification, exact bounded gap spectra, and the automorphism-extension criterion. The most concrete foundational project is the arbitrary-input condensation scheme. Each now has a precise point where the proved construction stops, rather than an undifferentiated request to study “all well-orders.”

[merge] Status of source 15’s questions, 3 October 2026. [Research question 113.51](#) is answered in its extension clause by source 17: a core automorphism extends to the global enumerations

exactly when it preserves the represented cuts (theorem 47.5), and some do not (theorem 47.7); the comparison of cores from baselines differing on a proper class stays open. Research question 113.52 is answered in part for the minimal slice (gap spectrum and multiplicities, theorems 30.11 and 30.16); local bases and isomorphism types stay open. Research question 113.49 and research question 113.56 are answered in part as recorded in section 60 (e)–(f); for research question 113.56 see also note 57.5. Research questions 113.46 and 113.47 are source 12’s research questions 113.11 and 113.12 beyond the cases answered in Part VI. The others remain open.

### 113.9 Source 16: further research questions, with the resolved parts removed

The following are proposed continuation problems, not a census of currently open problems in the literature. In particular, the exact termination family, represented-cut recognition with the labelled prefix tree, simultaneous residual blocks, and the stated regular-stage topological invariants have been settled under the assumptions of this article. They should not be relisted as wholly open.

#### 113.9.1 Highest-priority structural problems

**Research question 113.58** (Longer-stratum binary coding ranks). For  $\mathbf{No}_{<\kappa}$  and  $\mu = 2^{<\kappa}$ , determine the least ordinal  $\rho$  for which  $\mathcal{W}_\alpha(\mathbf{No}_{<\kappa}) \hookrightarrow 2_{\text{lex}}^\rho$  for every  $|\alpha| = \mu$ , and determine the reverse cube embeddings.

The topology is now known for all these strata, but it does not determine binary coding rank. The singular strong-limit transition (S16.2) and the finite residual permutation blocks give concrete starting cases. The first targets should be  $\alpha = \mu + 1$ ,  $\mu + 2$ , and  $\mu + \omega$ , with separate treatment of singular strong-limit  $\kappa$ .

**Research question 113.59** (Singular birthday gaps). Determine the unfilled cut-character spectrum of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  when  $\kappa$  is singular, and when  $\kappa$  is regular but  $\mu > \kappa$ .

The global characters  $\text{cf}(\kappa)$  and the exact density  $\mu^{<\mu}$  are known here. The missing information is local: which numerical gaps in the truncated alphabet combine with exhaustion and prefix edges to produce each pair of cofinalities? The bounded first-failure analysis should be formulated before attempting a general classification by cardinal arithmetic alone.

**Research question 113.60** (Centered increasing words). Classify the order of numerically increasing set-length words when the termination symbol is placed at a fixed interior numerical threshold.

Theorem 36.2 covers unrestricted and injective words. The increasing case has prefix-dependent available alphabets and already fails the centered saturation theorem. A useful first problem is to determine all point characters for the  $0^-$  and  $0^+$  placements, including words that cross the threshold only at a limit stage.

**Research question 113.61** (Recovering prefix structure from order alone). Which features of the labelled prefix tree can be reconstructed from the bare order  $\mathcal{P}_{\text{bd}}(b)$ , from  $\mathfrak{W}_{\text{sl}}$  as a definable comparison, or from  $\mathfrak{W}_{\text{all}}$ ?

Our cut recognition uses the family of cylinders and numerical labels as extra predicates. A bare core is isomorphic to  $\mathbf{No}$ , and singleton raw fibers can arise either from an exhaustive branch or from a branch omitting one label. Thus neither the core order nor the size of a fiber immediately identifies exhaustion. One can ask for the least additional predicates that make the tree and exhaustion relation definable.

**Research question 113.62** (Changing baselines and extending automorphisms). For two baselines  $b, c$ , characterize when an automorphism of the set-like global comparison carries  $\mathcal{P}_{\text{bd}}(b)$  onto  $\mathcal{P}_{\text{bd}}(c)$ .

An increasing numerical automorphism  $h$  gives the explicit example  $E \mapsto h \circ E$ , carrying  $\mathcal{P}_{\text{bd}}(b)$  onto  $\mathcal{P}_{\text{bd}}(h \circ b)$ . General abstract isomorphisms between the two cores need not preserve the distinguished set of exhaustive branch cuts. [Theorem 46.2](#) suggests an extension criterion stated in terms of precisely those cuts.

### 113.9.2 Foundational problems with explicit targets

**Research question 113.63** (Exact strength of uniform nonembedding). Can the conclusion of [Theorem 56.2](#) for elementary transformation formulas be proved in GBC alone? If not, what is its reverse-mathematical strength?

The missing step is sharply localized: forming the inverse evaluator ([S16.16](#)). A lower bound would need a model in which a specified elementary transformation exists or a reduction from a comprehension principle. The mere presence of an existential class quantifier in the present proof does not establish necessity.

**Research question 113.64** (Repeated condensation of the quotient). Determine the strength and possible stabilization behavior of the transfinite tower obtained by repeatedly taking least representatives of set-interval blocks and intersecting at limits.

[Theorem 52.6](#) has removed the need for ETR to extract all blocks of one order. The new question concerns repeated condensation of the resulting index orders. Suitable ETR is a sufficient bound; whether this particular operator needs it, and which class orders can remain nontrivial at prescribed stages, are separate questions.

**Research question 113.65** (Choice needed for the word isomorphisms). How far can [Theorems 35.1](#) and [36.2](#) be proved without a global well-order?

Their explicit embeddings and the termination saturation criterion use less than the GBC back-and-forth isomorphisms. Investigate whether set choice, a restricted class-enumeration principle, or a canonical sign construction suffices for particular cases. This does not settle the broader historical question about the choice strength of universal embeddability into **No**.

**Research question 113.66** (Class extensions and canonical data). For a fixed set universe with two admitted-class expansions, describe which new branch cuts, global well-orders, and uniform transformations become available.

Shared relations retain the same internal well-foundedness under GBC, but the available class graphs can change. It is useful to distinguish absoluteness of the elementary formulas for blocks and recognition from existence of their class parameters or of the transformations being considered.

### 113.9.3 Formalization and quantitative coding

**Research question 113.67** (A first verified theorem package). Implement the set-alphabet ordinal spectrum and the  $\mu, \mu + 1, \mu + 2$  versus later-strata density theorem, then instantiate them at the small birthday carriers already in ProveIt.

This package would verify both the combinatorial mechanism and its smallness boundaries without first formalizing arbitrary class models. The two-point-fiber case is a particularly useful regression target: counting jumps as disjoint open intervals would produce a false proof.

**Research question 113.68** (Quantitative compatibility of the constructions). Find sharp birthday and support bounds for prefix completion, termination encodings, and the tree isomorphisms; determine which maps commute with increasing birthday cutoffs.

Equation (S16.7) is explicit, while the global back-and-forth isomorphisms generally are not birthday-minimal. Compatibility should mean equality or a specified coherent commuting diagram of maps, not only the existence of unrelated embeddings at each stage.

[merge] Status of source 16's questions, 3 October 2026. [Research question 113.59](#) is **answered** by source 17 ([theorem 30.11](#); [section 33](#)). [Research question 113.60](#) is answered by source 18 for the threshold at zero ([section 37](#); [section 39 \(d\)](#)); other interior thresholds are open. [Research question 113.58](#) is answered for  $\alpha = \mu \cdot \gamma + n$ , which includes the first targets  $\mu + 1$  and  $\mu + 2$ , by source 15's [theorem 31.2](#);  $\alpha = \mu + \omega$  and the reverse cube embeddings beyond those types are open. [Research question 113.62](#) is answered in part by source 17's extension criterion and relabelling ([theorem 47.5](#) and [proposition 47.9](#)), which is the criterion the commentary anticipates. [Research question 113.65](#): source 18's proof of the word isomorphisms uses one set-like global well-order as a parameter ([section 39](#)). [Research question 113.61](#) and [research question 113.66](#) are answered in part as recorded in [sections 50](#) and [60](#). The others remain open.

## 113.10 Source 17: further research questions and a prioritized program

These questions are continuations of this article, not claims that each is a historically catalogued open problem. The results above narrow their scope: questions about minimal-slice characters, the displayed gap spectrum, or mere recognition with the full labelled prefix structure are no longer left open within this development.

### 113.10.1 Set-sized order geometry

**Research question 113.69** (Nonminimal enumeration types). For  $|\alpha| = \mu = 2^{<\kappa}$ , classify the characters, gap spectrum, density, and binary coding length of  $\mathcal{W}_\alpha(\mathbf{No}_{<\kappa})$ . Begin with  $\alpha = \mu \cdot 2$  and  $\mu + n$ .

A prefix can now use  $\mu$  labels before exhausting its coordinate domain, so residual alphabets can be small, have endpoints, or be finite. The proof of [Theorem 30.11](#) suggests replacing the single residual-alphabet interface by a tree whose nodes carry their actual residual order types. A theorem expressed only in  $|\alpha|$  cannot capture all such effects.

**Research question 113.70** (Noncardinal birthday cutoffs). Replace the initial cardinal  $\kappa$  by an arbitrary infinite ordinal  $\theta$ . Which local invariants depend on the ordinal tail of  $\theta$ , not merely on  $|\theta|$  and  $|\mathbf{No}_{<\theta}|$ ?

Our cone argument uses  $\delta + \gamma < \kappa$  for smaller ordinals. That property fails at many noncardinal cutoffs. A useful first target is a cutoff of the form  $\kappa + \omega$ , followed by  $\kappa \cdot 2$ , with the contributions of each birthday layer kept separate.

**Research question 113.71** (Isomorphism after the invariant calculation). When do two minimal permutation orders with the same values of  $r, q, \mu^{<\mu}$  and the same gap spectrum have the same order type? Which additional invariants distinguish them?

The explicit gap classification provides more information than binary equimorphism, but still need not determine an order. Candidate invariants include the arrangement of cylinder-boundary cuts, densities of particular convex suborders, and the interaction of branch cuts with a chosen prefix filtration. No general isomorphism conclusion is asserted here.

**Research question 113.72** (Beyond the proved fusion length). Determine the least size of a family of dense open sets whose intersection fails to be dense. When  $q = \omega$ , determine complete metrizability and more precise descriptive topological properties directly from the permutation presentation.

[Theorem 30.5](#) supplies a lower bound: every family of size at most  $q$  succeeds. For longer constructions, intermediate prefixes can already have length  $\mu$ , so the simple small-history argument no longer applies. This is an obstruction to that proof, not a proof that longer fusion always fails.

### 113.10.2 Global branches, automorphisms, and class realizations

**Research question 113.73** (The extendible automorphism group). Describe the stabilizer of the represented-cut predicate in  $\text{Aut}(\mathcal{P}_s(b))$ . Can one characterize it by preservation of fewer predicates than the entire labelled cylinder and coverage structure?

[Theorem 47.5](#) identifies this stabilizer abstractly, and [Theorem 47.7](#) shows it is proper. The remaining task is a useful structural description. Numerical relabellings give a natural family, but need not exhaust it.

**Research question 113.74** (Changing baselines). For two baselines  $b, b'$ , when does an automorphism of  $\mathfrak{W}_{\text{sl}}$  carry  $\mathcal{P}_s(b)$  onto  $\mathcal{P}_s(b')$ ? How does the answer depend on their eventual-agreement classes and on their represented-cut predicates?

Relabelling by an increasing numerical bijection is sufficient when it carries one baseline to the other. Abstract order-isomorphism of the two cores is not sufficient by itself; the obstruction proved here explains why the represented cuts must enter the analysis.

**Research question 113.75** (Recovering a class realization). What information about  $\mathcal{X}$  can be reconstructed from the labelled core together with its admitted represented cuts? What is lost if the baseline and cylinder predicates are forgotten?

[Theorem 48.4](#) detects every proper same-set extension through new represented cuts. Its pair encoding recovers an individual ordinal subclass from a suitable enumeration. A stronger reconstruction should specify the decoding language and distinguish existence of individual codes from a universal truth or satisfaction predicate.

**Research question 113.76** (Iterated proper-class blocks). Determine the precise recursion strength needed to organize successive canonical Ord-blocks of a raw well-order along a prescribed index order. Compare finite iteration, set-length iteration, and class-length iteration.

One extraction is elementary; iterating a procedure whose state is a class can require more. The distinctions involving ETR in [22] provide the appropriate setting for a reverse- mathematical analysis. Our direct comparison and branch recognition do not by themselves solve this recursion problem.

**Research question 113.77** (The condensed unrestricted order). Classify the dense comparison obtained by collapsing the finite components of [Theorem 54.4](#). Which residual fibres remain detectable from its bare order, and what embeds into it?

Finite adjacency is now fully described. The quotient can still contain nontrivial fibres with infinite or proper-class residual carrier. It would be incorrect to conclude from density alone that it is the set-like order or an ordinary surreal-sized class.

### 113.10.3 Effective bounds, coherence, and verification

**Research question 113.78** (Ordinal and birthday optima for supported completion). Refine the cardinal reserve formula to optimal ordinal support bounds and optimal birthdays of canonical support codes. Which optima are uniform without an additional global choice parameter?

Two fresh reserves of the same cardinality can occupy very different ordinal intervals. [Theorem 49.7](#) isolates the unavoidable cardinality; ordinal placement and coding complexity remain separate. A constructive version should specify the representation of partial injections and the operation used to choose a complement bijection.

**Research question 113.79** (Coherent cutoff embeddings). Construct embeddings between the orders at different birthday cutoffs which compose exactly and preserve a useful prefix filtration. Determine which can also preserve cut types or finite condensation.

Appending an arbitrary tail preserves some comparisons but can change the required enumeration type. A coherent reserve mechanism should be chosen once for the whole system rather than separately at each pair of cutoffs. The support theorem may help isolate its minimal size costs.

**Research question 113.80** (First checked milestones). Formalize the reserve theorem, elementary common-prefix comparison, and set-sized cut trichotomy before attempting the class automorphism theorem. Can the abstract alphabet interface support other saturated or non-Archimedean ordered alphabets without changes to the proofs?

These milestones have explicit input and output types and no dependency on a formal universe of all class well-orders. Their value is not merely in reproducing finite tests, but in certifying the limit and cardinal arguments that the tests cannot inspect.

**Research question 113.81** (Typed constructions indexed by presentations). Which algebraic or model-theoretic constructions can use the set orders  $\mathcal{W}_\alpha(X)$  or uniformly coded global subfamilies as index orders, while keeping every support and evaluation map within a specified size level?

A promising first investigation should use a bounded index set, verify that the output is independent of the chosen presentation in the intended sense, and only then consider a uniform class version. The analogy with Kanovei–Shelah is a guide to construction, not permission to use an uncoded higher-order totality as a set.

[merge] Status of source 17's questions, 3 October 2026. [Research question 113.77](#) is answered externally for countable  $\omega$ -standard models by source 18: there the collapsed order is the rational order, densely coloured by the factorial block sizes ([theorem 58.6](#)); its internal classification is open. [Research question 113.69](#) is answered for the binary coding length and the density of the strata  $\mu \cdot \gamma + n$  by sources 15 and 16 ([theorems 27.2](#) and [31.2](#)); characters and gap spectra beyond the minimal slice are open. [Research question 113.76](#) is answered in its block clause by the block decomposition ([note 52.1](#)). [Research questions 113.70](#) and [113.79](#) are source 12's [research questions 113.12](#) and [113.19](#). Source 17's own table of the earlier questions it addresses (in [section 4](#)) is corrected there. The others remain open.

## 113.11 Source 18: revised research questions and priorities

The following are proposed directions left after the theorems above. They are not presented as a list of previously catalogued open problems. Each states the extra information that is still needed.

### 113.11.1 Bounded order types and their completions

**Research question 113.82** (The arrangement of gaps). For fixed  $\kappa$ , classify  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  up to order isomorphism, or classify its completion together with the subset of realized points. Which features go beyond the complete character spectrum and the multiplicities proved here?

The new spectrum and counting formulas turn this into an arrangement problem. In particular, a large family of gaps of one character may have a highly nontrivial induced order. A first target is  $\kappa = \omega$ , followed by  $\omega_1$  under specified continuum arithmetic. Equimorphism with a binary cube does not settle this.

**Research question 113.83** (Longer fixed enumeration types). Determine gap spectra and binary coding lengths for  $\mathcal{W}_\alpha(\mathbf{No}_{<\kappa})$  when  $\alpha > \mu + 1$ , especially  $\alpha = \mu \cdot 2$  and  $\mu \cdot \gamma + n$ .

Density and cellularity are now known for every  $\alpha$  of cardinality  $\mu$ , and finite-tail point characters are explicit. Later infinite blocks can use up an entire  $\mu$ -sized residual region, so the minimal-type proof cannot simply be repeated.

**Research question 113.84** (Noncardinal birthday bounds). For a noninitial ordinal  $\theta$ , determine the spectrum of  $\mathcal{W}_{|\mathbf{No}_{<\theta}|}(\mathbf{No}_{<\theta})$ . Which ordinal features of  $\theta$  survive in interval sizes and cut characters?

The present proof uses the closure  $\beta + \gamma < \kappa$  for  $\beta, \gamma < \kappa$ , which may fail for  $\theta$ . The appropriate replacement is a stratified description of sign cones, not a substitution of  $|\theta|$  for  $\theta$ .

**Research question 113.85** (Coherent enlargement of cutoffs). Construct embeddings between order spaces for increasing birthday cutoffs that compose exactly, and specify whether they preserve minimal enumeration length, prefix cylinders, finite condensation, or selected cut characters.

Appending a fixed tail gives an embedding of full well-order spaces, but need not preserve minimum-length strata or compose with a second independently chosen tail. A global rank-layer schedule gives a candidate for coherent full spaces; the sharper minimal-stratum requirements remain separate.

### 113.11.2 Class cuts, blocks, and automorphisms

**Research question 113.86** (Iterating the quotient rather than removing blocks). Choose a precise limit rule and determine the strength of iterating  $R \mapsto B_R$  along specified class well-orders. Which fixed points, periodic behaviors, or invariants occur?

The single decomposition and ordinary ordinal-indexed block removal are elementary. The finite-support example is already a fixed point up to isomorphism. Any claim that repeated condensation automatically reduces complexity must confront that example. The axiomatic strength of the genuinely iterated operation is not determined here.

**Research question 113.87** (Order structure on represented class cuts). Study the class cuts satisfying the straddling-prefix criterion, with predicates marking exhaustive branches and residual tail types. Which natural automorphisms of the bounded-support core preserve that distinguished collection of cuts?

The criterion gives a recognition theorem. It does not classify the automorphism action on all class cuts, or show that every automorphism of the core extends to the global order. Baseline changes differing on a proper class of positions are a concrete first case.

**Research question 113.88** (The expanded countable model). Classify  $(\mathfrak{W}_{\text{all}}^{\mathcal{M}}, \mathfrak{W}_{\text{sl}}^{\mathcal{M}})$ , and then add the evaluation relation to the surreal labels. Which features depend on the countable class realization once the pure order has become the same factorial shuffle?

The pure order cannot define set-likeness even with finite parameters. An added predicate can therefore retain information that the shuffle classification necessarily discards.

**Research question 113.89** ( $\omega$ -nonstandard class models). Describe the external finite-condensation blocks and the elementary theory of  $\mathfrak{W}_{\text{all}}$  for countable  $\omega$ -nonstandard GBC models. Do these orders share the first-order theory of the standard factorial shuffle, while realizing additional types?

Internally finite permutation cylinders become externally infinite discrete intervals. Standard finite adjacency chains inside them already invalidate the standard classification. Determining the possible global assembly of these intervals is a concrete model-theoretic problem; no positive answer to the question is claimed here.

### 113.11.3 Words, encoding, and formalization

**Research question 113.90** (Sharp word-code bounds). Optimize the birthday of explicit order embeddings of injective and increasing words, recording separately preservation of numerical order, prefix extension, and simplicity. Can the centered encodings be made comparably efficient at singular stages?

The duplicated-sign delimiters provide transparent proofs, rather than optimal codes. Uniform tree isomorphisms obtained by back-and-forth supply little direct birthday control.

**Research question 113.91** (The centered increasing order itself). Classify the entire centered increasing-word order up to isomorphism and determine the intrinsic definability of its all-negative cones and its positive-limit points.

Its local characters, its complete set-cut obstruction, and the two types of rooted cones are known here. The contrast between that intrinsic information and the displayed entry signs makes the automorphism problem meaningful.

**Research question 113.92** (Weak choice and uniform constructions). Which word-tree isomorphisms and class-core identifications can be proved without Global Choice? For a specified operation, distinguish existence, a uniform definable implementation, and an effective implementation on concrete codes.

The explicit sign embeddings and many cut arguments need no Global Choice. Our class isomorphisms use deterministic global back-and-forth. These are different strength claims; a uniform family of class maps should not be selected without proof.

**Research question 113.93** (A first machine-checked milestone). Formalize the elementary common-prefix relation and the set-interval decomposition for a supplied class-model relation, alongside the set-level ordinal spectrum and minimal permutation cut trichotomy. Can one order-theoretic interface serve all four?

This is a realistic modular target because it avoids almost all surreal arithmetic. The initial deliverables should expose their size assumptions in the theorem signatures and make the conventional proof-to-formal-statement correspondence reviewable.

[merge] Status of source 18's questions, 3 October 2026. Source 18 was written before sources 13–17 arrived. [Research question 113.83](#) is answered in part by source 15 (binary coding lengths of  $\mu \cdot \gamma + n$ , [theorem 31.2](#)); [research question 113.87](#) in part by source 17's extension criterion ([theorem 47.5](#)), which shows that a core automorphism extends to the global order exactly when it preserves the represented cuts; [research question 113.92](#) bears on source 16's [research question 113.65](#). [Research questions 113.84](#) and [113.85](#) are source 12's [research questions 113.12](#) and [113.19](#); [research question 113.90](#) is source 11's [research question 113.6](#). The others remain open.

### 113.12 The questions of sources 19–30: index and status (3 October 2026)

[merge] Sources 19–30 ask 139 questions (13, 12, 12, 12, 10, 12, 11, 12, 12, 12, 12 and 9), printed per source in the following subsections as proposed continuations, not as a census of open problems; every source says so. Many repeat each other or an earlier question; the table groups them, names the earlier question each continues, and records the status after the whole batch-83 addition. A question answered by another batch-83 source is marked in the dated note after its source's subsection. The status of the earlier questions that batch 83 answers fully or in part is recorded in [section 113.25](#).

| Topic                                                          | Asked by                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        | Status, 3 October 2026                                                                                                             |

### 113.13 Source 19: further research questions after the new results

These questions are proposed continuations of the present work. They are not asserted to be a catalogue of historically established open problems. The distinction matters because a question may already have an answer in the wider literature even when the project has not yet identified it.

#### 113.13.1 Fixed enumeration types and bounded completions

**Research question 113.94** (The remaining coding gap). When a singular non-strong-limit residual cardinal at most  $\kappa$  produces different lower and upper weighted ranks  $\varrho_{\text{lo}} < \varrho_{\text{up}}$ , determine the least binary coding length of  $\mathcal{W}_\alpha(\mathbf{No}_{<\kappa})$ . Is the lower bound always attained? A stronger and especially useful target is an embedding into  $\mathbb{B}_{\varrho_{\text{lo}}} \times n!$ .

The embedded-cube spectrum is already settled by the constant-cylinder argument. The unresolved issue is an upper coding construction, not the existence of a still larger binary cube inside the order. The generic subproblem is whether  $\mathcal{W}_\lambda(Y)$  embeds into  $\mathbb{B}_\lambda$  for every alphabet  $Y$  of singular non-strong-limit size  $\lambda$ . Birthday-controlled insertion shows that all such alphabets occur in the relevant residual range when  $\lambda \leq \kappa$ .

**Research question 113.95** (From equimorphism to isomorphism). Classify the actual order types of the fixed strata whose binary coding ranks and cube spectra agree. Which additional arrangements of numerical gaps, residual alphabets, and finite cylinders distinguish equimorphic examples?

The first-cutoff theorem gives a warning: two familiar topological models can have the same ordered completion  $\mathbb{R}$  and different complements inside it. The canonical decorated-word completion is a more informative object than a list of cardinal invariants.

**Research question 113.96** (Gap arrangements in longer strata). Extend the bounded normal forms from minimum-length permutations to every fixed enumeration type, using the residual lexicographic sum and the cardinal-layer decomposition. Compute the order of the gap loci, together with their point characters and multiplicities.

Infinite tails introduce several successive residual alphabets. The completion should record those transitions; merely adding the minimal-stratum spectra cannot determine how the gaps are arranged.

**Research question 113.97** (Noninitial birthday bounds). For an arbitrary ordinal  $\theta$ , study  $\mathcal{W}_{|\mathbf{No}_{<\theta}|}(\mathbf{No}_{<\theta})$  and its longer strata. Which features depend on  $\theta$  as an ordinal rather than just on its cardinality?

The full-interval-size and sign-cone arguments above use the closure of an infinite initial cardinal under sums of two smaller ordinals. A noninitial bound requires a finer decomposition of its sign tree.

### 113.13.2 Residual class alphabets and automorphisms

**Research question 113.98** (Stability of first-block separation). Analyze the set-deletion criterion of Proposition 99.3 in residual surreal alphabets defined by sign, birthday, or algebraic conditions. Which natural embeddings, convex restrictions, or extensions of the class realization preserve injectivity of the initial-word trace map?

The surreal fresh-label property is sufficient: at a first difference  $a < b$  after a set prefix, an unused label strictly between them gives an exhaustive separator. Requiring every open interval of  $Y$  to remain nonempty after deleting any set guarantees this step. The exact obstruction is now an initial Ord-segment and a final Ord\*-segment exposed by deleting a set, with admitted witnesses. The Ord + Ord\* counterexample shows that cardinality of the carrier alone is insufficient. Applying the criterion systematically, and tracking the admission of its witnesses under a change of class realization, would make recursive residual analysis more effective.

**Research question 113.99** (Residual fiber isomorphism types). Determine which orders  $\mathcal{W}^{\mathcal{M}}(Y)$  occur as fibers over core cuts and when two such fibers are isomorphic. Can useful invariants be extracted from the numerical order on  $Y$  without classifying its entire family of well-orders?

This is the remaining mathematical content in the automorphism extension criterion. The decorated reconstruction is exact, but a decoration by the full fiber order type is not by itself a simple classification of those fibers.

**Research question 113.100** (Which core automorphisms extend?). Compute the decoration-preserving subgroup of  $\text{Aut}(C)$  in specified external class models. How does it depend on the chosen baseline enumeration and on a change of baseline with proper-class support?

Preservation of represented versus unrepresented cuts is necessary but may omit the residual order type. The exact criterion requires preserving that full type. It would be valuable to replace it with more concrete combinatorial invariants in important models.

**Research question 113.101** (Enrichments that remember the class theory). Expand the pure global order by its set-like suborder, a selected core, its prefix tree, and an evaluation relation. Which fragments of the underlying class theory become interpretable in these successively richer structures?

The common pure first-order theory cannot distinguish even  $\omega$ -standardness. This makes the question of the smallest informative enrichment precise. Retaining the numerical alphabet and the prefix-evaluation relation is a natural first experiment.

### 113.13.3 External models and foundational strength

**Research question 113.102** (Uncountable external isomorphism spectra). Classify  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  and  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}}$  for specified uncountable class models. What additional conditions on their quotients and nonstandard internally finite cylinders are forced by saturation or by a full-class realization?

The common elementary theory is already fixed. Uncountable isomorphism types must retain information beyond finite games, including cut cofinalities and the external geometry of internally finite intervals. The full-class model at an inaccessible cardinal is a concrete first case.

**Research question 113.103** (Admitted versus amenable branches). Study the order and descriptive complexity of the persistent external cuts whose bounded prefixes are all internally coded but whose full branches are not admitted. How does this family change when the class realization is enlarged while the set universe is kept fixed?

Theorem 100.1 produces continuum many such cuts in every countable realization. The next issue is how these cuts are arranged and which extensions admit selected branches without adding sets.

**Research question 113.104** (Iterating set-interval condensation). Specify a limit-stage rule for iterating  $R \mapsto J_R$  and determine the exact recursion or comprehension principles needed for the resulting construction. Which fixed points and strictly changing orbits occur?

The one-step quotient is elementary and may preserve isomorphism type. Any iteration theorem must therefore prove its own structural or well-foundedness claim rather than infer descent from the word “quotient.”

### 113.13.4 Coherence and formal proof development

**Research question 113.105** (Coherent enlargement maps). Construct a directed system of embeddings between birthday-cutoff well-order spaces, with explicitly stated preservation of prefixes, finite-tail cylinders, or selected completion data.

The restriction theorem proves that arbitrary carrier restriction cannot provide the required monotone maps. A construction should instead specify how new labels are inserted and how the schedules compose. Full well-order spaces and minimum-length strata impose different scheduling requirements.

**Research question 113.106** (A small certified core of the theory). Formalize the restriction classification, first-disagreement comparison, prefix-code concatenation, and cylinder fusion as general set-level lemmas, then derive the weighted fixed-type spectrum from them.

This would convert the most reusable part of the present analysis into a compact foundation for later work. It also provides a clear test of which cardinal-arithmetic lemmas and ordinal-sum bounds are actually needed by the proof.

[merge] Status of source 19's questions, 3 October 2026. [Research question 113.94](#) is open; sources 29 and 30 ask it again ([research questions 113.212](#) and [113.224](#)). [Research question 113.95](#) is open; at the countable alphabet the finite-tail strata are pairwise nonisomorphic ([corollary 68.7](#)). [Research question 113.96](#) is open beyond the characters of  $\mathcal{W}_{\mu+\omega}$  ([theorem 63.15](#)). [Research question 113.97](#) is answered in part by source 21 ([theorem 77.4](#)) and source 29 ([theorem 76.5](#) and [corollary 78.10](#)); the order type is open. [Research questions 113.98](#) to [113.100](#), [113.102](#) and [113.103](#) are open. [Research question 113.101](#) is answered in part: the labelled global enumerations of a realization recover its whole class part (sources 22, 27, 30: [theorem 102.3](#) and [notes 102.5](#) and [102.16](#)), while a setwise-named core does not ([proposition 102.19](#)). [Research question 113.104](#) is answered over GBC for canonical histories: they exist for all class well-orders exactly when strong class comparability holds (source 29, [theorem 108.19](#)), and a supplied history terminates (source 20, [theorem 108.1](#)); the limit convention is [corollary 108.14](#). [Research question 113.105](#) is answered in part by source 20's append-tail system ([theorem 74.8](#)) and source 21's fixed-slot embeddings ([theorem 75.1](#)). [Research question 113.106](#) is a proposal.

### 113.14 Source 20: a revised research agenda

The following questions concern extensions not established by this article. They are project proposals, except where their background is explicitly cited. The previous broad question whether *every* core automorphism extends has a negative answer in [theorem 97.7](#); it should no longer appear as unresolved.

**Research question 113.107** (The extendible subgroup). Give useful generators or intrinsic descriptions of the subgroup of core automorphisms preserving exhaustive represented cuts. How does it depend on the chosen baseline and the displayed prefix structure?

[Note 97.8](#) supplies an exact criterion, but it does not compute that subgroup. A concrete starting point is the automorphism group of the labelled prefix structure together with its exhaustion predicate. Numerical relabelling alone does not stabilize a fixed core, by [proposition 97.9](#).

**Research question 113.108** (Extensions across raw residual fibers). Which core automorphisms preserving all injective represented cuts extend to the entire raw comparison structure? Formulate necessary and sufficient conditions including the order types of residual fibers and the uniformity of the chosen fiber identifications.

Different raw well-orders can have the same first ordinal block and hence the same core cut. A cut-preservation criterion alone cannot choose their relative images. The local-size blocks of [theorem 107.5](#) offer a first manageable family of fibers.

**Research question 113.109** (The expanded countable structure). Classify the external pairs  $(\mathfrak{M}_{\text{all}}^{\mathcal{M}}, \mathfrak{M}_{\text{sl}}^{\mathcal{M}})$ , or expand further by prefix evaluation. Which distinctions between class realizations survive after the pure order has collapsed to the two types in [note 109.13](#)?

The pure order forgets almost all class-theoretic information. Set-likeness is a natural first predicate to restore, but its distribution inside singleton or larger cut fibers can depend on admitted branches. A full answer should specify whether the underlying set model is fixed.

**Research question 113.110** (Effective theory with additional predicates). Determine the theory and decision complexity after adding a named set-like fragment, selected prefix predicates, or a baseline evaluation relation to the pure countable order.

The pure order theory is decidable by [corollary 109.22](#); adding the enumeration data can reintroduce much more information. It is useful to identify the smallest expansion that detects a change of class realization, rather than assuming that the pure order already does so.

**Research question 113.111** (The strength of complete condensation histories). Over GB or GBC, what is the exact strength of the assertion that every supplied class well-order admits its nested least-representative condensation history through the input order plus one stage?

[Theorem 108.1](#) proves the terminal behavior conditional on the history and gives ETR as a sufficient existence principle. A reversal would require encoding a genuinely class-valued recursion into this particular elementary operator. Merely observing its transfinite appearance would not establish such a reversal.

[merge] (4 October 2026, batch 96.) Answered over GBC by source 29 and over GB by sources 34 and 35: the assertion is equivalent to strong comparability CWO ([theorems XVI.5.8](#) and [108.19](#) and [note XVI.5.19](#)); whether it implies ETR is open ([research question 113.219](#)).

**Research question 113.112** (Alternative limits for quotient iteration). Which other mathematically natural limit rules give canonical condensation histories, and how do their heights compare with  $h_\kappa(\theta)$  in the full model?

The nested-carrier convention retains embedding information at limits. An isomorphism-type-only process discards that information. One should first define any replacement rule as an actual operator and examine the self-similar examples before seeking a general height theorem.

**Research question 113.113** (Embeddings that retain more than order). Can birthday-stage embeddings preserve designated cylinders, finite condensation blocks, or chosen cut characters while composing exactly? What is possible for specified minimal enumeration strata?

The append-tail maps in [theorem 74.8](#) solve coherence for all enumeration types. They need not stay in a prescribed minimal stratum. The local-rank criterion identifies the obstruction to set-likeness; preserving exact local ordinal types is a stricter requirement.

**Research question 113.114** (Exact birthday profiles and club diagnostics). Classify the attainable functions  $\kappa \mapsto \text{otp}(R \upharpoonright \mathbf{No}_{<\kappa}^2)$  and the associated classes  $\text{Min}_R$  of strong-limit cutoffs at which the minimum type is attained. Which finer invariants remain after passing to equivalence modulo the club filter?

[Theorem 74.7](#) detects set-likeness:  $\text{Min}_R$  contains a club in the set-like case and misses a club otherwise (source 20 writes  $A_R$ ). Unboundedness alone does not suffice, as the sparse-beth example shows. A natural next step is to apply analogous diagnostics to the successive canonical ordinal blocks and ask whether their combined profiles recover more of a raw class well-order.

**Research question 113.115** (Gap arrangements beyond spectra). Classify the ordered pair consisting of the Dedekind completion of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  and its distinguished realized subset. At the countable cutoff, how much of the prefix tree is recoverable from that pair?

[Theorem 67.11](#) identifies the countable completion and the topological complexity of the realized points. Equal gap counts and equal topology do not by themselves identify the arrangement of the missing cuts. At uncountable stages a generalized topology must first be specified.

**Research question 113.116** (Longer strata and noninitial birthdays). Determine the full proper-gap spectra and their arrangement for  $\mathcal{W}_{\mu,2}(\mathbf{No}_{<\kappa})$  and longer strata, and for birthday cutoffs which are not initial cardinals.

The known density transition and binary coding ranks do not determine these arrangements. At noninitial cutoffs, ordinal tails can destroy the closure of the cones used in the cardinal-cutoff proofs. A first target is a single additional infinite enumeration block with a fixed finite terminal tail.

**Research question 113.117** (Robustness under class extensions). For extensions of the class collection with the same sets, characterize which new represented cuts, automorphisms, and condensation histories can appear while all old comparisons remain fixed.

The absoluteness result in [section 111.6](#) rules out changing the well-foundedness of an old common relation. The remaining freedom lies in new relations and in new uniform witnesses. This sharper formulation avoids a false source of model dependence.

**Research question 113.118** (A verified generic first-divergence library). Formalize common-prefix comparison, two-label persistence, finite changes along restrictions, and the sharp coherent-gluing criterion for arbitrary ordered carriers. Then instantiate at the inspected ProveIt sign carrier.

This is a concrete first milestone: its dependencies are relation restriction, set-valued recursion, ordinal first difference, and well-foundedness. It would verify several central mechanisms before the more demanding task of formalizing the class automorphism and nonstandard-model arguments.

[merge] Status of source 20's questions, 3 October 2026. [Research question 113.107](#) is open; it is asked again by sources 21, 25, 27 and 29 ([research questions 113.119](#), [113.165](#), [113.193](#) and [113.218](#)), with partial results in [theorem 96.4](#) and [corollary 96.12](#). [Research question 113.108](#) is **answered** in the external formulation by source 19, which source 20 did not see: a core automorphism extends to the admitted raw orders of a set-sized model exactly when it preserves the isomorphism types of the residual fibres ([theorem 98.5](#)). [Research question 113.109](#) is answered in part for countable models by source 30 ([proposition 102.19](#)) and, for labelled data, by [theorem 102.3](#) and [note 102.16](#). [Research question 113.110](#) is open. [Research question 113.111](#) is **answered** over GBC by source 29: the assertion is equivalent to strong comparability of class well-orders ([theorem 108.19](#)); its relation to ETR is open ([research question 113.219](#)). *Dated note, 4 October 2026 (batch 96)*: answered over GB as well ([section 113.29](#) (a)). [Research question 113.112](#) is answered in part ([corollary 108.14](#): under the nested rule the limit equivalence is the union of the earlier ones). [Research question 113.113](#) is answered within a cardinality band by source 21 ([theorem 75.1](#)); across cardinalities it is open ([research question 113.124](#)). [Research questions 113.114](#) and [113.115](#) are open; the countable completion is described further by sources 21, 24 and 29 ([theorems 67.2](#), [67.10](#) and [68.2](#)). [Research question 113.116](#) is answered in part: characters at  $\mu + \omega$  ([theorem 63.15](#)) and the spectrum level at noncardinal cutoffs (Part XI); the gap spectra are open. [Research question 113.117](#) is answered in part by the reconstruction theorems ([theorem 102.3](#) and [notes 102.5](#) and [102.16](#)). [Research question 113.118](#) is a proposal.

### 113.15 Source 21: further research questions and concrete targets

The following are proposed continuations. They are not a claim that each question has already appeared as an established open problem in the literature. Each is formulated after the results

proved here, so it does not ask again whether core extension always works or whether noncardinal cutoffs have computable basic invariants.

**Research question 113.119** (Classify the extendable subgroup). For a fixed baseline  $b$ , describe  $\text{Stab}_{\text{Aut}(\mathcal{P}_{\text{bd}}(b))}(\mathcal{C}_{\text{exh}})$  by useful generators, definability conditions, or an intrinsic expansion of the core. Which such descriptions avoid explicitly naming every exhaustive represented cut?

The stabilizer criterion is exact, and the subgroup is proper. The remaining task is a structural description. Cofinalities alone cannot suffice: exhaustive, nonexhaustive, and vertical large cuts are conjugate in the unexpanded core order.

**Research question 113.120** (Extension to the full class-well-order space). Which core automorphisms preserve the represented injective cuts and the order types of their residual fibers, and when can their induced fiber isomorphisms be made uniform?

The full extension problem requires more than the set-like criterion: two orders with the same initial word may have different residual well-orders. A sufficient theorem should construct the fiber maps explicitly or state the additional choice principle used to assemble them. The vertical-cut obstruction already rules out arbitrary extension.

**Research question 113.121** (Prefix-preserving automorphisms). Classify automorphisms of the displayed prefix tree that preserve its exhaustive branches. Which numerical relabelings and coordinate-dependent successor-order isomorphisms generate them?

The countable theorem shows that bare-order automorphisms can destroy the cylinder family. Even a tree automorphism need not visibly preserve the global requirement that every label eventually occurs. This asks for the precise extra condition, rather than assuming that local compatibility implies exhaustivity.

**Research question 113.122** (Noncardinal cut spectra and isomorphism types). Determine the complete cofinality spectrum of missing cuts in  $\mathcal{W}_{2|\theta|}(\mathbf{No}_{<\theta})$  for noncardinal  $\theta$ . When do two such spaces with equal basic invariants have the same order type?

For example, the cutoffs  $\omega + 1$ ,  $\omega \cdot 2$ , and  $\omega^2$  have the same cardinality, density, global cofinalities, point characters, and binary coding rank calculated here. These equalities do not prove an isomorphism. The finite numerical end blocks and the different sign-prefix structures suggest concrete cut configurations to compare first.

**Research question 113.123** (Fixed nonminimal enumeration types). Extend fixed-type cardinal and character formulas to full isomorphism and embedding classifications for  $\mathcal{W}_\alpha(\mathbf{No}_{<\theta})$ , with  $|\alpha| = |\mathbf{No}_{<\theta}|$ , and describe the relative closures of these strata.

Existing finite-terminal and density calculations are not by themselves a classification. The first-cardinality decomposition and closure theorem give a starting point that tracks the unused alphabet, not only the ordinal length. A useful next case is to compare consecutive finite terminal lengths while retaining the prefix-fiber structure.

**Research question 113.124** (Coherence across a change of cardinality). Can the fixed-slot construction be replaced by embeddings between minimum-length spaces when their cardinalities change, with strict composition identities along a specified chain of birthday cutoffs?

Within a fixed band, [theorem 75.1](#) supplies such a system. Across a cardinal jump the coordinate domains change; across a proper class of cutoffs, the uniform family itself requires a size audit. Specify whether the embeddings should preserve the order topology, prefix structure, or both.

**Research question 113.125** (The uncountable colored quotient). For uncountable external realizations, classify the quotient of  $\mathfrak{W}_{\text{all}}$  by its canonical terminal permutation blocks, with the factorial-size colors retained. Which saturation and homogeneity properties follow from the underlying class realization?

The countable standard and nonstandard types are completely described here. Their local block analysis remains available in larger models, but dense colors no longer imply uniqueness of the quotient order. This is a natural setting for separating cardinal invariants from actual order type.

**Research question 113.126** (How much model structure does a marked core retain?). When are two pairs  $(H_{\mathcal{X}}, \mathcal{P}_{\text{bd}}(b))$  and  $(H_{\mathcal{Y}}, \mathcal{P}_{\text{bd}}(c))$  isomorphic if the core is preserved setwise but its individual codes are allowed to move?

Pointwise identification of a common core detects proper class expansions through represented cuts, while the unmarked countable orders are always rational. The intermediate classification should be expressed through the action of core automorphisms on represented-cut families. It could distinguish model-theoretic information that neither extreme viewpoint captures.

**Research question 113.127** (Automorphism and descriptive complexity of the countable-alphabet space). Give an explicit description of the subgroup of  $\text{Aut}(\mathbb{R}, <)$  preserving the embedded set  $P = \mathcal{W}_{\omega}(\mathbb{Q})$  in its Dedekind completion. Classify its orbits on omitted cuts and determine the complexity of the branch-exhaustivity condition in a chosen completion code.

The Baire homeomorphism, finite homogeneity, and continuum many missing cuts are already proved. A sharper description would separate vertical numerical cuts, omitted-range branch cuts, and any further cut types by explicit invariants.

**Research question 113.128** (Presentation orders under forcing). Under hypotheses preserving old class well-order types, which lexicographic presentation orders acquire new cuts or new automorphism obstructions? What changes after identifying old and new carriers through specified interleavings?

Preservation of old relations is proved above; preservation of all new abstract types is a different issue studied under stronger hypotheses in [27]. New sign sequences can enlarge the carrier even when ordinals are unchanged. A useful first target is a forcing extension adding one real, with the old carrier named explicitly.

**Research question 113.129** (Relation-table comparison with extra structure). Which choices of the coordinate enumeration of  $\mathbf{No}^2$  give isomorphic expanded relation-table orders, and which preserve a specified set-coded dense family? Can any of them recover the numerical first-prefix comparison after adding a small amount of structure?

Binary equimorphism does not settle these questions. The two-label example already rules out identifying the comparisons on the nose.

**Research question 113.130** (Formal verification of the obstruction). Formalize first the small-carrier prefix comparison and fixed-slot coherence theorem, then the abstract cut-reconstruction and nonextension argument over a universe-relative class interface.

The theorem dependencies are short and arithmetic-free. A verified result should include an axiom report and an explicit smallness boundary. In particular, the final nonextension theorem should be checked as a statement about permitted uniform operators or about a specified larger-universe collection, not an undeclared type of all classes.

[merge] Status of source 21's questions, 3 October 2026. Research question 113.119 is open (with source 20's research question 113.107). Research question 113.120 is **answered** in the external formulation by source 19 (theorem 98.5); the uniformity of internal fibre isomorphisms is open. Research question 113.121 is answered in part: tree automorphisms preserving the core and every cylinder act on branches with exactly two orbits (theorem 90.1); label-coherent ones are coordinatewise (theorem 93.1, and source 27's note 96.5); exhaustion-preserving families are in theorem 96.4 and proposition 96.11. Research questions 113.122, 113.124, 113.125 and 113.128 are open. Research question 113.123 is answered in part (embedding spectra by sources 19 and 30, theorem 64.11 and note 64.18; cardinal invariants by source 22, theorem 63.4); isomorphism is open. Research question 113.126 is answered for countable models by source 30: the two pairs are always isomorphic, by an isomorphism fixing the baseline (proposition 102.19). Research question 113.127 is answered in part (the omitted cuts form a dense meagre  $F_\sigma$  of size  $\mathfrak{c}$ , theorem 67.4; complexity of the  $E_n$ , theorem 68.2). Research question 113.129 is answered in part at set level by source 27 (theorems 84.2 to 84.4). Research question 113.130 is a proposal.

### 113.16 Source 22: further research questions and proposed projects

The following questions are continuations of the present program. They are not advertised as a list of historically established famous open problems. In particular, the fixed-length density/cellularity/weight table and the redundancy of cylinder heights are now treated as proved results rather than left open.

#### 113.16.1 Residual orders and topology

**Research question 113.131** (Nonminimal cut spectra). Classify the nonprincipal cut-character spectra of  $\mathcal{W}_{\mu+n}(\mathbf{No}_{<\kappa})$ ,  $\mathcal{W}_{\mu+\omega}(\mathbf{No}_{<\kappa})$ , and  $\mathcal{W}_{\mu\cdot 2}(\mathbf{No}_{<\kappa})$ . Which cuts arise inside a residual fibre, and which occur at a boundary where a limiting prefix loses extendibility?

The general first-disagreement formula settles point characters only after the relevant residual orders are understood. A cut may follow a coherent prefix chain whose union exhausts too many labels. Such a failure is not detected by the three cardinal topological invariants.

**Research question 113.132** (The dense quotient orders  $Q_n(X)$ ). When are  $Q_n(X)$  and  $Q_m(X)$  isomorphic for distinct finite  $n, m$ ? Does the answer depend only on the numerical order type of  $X$ , or on additional saturation properties not implied by richness?

They share the invariants computed in proposition 63.8, but equality of those invariants is not an isomorphism theorem. An isomorphism would sharpen the finite-tail normal forms and compare their nonisolated derivatives.

**Research question 113.133** (Long-tail local characters). Describe the possible point characters for  $\alpha = \mu \cdot 2$  by a tractable invariant of the residual alphabet. Can the iterated first-disagreement reduction be organized as a useful normal form rather than an arbitrary tree of residual orders?

The main topological table already applies. The remaining issue is local order structure, including endpoints of residual permutation orders and cofinalities of their extremal fibres.

**Research question 113.134** (Descriptive topology when cofinalities are countable). For which alphabets and lengths are these first-countable spaces metrizable, completely metrizable, or representable by familiar ordered spaces? In particular, analyze the split space at  $\mu + 2$  without mistaking separability for second countability.

The countable-alphabet examples provide controlled test cases:  $\omega + 2$  has many jumps,  $\omega + 3$  has a dense set of isolated points, and  $\omega + \omega$  has no jumps but continuum cellularity.

### 113.16.2 What structure must be retained?

**Research question 113.135** (Eliminating label data). After unranked cylinder incidence is supplied, what is the weakest additional relation that recognizes exhaustive branches? Can label occurrence be replaced by a coarser invariant, or can two incidence presentations with identical unlabelled data disagree on the exhaustive-trace predicate?

Height is no longer an unknown ingredient: [theorem 87.1](#) recovers it. The open issue is label coverage. No claim that it is eliminable, or provably indispensable in every presentation, is made here.

**Research question 113.136** (Reconstruction without fixed coding parameters). How much of [theorem 102.3](#) survives when  $b$  or  $g$  is not named? Can one formulate a functorial reconstruction up to isomorphism of two-sorted models, rather than inclusion over an identical set universe with shared parameters?

The elementary decoder is exact once the parameters are fixed. Removing them introduces an automorphism and definability problem, not a failure of the existing decoder.

**Research question 113.137** (Automorphisms preserving admitted traces). Characterize the automorphisms of the unranked incidence structure which preserve exhaustive traces in a given class realization. Which core-order automorphisms extend to this incidence structure, and which preserve the binary-swap trace substructure after changing the baseline?

The earlier reports supply extension obstructions for pure core automorphisms. The present reconstruction suggests that preservation of admitted traces can constrain the induced action on the entire class sort.

### 113.16.3 Bounds, foundations, and verification

**Research question 113.138** (Noncardinal birthday cutoffs). For an ordinal cutoff such as  $\kappa + \omega$  or  $\kappa \cdot 2$ , determine exactly which intervals retain full alphabet cardinality. Extend the topological classification to fragments where richness fails or varies from interval to interval.

The proof of [note 62.15](#) uses  $\delta + \eta < \kappa$  for smaller ordinals at an initial-cardinal cutoff. That mechanism must be replaced, not assumed, for arbitrary ordinal cutoffs.

**Research question 113.139** (Coherent length and cutoff embeddings). Construct embeddings among different birthday fragments and enumeration strata which compose exactly and preserve a useful prefix filtration. Determine the optimal additional support or reserve needed for this coherence.

An arbitrary appended tail preserves a comparison but may change the prescribed order type or destroy compatibility with another embedding. The earlier optimal support-cardinality theorem is a natural input; optimal ordinal placement remains separate.

**Research question 113.140** (Iterated raw heads and recursion strength). Determine the exact class-recursion strength needed to iterate the canonical common-head or ordinal-head decomposition through set and class lengths. Which bounded iterations are elementary, and which imply fragments of ETR?

The elementary direct comparison in [note 111.17](#) does not settle this. A reverse-mathematical treatment should specify whether a stage is a set object or a whole class relation.

**Research question 113.141** (Binary coding lengths for long strata). Extend the earlier binary equimorphism and singular strong-limit coding-length results to nonminimal lengths. How do finite jumps, infinite residual orders, and failures of residual extendibility affect the least binary-word length admitting an order embedding?

The constant ordinal embedding spectrum does not answer this finer question. Nor does cardinality  $2^\mu$  alone determine a binary lexicographic coding length.

**Research question 113.142** (First kernel-checked milestones). Formalize the residual-cylinder identity, the first-disagreement character formula, and height recovery from unranked incidence. Then instantiate the richness and fresh-separator interfaces using the repository's sign carrier.

These milestones are small enough to isolate precise size hypotheses but substantial enough to verify the limit arguments which finite regression checks cannot reach. Only after they are checked should the class-realization decoder be encoded in an explicit model interface.

[merge] Status of source 22's questions, 3 October 2026. [Research questions 113.131 to 113.133](#) are open (for  $\mu = \omega$  the finite-tail spaces are classified by sources 29 and 30, [theorems 68.8](#) and [68.9](#)). [Research question 113.134](#) is answered for the minimal lengths by source 26 (completely metrizable exactly at  $\mu = \omega$ , [theorem 69.18](#)) and for the lengths  $\omega + n$  of a countable alphabet by sources 29 and 30 (same references). [Research question 113.135](#) is **answered** by source 25: unranked cylinders, the core order and any set of parameters do not recognize exhaustive branches ([theorems 91.1](#) and [91.2](#)), and equality of labels across edges does ([theorem 93.1](#)); a minimal relation is open ([research question 113.166](#)). [Research question 113.136](#) is answered in part: source 27 needs only the baseline ([note 102.5](#)), source 30 needs no common baseline in advance ([note 102.16](#) and [corollary 102.22](#)). [Research question 113.137](#) is answered in part by source 25 ([theorems 90.1](#) and [93.3](#)). [Research question 113.138](#) is answered in part (Part XI). [Research question 113.139](#) is answered in part ([theorems 74.8](#) and [75.1](#)). [Research question 113.140](#) is answered for canonical histories ([theorem 108.19](#)). [Research question 113.141](#) is **answered** by source 19 except at singular non-strong-limit residual cardinals at most  $\kappa$  ([theorem 64.11](#); source 30's route, [note 64.18](#)). [Research question 113.142](#) is a proposal.

## 113.17 Source 23: further research questions and proposed projects

The termination question for the two unrestricted set-word carriers is settled by [Theorem 81.9](#); the questions below begin beyond that result. The explicit polynomial hierarchies likewise answer an existence problem, not the full classification or proof-strength problem for arbitrary raw orders.

### 113.17.1 Word orders and enriched lexicographic structure

**Research question 113.143** (Classification of the nonsaturated marker orders). For a fixed infinite regular  $\theta$ , are all word orders arising from marker cuts of type  $(\theta, \text{Ord})$  isomorphic? Does the answer change between arbitrary and injective words? Which cut spectra, beyond point characters, decide the answer?

The character computation gives necessary invariants but not a complete classification. A focused first step is a cut reconstruction theorem for the nonsaturated word orders, keeping their named cylinders.

**Research question 113.144** (Restricted increasing-word repairs). Which length restrictions or endpoint decorations make an increasing-word order saturated at a prescribed small cardinal? Can one characterize the obstruction by cofinal subsets of the terminally available alphabet at each prefix, rather than by one global marker?

Theorem 82.1 rules out every fixed marker for all set lengths. Prefix-dependent markers or extra continuation labels are substantive new structures, not exceptions to that theorem.

**Research question 113.145** (Intrinsic versus named cylinders). For which expansions of the outer linear order are prefix cylinders, termination points, or inherited monotonicity recoverable? Can one find a minimal additional relation that distinguishes these presentations without naming every prefix individually?

The previous work's prefix non-rigidity makes a claim of recovery from bare order alone unsafe. The new admissible-marker isomorphisms supply further examples in which the same linear order has different alphabet presentations.

**Research question 113.146** (Quantitative birthday bounds). For a small input cut of words, bound the separator's length and the birthdays of its letters in terms of the input and forbidden-label bounds. Can the two-cut fresh-separator construction be arranged to use one prescribed extra birthday level?

The crossing chain already gives a set length bound from the input. Optimizing the label bound would connect the abstract proof directly to `exists_cut_separator_of_birthday_lt`.

### 113.17.2 Raw orders and condensation

**Research question 113.147** (Proof strength of general condensation iteration). Over GBC, what is the exact strength of the assertion that every raw class well-order admits its set-interval condensation hierarchy along a given class well-order? Is a restricted form of ETR sufficient and necessary, or does this particular operator admit a weaker construction?

Theorem 108.8 shows that long explicit examples by themselves cannot establish a lower bound on the recursion principle. A reversal would need to encode genuinely arbitrary recursive information.

**Research question 113.148** (Which orders eventually collapse?). In a theory providing the required hierarchy, does every raw class well-order collapse at some admitted class-well-order stage? How should collapse length be represented without an illegitimate order type object for every proper-class well-order?

The polynomial theorem realizes every prescribed admitted length. It does not give a universal bound or prove eventual collapse for all raw orders.

**Research question 113.149** (Lexicographic distribution of internal invariants). Can Theorem 108.23 be sharpened from existence in every set-like interval to a uniform embedding of a specified parameter order, with its points carrying prescribed condensation hierarchies? Which such families remain definable from a fixed baseline enumeration?

The quantifier order matters: a single class parameter  $\Gamma$  is allowed in the proved theorem. A uniform family ranging over all class well-orders needs an explicitly higher-order interpretation.

**Research question 113.150** (Condensation versus finite residual adjacency). How do set-interval blocks inside a raw well-order interact with finite adjacency components in the outer lexicographic order? Can an enriched outer order describe the distinction between an exhausted finite residual tail and a proper residual class?

These are different condensations on different orders. Treating them as one operation would erase the key carrier distinction.

### 113.17.3 Foundations and implementation

**Research question 113.151** (Choice strength of the new classification). What is the weakest class theory proving the separator part of Theorem 81.9, with a supplied saturated alphabet and marker cut? Can its order-isomorphism conclusion be proved without a supplied global enumeration, for the special surreal presentations?

Most local proofs use only set-sized constructions with class parameters. The back-and-forth conclusion deliberately uses global choice. These should be optimized separately.

**Research question 113.152** (A checked pair of contrasting theorems). Formalize the admissible-marker theorem for the injective sign-carrier word order and, in the same framework, the failure for increasing words. Then formalize the explicit  $\omega$  polynomial hierarchy and its non-stabilizing limit, before addressing arbitrary  $\Gamma$ .

This yields a manageable development with positive and negative tests. The finite diagnostics supplied here can guide examples, but the kernel proof must retain the universe and cofinality distinctions.

[merge] Status of source 23's questions, 3 October 2026. [Research question 113.143](#) was **answered** by source 16 before source 23 was placed: all marker orders of type  $(\theta, \text{Ord})$  are  $\mathbf{T}_\theta$ , and arbitrary and injective words give isomorphic orders ([theorem 36.2](#)). [Research questions 113.144, 113.146 and 113.149 to 113.151](#) are open. [Research question 113.145](#) is answered in part, negatively: cylinders are not intrinsic ([theorem 47.12](#) and [corollary 67.9](#)) and not enough to recognize exhaustion ([theorem 91.1](#)). [Research question 113.147](#) is answered for canonical histories over GBC by source 29 ([theorem 108.19](#)); whether ETR is necessary is open. [Research question 113.148](#) is answered for supplied histories by source 20: a history along  $W + 1$  terminates ([theorem 108.1](#)), with exact heights in the full model ([corollary 108.3](#)). [Research question 113.152](#) is a proposal.

## 113.18 Source 24: further research questions and proposed projects

These are proposed continuations of the results proved here. They are not all claimed to be previously published open problems. Questions about structured cut recognition, prefix non-rigidity, optimal support reserves, and some automorphism extensions have already been addressed in the earlier drafts; a new project should use those results instead of restating them as untouched.

### 113.18.1 Singular topology and completeness

**Research question 113.153** (Complete metrizability at uncountable countable cofinality). Let  $\mu > \omega$  be singular with  $\text{cf } \mu = \omega$ . Is the forward-prefix space  $\mathcal{W}_\mu(X)$  completely metrizable? Equivalently, can the dense permutation subspace of its metrizable injection completion be characterized as a  $G_\delta$  subset? Determine whether the answer depends on cardinal arithmetic.

The equivalence is justified directly in Appendix 69.2; its ambient injection space is completely metrizable by Theorem 65.1 and Proposition 62.7. The question concerns the original topology, not the finer two-sided topology. The shift-type counterexample proves only the incompleteness of one uniformity. A constructive positive answer would need to enforce uncountably many coverage requirements while keeping the appropriate neighborhoods; a negative answer could be obtained by showing that no countable open intersection in the injection space characterizes exhaustiveness.

**Research question 113.154** (A singular replacement for the exhaustion tree). Classify  $\mathcal{W}_\mu(X)$  up to homeomorphism when  $\mu$  is singular. Can it be represented as the body of a tree with an explicit acceptance condition at prematurely full prefixes, rather than as the unrestricted body of a regular-height tree?

The exact obstruction in Section 66 suggests retaining both domain-length growth and coverage growth as separate coordinates. A useful result would identify an invariant that distinguishes singular spaces with the same cofinality and weight.

**Research question 113.155** (Dense-open intersection thresholds). Determine the least cardinality of a family of dense open subsets of  $\mathcal{W}_\mu(X)$  whose intersection is not dense. Compare that number with  $\text{cf } \mu$ , the exhaustion family in  $\mathcal{I}_\mu(X)$ , and any stronger point-preserving fusion properties.

The existing fusion theorem is a lower bound, not a complete classification. An intersection theorem in the permutation space and one in the injection completion are different statements: the latter has all the closed missing-label boundaries available.

### 113.18.2 Order structure beyond the topological classification

**Research question 113.156** (The embedded real-line model at countable size). Describe the complement  $\mathbb{R} \setminus \mathcal{W}_\omega(X)$ , up to increasing homeomorphism of  $\mathbb{R}$ , using its cylinder-edge, numerical-gap, and nonexhaustive-branch parts. Which of these parts are recoverable from the bare linear order and which require named prefix predicates?

The present paper gives its Borel class, category, density, and cardinality, but not a complete orbit classification of its placement in  $\mathbb{R}$ . The earlier non-rigidity results warn that a prefix-based description need not be intrinsic to the bare order.

**Research question 113.157** (Regular homeomorphisms versus order embeddings). Theorem 66.2 forgets the numerical alphabet. Which additional data on the exhaustion tree recover lexicographic order, and what order-embedding or order-isomorphism criteria can be proved from those data?

Even the countable case shows that recognizing Baire topology does not identify the order with its standard irrational model. Quantitative versions could track birthday bounds and support costs during the tree coding.

**Research question 113.158** (Completion-preserving automorphisms). Characterize those order or topological automorphisms of the permutation space that extend to its forward injection completion, its two-sided completion, or its Dedekind completion while preserving specified boundary types.

Every order isomorphism extends to the Dedekind completion, but preservation of the branch subspace is an extra condition. Earlier represented-cut criteria should be combined with the uniform-continuity obstruction, rather than replaced by a blanket extension claim.

### 113.18.3 Permutation algebra at singular cardinals

**Research question 113.159** (The boundedness-preserving subgroup). Analyze  $H_\mu$  intrinsically at singular  $\mu$ : its closure properties in the two ambient topologies, its normalizers, and the possible topological-group structures on larger natural subgroups. How much of the ordinal bounded-set ideal is recoverable from this group together with its topology?

Theorem 69.2 is an exact local criterion, but it does not classify the subgroup algebraically. The explicit transposition between a bounded cofinality-sized set and a cofinal set provides a basic test witness for any proposed extension.

**Research question 113.160** (Uniformities with an exhaustion interpretation). Classify compatible complete uniformities on the regular permutation space that admit a direct label-coverage interpretation. At singular sizes, determine which inverse-control conditions can be added without changing the original topology on a specified subspace.

The forward, two-sided, and exhaustion-tree uniformities already separate three natural notions. A useful classification should distinguish equality of topology, uniform equivalence, and equality of completion boundary.

### 113.18.4 Class theory, models, and formal verification

**Research question 113.161** (An axiomatization of virtual completion). Give a reusable formal theory of prefix-completion schemes for class-coded structures, with the exact hypotheses needed for coherent unions, small-net rigidity, and inverse reconstruction. Can the whole theory be developed over a fragment weaker than the full assumptions used here?

The small-net argument isolates Class Replacement as the source of the uniform disagreement bound. An appropriate reverse-mathematical analysis would test that dependency, rather than assuming all class-theoretic principles have the same strength.

**Research question 113.162** (Changing the class part without changing the sets). For models  $(M, \mathcal{X}) \subseteq (M, \mathcal{Y})$ , characterize which newly available injective branches are exhaustive and which new boundary traces they induce. Relate this to the existing preservation results for old, prefix-structured cuts.

A new class may be a new net, a new limit, or a new parameter defining a cut. Those are different mechanisms. Any forcing interpretation should separately verify the relevant class-forcing theorem and preservation hypotheses; none is assumed in this article.

**Research question 113.163** (Unrestricted tails and their completion theory). Develop analogues of the present completion constructions for arbitrary non-set-like labelled class well-orders. What prefix index structures are appropriate after a proper-class common segment, and how does finite-tail adjacency interact with those structures?

An Ord-word model cannot merely be reused: it forgets the very tail that makes such an order non-set-like. The elementary common-prefix relation is a starting point that does not presuppose a comparison theorem for all class order types.

**Research question 113.164** (A small trusted Lean core). Formalize, without admitted new mathematical axioms, the short-prefix extension lemma, the cylinder-base theorem, forward completion, and the regular exhaustion-tree homeomorphism. Then instantiate them at  $\mathbf{No}_{<\kappa}$  and separately formalize the class-model comparison theorem.

This would convert the main set-sized advances into checked mathematics while preserving the explicit boundary around global class semantics. The inspected simplicity interface can be reused when simplest separators are needed, but its existence hypothesis must still be discharged by an independent small-cut theorem.

[merge] Status of source 24's questions, 3 October 2026. [Research question 113.153](#) is **answered negatively** in ZFC by source 26: for uncountable  $\mu$  of countable cofinality  $\mathcal{W}_\mu(X)$  is not Borel in  $\mathcal{I}_\mu(X)$  and has no compatible complete metric, on any nonempty open subspace ([theorems 69.17](#) and [69.18](#)); the answer does not depend on cardinal arithmetic ([note 69.7](#)). [Research question 113.154](#) is answered in part by the same theorems and by closed universality ([theorem 69.20](#)); the homeomorphism type is open. [Research question 113.155](#) is open (asked again as [research question 113.183](#)). [Research questions 113.156](#) to [113.158](#), [113.161](#) and [113.163](#) are open. [Research question 113.159](#) is **answered** in the natural action by source 28:  $H_\mu$  is the largest subgroup containing the finitary permutations on which the prefix topology is a group topology, it is self-normalizing at singular  $\mu$ , the bounded ideal is recovered from it with its action, and its closure and completion are described ([theorems 70.4](#), [70.6](#), [70.10](#) and [70.26](#) and [proposition 70.8](#)). [Research question 113.160](#) is answered in part by source 28's group envelope and its two-sided completeness ([theorems 70.18](#) and [70.27](#)). [Research question 113.162](#) is answered in part by the reconstruction theorems ([theorem 102.3](#) and [note 102.16](#)). [Research question 113.164](#) is a proposal.

### 113.19 Source 25: further research questions and proposed projects

The questions below continue beyond the results proved here. They are proposed research problems arising from this investigation, not assertions that each is a previously published open problem.

**Research question 113.165** (The exhaustive-branch stabilizer). Characterize the subgroup of cylinder-preserving core automorphisms whose induced action permutes  $\mathfrak{W}_{\text{sl}}$ . Can it be described by local compatibility conditions on the increasing maps between residual alphabets, rather than the global requirement that every branch still cover every label?

The represented-trace criterion is exact but global. [Theorem 92.2](#) shows that the entire cylinder group is too large. The countable rational-alphabet case is already a substantial, concrete version of this classification problem.

**Research question 113.166** (Recognition without full rigidity). Find natural enrichments strictly weaker than edge-label equality that recognize exhaustive branches while still admitting nontrivial automorphisms. Which relations are necessary to connect label occurrences across different depths, and which merely overdetermine that information?

Our negative result rules out recognition from the unlabelled core and any set of parameters. Our positive enrichment is sufficient and rigid. It does not establish a minimal language between those two extremes.

**Research question 113.167** (Preserving a support filtration). Let  $\mathcal{P}_s(b)_\alpha$  consist of core branches whose transition permutation is supported below  $\alpha$ . What remains of the automorphism group after requiring preservation of every  $\mathcal{P}_s(b)_\alpha$ , or a cofinal subsequence of these levels? Does a support filtration recover any part of edge-label coherence?

The present back-and-forth preserves membership in the whole core but does not control the support of each image. The filtration is additional structure, distinct from the prefix-height relation, which is already recovered by cylinders.

**Research question 113.168** (Larger configurations and exact obstruction patterns). Which uniformly class-indexed configurations admit a simultaneous profile-preserving automorphism? Is there a useful criterion combining boundedness of divergence constraints at each stage with the avoidance of already determined noncore limit branches?

Theorem 95.1 supplies one necessary obstruction. A full characterization would need to distinguish failure of one-point realization from failure of completing an otherwise compatible partial automorphism.

**Research question 113.169** (Singular-cardinal automorphism groups). For singular  $\kappa$ , compare the cylinder structures of bounded-support and less-than- $\kappa$ -support cores. Determine their orbit invariants, first-disagreement realization spectra, and automorphism-group cardinalities for saturated fragments or specified surreal birthday alphabets.

One must keep track of  $|\mathbf{No}_{<\kappa}| = 2^{<\kappa}$  as well as cf  $\kappa$ . Remark 95.2 shows that even the underlying prefix families can differ. The regular formula  $2^\kappa$  cannot simply be transferred by notation.

**Research question 113.170** (Two baselines at once). Given global enumerations  $b, c$ , study the structure carrying both cores  $\mathcal{P}_s(b)$  and  $\mathcal{P}_s(b)_c$  and their common prefix tree. How does the transition permutation  $b^{-1} \circ c$  affect the joint automorphism group and recognition of exhaustive branches?

The elementary intersection question has an immediate answer: the two cores coincide exactly when  $b$  and  $c$  eventually agree, and otherwise they are disjoint. Indeed, a common core member would express both baselines as set-supported modifications of that member, making their transition permutation set-supported. A second, disjointly positioned core may constrain the symmetries of the first without naming every label; that joint structure is the unresolved part of the question.

**Research question 113.171** (The bare order of exhaustive enumerations). Classify order automorphisms of  $\mathfrak{W}_{\text{sl}}$  without assuming that they preserve a chosen core or its cylinder family. Which invariants of the enriched structures survive after both are forgotten? How do answers depend on the admitted class realization and on permitted uniformity of maps?

The earlier pure-order nonrigidity results and the present cylinder-preserving nonextension theorem constrain different directions. Neither is a classification of the full bare-order automorphism problem.

**Research question 113.172** (Raw tails and outer-order invariants). Can structural properties of the non-set-like tail of a raw class well-order be recognized from the outer lexicographic order, perhaps after adding a natural incidence relation? Which convex-fibre invariants distinguish raw well-orders that share the same initial set-like head?

Earlier condensation constructions produce complicated encoded tail orders [51]. The complication of an order encoded by a point is not automatically an invariant definable from the outer order of points. An explicit reconstruction or non-invariance argument is needed.

**Research question 113.173** (The increasing-word analogue). For the subtree of numerically increasing set-length words, determine the exact one-point extension property and its obstructions. Can an appropriate language of cross-coordinate inequalities yield an orbit classification analogous to Theorem 90.1?

The present automorphism group does not preserve this subtree. A successful analogue must retain more than sibling order and divergence, but perhaps less than full equality of labels across all edges.

**Research question 113.174** (Class-realization reconstruction after forgetting labels). Earlier continuation work reconstructs an admitted class realization from exhaustive traces over a labelled core. What part of that reconstruction survives under unlabelled isomorphism of core-and-cylinder structures? Which additional relations recover the lost distinction between exhaustive and nonexhaustive traces?

Theorem 91.1 prevents a direct label-free transfer of the coverage test. The question is now to identify surviving invariants, not to assume that the original decoder remains canonical in the reduct.

**Research question 113.175** (A checked minimal development). Formalize the regular set theorem, the countable two-orbit case, and the edge-coherent rigidity theorem with a common abstract alphabet interface. Can the maximum/no-maximum extension lemma be isolated as a reusable ordered-tree theorem independent of surreal numbers?

The suggested first deliverable is a kernel-checked one-point lemma plus supported completion. These are the two nontrivial inputs on which the longer back-and-forth proof depends.

[merge] Status of source 25's questions, 3 October 2026. [Research question 113.165](#) is answered in part by source 27's exact obstruction and sufficient bounds ([theorem 96.4](#)) and source 29's fixed-stage family ([proposition 96.11](#) and [corollary 96.12](#)). [Research questions 113.166 to 113.169](#) and [113.171](#) are open (source 27 asks [research question 113.166](#) again, [research question 113.194](#)). [Research question 113.170](#): its intersection part is settled in its own commentary; source 20 shows that an increasing relabelling makes the two cores disjoint ([proposition 97.9](#)); the joint structure is open. [Research question 113.172](#) is open; source 23 shows that every interval between distinct set-like enumerations contains raw orders of any prescribed condensation complexity ([theorem 108.23](#)). [Research question 113.173](#) is answered in part by source 29's transitivity on the increasing tree ([theorem 96.7](#)). [Research question 113.174](#) is answered in part: the pure order and a setwise-named core lose the realization ([propositions 102.19](#) and [102.20](#)). [Research question 113.175](#) is a proposal.

## 113.20 Source 26: further research questions and proposed projects

The following questions are proposed continuations. They are not all claimed to be previously published open problems. The singular complete-metrizability question of the earlier draft is no longer on this list: it is answered by Theorem 69.18. Likewise, the existence of direct comparison for non-set-like orders and the basic support-core coding are established background, not unresolved proposals.

### 113.20.1 Descriptive complexity and closed subspaces

**Research question 113.176** (Generalized Borel complexity). Determine the sharp complexity of  $\mathcal{W}_\mu(X)$  in appropriate generalized Borel and projective hierarchies when  $\mu > \omega$  and  $\text{cf } \mu = \omega$ . Which hierarchy matches the actual weight of the prefix space, rather than merely the cardinality of its index set?

The ordinary non-Borel theorem is a lower bound, not a complete answer to a generalized hierarchy question. The exhaustion formula is a  $\mu$ -indexed intersection of opens, and should be compared with the definitions and weight assumptions in singular generalized descriptive set theory [58].

**Research question 113.177** (Closed universality without  $\mu > \mathfrak{c}$ ). For an uncountable cardinal of countable cofinality with  $\mu \leq \mathfrak{c}$ , characterize the separable metrizable spaces occurring as closed subspaces of  $\mathcal{W}_\mu(X)$ . Must a closed copy of  $\mathbb{Q}$  exist in ZFC?

The present coding handles complements indexed by fewer than  $\mu$  branches. It settles noncomplete metrizability in this regime but does not supply arbitrary Cantor traces. Improving the reservoir scheme or finding a genuinely different closed-subspace construction would be meaningful progress.

**Research question 113.178** (Higher cofinality coding). For cf  $\mu = \tau > \omega$ , is there an analogue of Theorem 69.13 with a bounded-topology binary space of height  $\tau$ ? What compactness, closed-image, and perfect-set substitutes remain valid?

A transfinite release schedule retains the least-disagreement combinatorics, but its topology is no longer ordinary compact metrizable Cantor space. The continuity and closed-image arguments must be replaced, not merely relabelled.

**Research question 113.179** (The exact role of bounded inverse images). Classify the topological and descriptive complexity of the intermediate spaces between  $H_\mu$  and  $\mathcal{I}_\mu^b \cap \mathcal{W}_\mu(\mu)$  (source 26's  $\mathcal{B}^+ \cap \mathcal{P}_\kappa(\kappa)$ ). Can the trace calculation involving  $A$  and  $\bar{A}$  be extended to higher closure or derived-set operations by additional inverse-control conditions?

Proposition 69.24 provides a concrete starting model: the inverse condition transforms arbitrary exclusion of  $A$  into exclusion of its topological closure. Any proposed hierarchy should state the controlled family of label sets exactly.

### 113.20.2 Enumeration lengths and order structure

**Research question 113.180** (A classification across nonminimal strata). For every ordinal  $\lambda$  with  $|\lambda| = |X|$ , classify the prefix topology of  $\mathcal{W}_\lambda(X)$  and determine when it agrees with the enumeration order topology. Which residual-tail invariants govern complete metrizability?

Successor lengths are prefix-discrete, whereas initial infinite cardinal lengths have the classification proved here. Limit lengths with long finite or small-cardinal residual configurations form the next natural family. A statement depending only on  $|\lambda|$  cannot suffice.

**Research question 113.181** (Closed order embeddings versus topological embeddings). For thick surreal alphabets, characterize which linear orders admit embeddings with closed image in the minimal enumeration space, and distinguish this from merely embedding their order topologies. Can prescribed Cantor traces be required to be convex or to respect named cylinder relations?

The marker construction gives closed images relative to the permutation space, but does not generally give convex images. Earlier prefix non-rigidity results caution that bare order automorphisms need not preserve an externally named prefix structure.

**Research question 113.182** (Embedding spectra refined by topology). Refine the earlier cardinal and ordinal embedding spectra by asking for continuous, closed, or prefix-preserving embeddings. Which of these spectra distinguish equimorphic surreal enumeration slices?

The new obstruction shows that mutual order embeddings alone leave substantial topology unresolved. The unconditional  $\beth_\omega$  example is a useful test case because it does not depend on additional cardinal arithmetic.

**Research question 113.183** (Dense-open intersection thresholds). Determine the least cardinality of a family of dense open subsets of  $\mathcal{W}_\mu(X)$  whose intersection is not dense, and compare it with the corresponding invariant of  $\mathcal{I}_\mu(X)$  and of  $H_\mu$ .

Theorem 69.12 settles the countable lower bound. The injection space has the explicit missing-label closed sets, while the bounded subgroup has the countable uniform-exhaustion description (31). These different structures may lead to different thresholds.

### 113.20.3 Foundations, global orders, and verification

**Research question 113.184** (A topology that retains unrestricted class tails). Develop a precise higher-sort or model-relative topology for arbitrary labelled class well-orders that distinguishes tails after a common proper-class prefix. How do the finite residual adjacent pairs sit in its completion theory?

Set-length prefix agreement alone is not Hausdorff on the unrestricted domain. The common-labelled-prefix formula gives an elementary comparison, but not by itself a full higher-order topology.

**Research question 113.185** (Reverse foundations of uniform approximation). What fragments of Class Replacement and choice suffice for small-net rigidity, the reserve extension theorem, and the diagonal noncoding theorem? Which implications can be reversed over a weak two-sorted base theory?

The proofs isolate different resources: set collection of disagreement bounds, completion of set partial permutations, and an elementary pair-swap diagonal. They need not all have the same axiomatic strength.

**Research question 113.186** (Changing admitted class families). For class-model extensions with the same sets, describe which new injective or exhaustive branches become available and how their traces interact with old uniformly coded cuts. What preservation principles keep the relevant prefix-completion schemes intact?

The problem concerns new relations and new uniform families, not a change in the internal well-foundedness of an old fixed relation under the GBC hypotheses explained in Section 71.3.

**Research question 113.187** (A minimal kernel-checked continuation). Formalize the compact omitted-label theorem, the non-Borel corollary, and the complete-metrizability classification on a general alphabet, then instantiate the result at  $\mathbf{No}_{<\beth_\omega}$ . How small can the trusted interface to classical descriptive set theory be made?

A useful milestone is a machine-checked exact range equation for the code, before any Borel hierarchy formalization. That theorem captures the main construction and can be reused independently of the final topological obstruction.

[merge] Status of source 26's questions, 3 October 2026. [Research questions 113.176 to 113.178](#) and [113.181 to 113.185](#) are open. [Research question 113.179](#) is answered in part by source 28's one-sided loci ([theorems 70.10 and 70.11](#)). [Research question 113.180](#) is answered in part for the lengths  $\omega + n$  of a countable alphabet ([theorems 68.8 to 68.10](#)). [Research question 113.186](#) is answered in part by the reconstruction theorems ([theorem 102.3](#) and [note 102.16](#)). [Research question 113.187](#) is a proposal.

### 113.21 Source 27: further research questions and priorities

The following questions are continuations motivated by the proved results. They are not asserted to be a catalogue of open problems recognized in the published literature.

**Research question 113.188** (Classify intermediate scan types). For a set carrier of cardinality  $\mu$ , classify density, cellularity, point characters, and finite convex blocks in  $\mathcal{W}_s(X)$  when the scan has type  $\vartheta$  with  $|\vartheta| = \mu$ . The cases  $\vartheta = \mu$  and a carefully chosen  $\mu + 6$  are settled here; the arrangement of dependencies between scanned pairs, not only  $\theta$ , may matter. A first target is the complete classification of countable scans of type  $\omega + n$ .

**Research question 113.189** (Recover the effective scan). Which oriented pair priorities are determined by the labelled order on well-orders? Swapping a single adjacent pair recovers its first orientation; swapping two disjoint adjacent pairs recovers their relative priority. Priorities of pairs sharing a label can be redundant because transitivity constrains their bits. Classify effective scans modulo equality of their induced labelled orders. The three-label diagnostic gives 36 orders from 48 scans.

**Research question 113.190** (The table-ordered bounded-support core). The same set-coded core is dense in the raw table order under a set-like scan, but its order now depends on that scan. Determine when it has endpoints, which uniform set cuts it fills, and which scan invariants control its isomorphism type. Its numerical-enumeration order is isomorphic to **No**; that fact cannot simply be transferred to its table order.

**Research question 113.191** (A sharper type for centered increasing words). Is

$$\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min} \cong \mathbf{T}_{\min}^+?$$

The product theorem answers the factorization problem, and (36) proves several sum identities, but neither settles this isomorphism. Determine a distinguishing invariant or construct an isomorphism. Equality of known local character spectra would not alone suffice.

**Research question 113.192** (Orders at genuine surreal gaps). Classify  $\mathcal{T}_{\varepsilon}^{\text{inc}}(\mathbf{No})$  (source 27's  $\text{Inc}_C(\mathbf{No})$ ) for cuts  $\mathbf{No} = L + R$  with one side of set cofinality or coinitality. [Proposition 82.8](#) computes point characters, and a gap with a set-coinitial right side is separated from the standard centered order. Do those characters classify all such constructions? A stronger classification of every unfilled set cut has not been proved here and should be treated as a new theorem to establish, not inferred from the point table.

**Research question 113.193** (The subgroup preserving exhaustive branches). Classify the ordered-prefix-tree automorphisms for which both the map and its inverse preserve exhaustive Ord-branches. The exact obstruction is an exhaustive branch through a subtree avoiding one output label. Uniform birthday bounds are sufficient but not necessary, and antichain tail transformations give additional examples. An ordinal-valued progress condition for the varying forbidden labels is a concrete next target.

**Research question 113.194** (Weaker enrichments than label equality). Cross-node equality of appended labels yields exactly global numerical relabellings. Which strictly weaker predicates already force preservation of exhaustiveness? Possible data include birthday strata, equality of birthdays, and incidence with designated bounded label sets. These enrichments should be tested separately; preserving the unlabelled tree and sibling orders is now known to be insufficient.

**Research question 113.195** (Raw extensions of core automorphisms). For a class part fixed externally, characterize automorphisms of a chosen core that extend to the full raw order, taking account of the complete tail fiber over each represented nonexhaustive branch. The set-like extension criterion concerns exhaustive traces; raw extensions must also preserve the residual orders.

**Research question 113.196** (Marked model reconstruction with fewer constants). [Note 102.5](#) fixes every core element pointwise. What smaller collection of predicates or distinguished subsets suffices to recover the class part, perhaps up to an automorphism of the set universe? Investigate expanded countable models before claiming an intrinsic invariant of the unmarked order.

**Research question 113.197** (Optimize the interpolant, not just a fixed prefix). The ordinal support optimum is exact for a prescribed partial injection. For a separated cut, many prefixes may yield an interpolant. Minimize the optimum over those prefixes, then compare ordinal support height with sign-code birthday. This may produce sharper constructive bounds for the dense-core realization theorem.

**Research question 113.198** (Controlled bounded approximations). Determine which class constructions admit coherent versions across birthday stages, especially singular and noninitial cutoffs. The set self-copy theorem here works at every infinite cutoff, but the homogeneous back-and-forth used for word and prefix isomorphisms requires additional closure at a fixed stage. Preserve the difference between full set-word trees and trees truncated before their terminal level.

**Research question 113.199** (First machine-checked theorem package). Implement the generic terminal-cut factorization, the six-coordinate scan theorem, and the support cutoff criterion first. These give small, independently useful milestones with explicit set-level statements. The next milestone should be the elementary labelled class-prefix comparison inside an explicit model, followed by the uniform diagonal theorem. This ordering resolves concrete foundational obligations before attempting the larger automorphism constructions.

### 113.21.1 What the continuation has resolved

The new results locate several boundaries more sharply than an ordinal spectrum alone can. A scan can retain that spectrum while changing isolation and density. An ordered prefix tree can retain every local numerical comparison while losing exhaustive coverage. An ordinary class core can be dense for relation tables while no uniform ordinary class family is dense for raw enumeration comparison. A support bound can be optimal in cardinality while far from optimal in ordinal height. The surviving questions ask which additional structure recovers the information lost at each boundary.

[merge] Status of source 27's questions, 3 October 2026. [Research questions 113.188, 113.189, 113.191 and 113.197](#) are open. [Research question 113.190](#) is answered in part by source 30's canonical max-index scan ([theorem 84.13](#)) and its density theorem ([theorem 84.11](#)). [Research question 113.192](#) is answered in part: actual thresholds and gaps with two large sides by source 29 ([proposition 82.14](#)); no marker makes increasing words saturated ([theorem 82.1](#)); gaps with one small side are open ([research question 113.216](#)). [Research question 113.193](#) is answered in part ([proposition 96.11](#) and [corollary 96.12](#)). [Research question 113.194](#) is open ([research question 113.166](#)). [Research question 113.195](#) is **answered** in the external formulation by source 19 ([theorem 98.5](#)). [Research question 113.196](#) is answered in part: a core named setwise with the baseline does not suffice in countable models ([proposition 102.19](#)). [Research question 113.198](#) is answered in part ([theorems 74.8 and 75.1](#)). [Research question 113.199](#) is a proposal.

## 113.22 Source 28: further research questions and topics

### 113.22.1 Singular topology and descriptive complexity

**Research question 113.200** (Complete metrizability of the full singular space). Let  $\mu > \omega$  be singular with  $\text{cf } \mu = \omega$ . Is  $\text{Sym}(\mu)$ , with its bounded-prefix topology, completely metrizable? Equivalently, is it a  $G_\delta$  subspace of the complete forward injection space?

The dense complete locus  $B_\mu^-$  and the Baire property do not decide this question. Nor does the incompleteness of the forward metric. A positive proof must organize all label-coverage requirements

into countably many ambient open requirements, or construct a complete compatible metric directly. A negative proof must rule out all compatible complete metrics, not just the chosen forward one. Appendix 69.9 supplies the precise equivalence.

**Research question 113.201** (The singular envelope’s exact character). Determine  $\text{cof}([\mu]^{<\mu}, \subseteq)$  for significant singular cardinals, and isolate which additional cardinal-arithmetic hypotheses yield an exact value between  $\mu^+$  and  $\mu^{<\mu}$ .

The elementary diagonal gives a uniform strict lower bound, not an exact formula. Further work should compare the cofinality of the whole small-subset poset with fixed-size subset cofinalities and with appropriate possible-cofinality methods, without replacing one invariant by another on the basis of notation alone.

**Research question 113.202** (Descriptive complexity of the one-sided loci). For uncountable cf  $\mu$ , determine the natural generalized Borel complexity of  $B_\mu^+$ ,  $B_\mu^-$ , and  $H_\mu$  in the forward injection and permutation spaces. For countable cofinality, classify  $B_\mu^-$  as a complete nonseparable metric space and its placement inside  $S_\mu$ .

The formulas in Section 70.3 are exact starting points. A classification should keep track of the actual weight  $\mu^{<\mu}$ , which can exceed  $\mu$ . The singular descriptive-set-theoretic framework of Dimonte and Motto Ros [58] is relevant background, but applying its results requires matching the space’s weight and topology rather than only its indexing cardinal.

### 113.22.2 Algebra and reconstruction

**Research question 113.203** (Abstract automorphisms versus the natural normalizer). Is every abstract or continuous automorphism of  $H_\mu$  induced by a permutation of its natural carrier? Under what hypotheses can the action, or the bounded-set ideal, be reconstructed intrinsically?

Theorem 70.6 only classifies conjugations by carrier permutations that preserve the subgroup. Proposition 70.8 reconstructs the ideal when the action is already named. These are useful constraints, but neither is an automatic solution of the abstract automorphism problem.

**Research question 113.204** (Subgroups without all finitary permutations). Classify natural subgroups not contained in  $H_\mu$  and not containing all finitary permutations on which the inherited forward topology is a group topology. Which non-discrete examples exist?

The maximality theorem identifies its exact hypothesis rather than forbidding every alternative subgroup. Such a classification should determine when internal transposition witnesses are absent and whether that absence reflects a useful structural constraint or merely a very small group.

**Research question 113.205** (Intermediate coordinate ideals). For admissible ideals  $\mathcal{J}$ , classify  $H_{\mathcal{J}}$ , the closure of  $H_{\mathcal{J}}$  in  $\tau_{\mathcal{J}}$ , and the gap between  $\mathcal{J}$  and  $\mathcal{J}^{\text{sym}}$ . Which ideals lead to self-normalizing ideal-preserving subgroups?

The general continuity and envelope theorems already apply. The self-normalizer proof for boundedness uses a special “bounded part plus cofinal part” lemma, so its extension should isolate an analogue of that lemma rather than assume every ideal behaves like the bounded ideal.

### 113.22.3 Numerical order and nonminimal enumerations

**Research question 113.206** (Order automorphisms and the coordinate bornology). Which order automorphisms of a thick minimal enumeration order preserve its forward uniformity, its injective completion, or the small-set group envelope? What additional named structure is needed to recover prefix cylinders or the chosen label filtration?

The earlier continuation [41] exhibits prefix non-rigidity, so a universal reconstruction claim from the pure order alone is not the right target. The question is to identify the appropriate expanded structure or the exact extension criterion.

**Research question 113.207** (Nonminimal ordinal lengths and residual tails). For  $\text{Bij}(\alpha, X)$  with  $|\alpha| = |X|$  but  $\alpha$  not the initial cardinal, develop analogues of the ideal-continuity and completion results. How do finite residual tails and limit positions change local character, adjacency, and the supply of extendible prefixes?

The initial-cardinal hypothesis in Lemma 62.12 should be replaced by exact residual-domain and residual-range conditions. This is likely a more informative approach than trying to transfer the minimal-slice theorems wholesale to the full fixed-carrier order.

**Research question 113.208** (Order-type classification beyond topology). Which numerical features of two thick alphabets force their minimal enumeration orders to be isomorphic, equimorphic, or nonisomorphic? Which invariants survive after their homeomorphic prefix spaces have forgotten the alphabet order?

The countable comparison with the irrationals already shows that topological classification is insufficient. Dedekind boundary types, interval decompositions, and the interaction with label order provide concrete candidates, whereas cardinality and ordinal spectrum alone are too coarse.

### 113.22.4 Class foundations and verification

**Research question 113.209** (Global control schemes over weaker theories). What are the weakest class-theoretic assumptions sufficient for the supported-prefix extension, small-net rigidity, and inverse-reconstruction schemes? Can their uses of Class Replacement and uniform set choice be separated sharply?

These proofs have different logical mechanisms: image bounding, choosing residual set bijections, and elementary eventual-value comprehension. A reverse-mathematical analysis should examine those mechanisms individually rather than assign the same strength to every global completion assertion.

[merge] (3 October 2026, batch 89.) Answered in part by source 31 (Part XV), which names this question. It separates three mechanisms, selection, collapse and coding, and image bounding (section XV.12). Over Zermelo set theory with Choice, selection restricted to countable inputs, with Separation for the selector, is already nonconservative (theorem XV.5.1, through an unreviewed interface to Glazer’s countermodels); in the full-class rank models global choice holds at every height, while ordinal coding and image bounding have different exact thresholds, and Class Replacement on a set holds exactly when its size is below the cofinality of the height (lemma XV.9.2, theorem XV.9.3, and corollary XV.9.4). The weakest assumptions for each of the three named schemes are not determined; source 31 restates that remainder as its research question 113.242 (section 113.27).

**Research question 113.210** (Non-set-like tails and class completion). Construct a completion theory for arbitrary class well-orders that uses the direct common-prefix relation and continues through proper-class initial segments. Which kinds of index orders, or external universe levels, are necessary to retain the tails?

An Ord-word completion cannot see a tail following a full Ord prefix. The finite-tail examples give mandatory tests for any proposed theory, and Theorem 71.13 supplies a comparison relation that does not presuppose a class-order-type calculus.

**Research question 113.211** (A verified ideal-to-surreal pipeline). Formalize the generic ideal-envelope and maximal-subgroup results, the singular self-normalizer, and the character diagonal, then instantiate them at a rigorously sized surreal cutoff. Develop the global class-model statements as a separate semantic layer.

This target directly extends the inspected source without conflating its simplicity theorem with cut existence. A successful implementation should record theorem-to-file mappings, universe levels, and the distinction between compiled proofs, imported assumptions, and model-theoretic hypotheses.

[merge] Status of source 28's questions, 3 October 2026. [Research question 113.200](#) is **answered negatively** in ZFC by source 26, which source 28 did not see: for uncountable  $\mu$  of countable cofinality,  $\text{Sym}(\mu) \cong \mathcal{W}_\mu(\mu)$  with the bounded-prefix topology is not a  $G_\delta$  in the forward injection space, so it is not completely metrizable, and no nonempty open subspace is ([theorem 69.18](#)). Source 28's statement that its own dense complete locus does not settle the question stays true ([note 70.13](#)). [Research questions 113.201, 113.203 to 113.205, 113.209 and 113.210](#) are open. [Research question 113.202](#) is answered in part at countable cofinality by source 26 ([theorem 69.23](#)). [Research question 113.206](#) is answered in part at  $\mu = \omega$ : prefix cylinders are not invariant ([corollary 67.9](#)). [Research question 113.207](#) is answered in part ([proposition 69.29](#); the lengths  $\omega + n$ , [theorem 68.8](#)). [Research question 113.208](#) is answered in part at  $\mu = \omega$  ([theorems 67.2 and 67.8](#)). [Research question 113.211](#) is a proposal. [merge] (3 October 2026, batch 89.) [Research question 113.209](#) is now answered in part by source 31 ([section 113.27 \(a\)](#)); the other questions listed above as open are not affected by it.

### 113.23 Source 29: further research questions after these results

The agenda below is revised in light of both the pinned source and the present proofs. Several questions in older lists have acquired answers: the centered increasing-word type has a product description; actual numerical thresholds reduce by translation; all noninitial strata have the stated residual analysis; and complete condensation histories have an exact equivalence with strong class comparability. The following questions concern what is still missing.

**Research question 113.212** (The remaining singular upper code). Let  $\lambda$  be singular and not strong limit. Under what hypotheses on a  $\lambda$ -sized ordered residual alphabet  $Y$  does

$$\mathcal{W}_\lambda(Y) \hookrightarrow \mathbb{B}_\lambda$$

hold? In particular, settle the residual cases  $\lambda \leq \kappa$  in [Corollary 78.9](#) for which the ordinal bounds  $\varrho_{\text{lo}} < \varrho_{\text{up}}$  remain different after absorption.

The exact embedded-cube spectrum does not answer this question. A proof must construct an upper code, or exhibit an obstruction stronger than the absence of a larger binary cube. The countable and finite-aleph birthday bands avoid the unresolved residual case and supply useful fully classified test instances.

**Research question 113.213** (Isomorphism on a constant-cardinality birthday band). For fixed  $\alpha$  of cardinality  $\mathfrak{c}$ , determine when

$$\mathcal{W}_\alpha(\mathbf{No}_{<\theta}) \cong \mathcal{W}_\alpha(\mathbf{No}_{<\eta}), \quad \omega < \theta, \eta < \omega_1.$$

Do some of these orders distinguish  $\theta$  and  $\eta$  even though all have the same equimorphism type given by [Corollary 78.10](#)?

The native alphabets themselves form a strict embeddability chain. The problem is to identify which of that information survives in the pure permutation order. Gap arrangement, local completeness, and the distribution of residual order types are possible invariants; the finite-tail topology illustrates why cardinal spectra alone can miss a distinction.

**Research question 113.214** (Infinite tails at the countable alphabet). Classify the native topology and Borel structure of  $\mathcal{W}_\alpha(\mathbb{Q})$  for countable  $\alpha \geq \omega \cdot 2$ . Determine their exact relation to the coordinate Borel structure, and identify natural standard Borel subspaces or quotients.

The article compares the coordinate and native topologies at every countable length, but gives the complete measurable classification only for finite tails after  $\omega$ . For longer types, the tail is an infinite order varying with the omitted alphabet. It cannot be replaced by a constant finite split. The cellularity argument in [Proposition 68.11](#) already implies that all these full native Borel structures are non-countably-generated and hence nonstandard: they contain  $2^\mathfrak{c}$  distinct open sets, whereas a countably generated sigma-algebra has at most  $\mathfrak{c}$  members.

**Research question 113.215** (Intrinsic geometry of the centered product). What are the order automorphisms of  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ ? Are its displayed lower-prefix fibers recognizable from the pure order, perhaps after naming a small amount of structure? Is there a simpler canonical presentation that explains its full cut arrangement?

The factorization is an explicit isomorphism theorem. It does not assert that its fibers are definable from the resulting bare order. The earlier failures of prefix recovery make this a real additional problem rather than a notational reformulation.

**Research question 113.216** (Nonprincipal termination cuts). Classify increasing-word orders whose distinct terminator lies at a nonprincipal class cut with a set cofinal family on the lower side or a set cointial family on the upper side.

The factorization in [Note 82.9](#) reduces the question to increasing words over the two cut sides. Actual surreal thresholds and nonprincipal cuts whose two sides both retain the full set-cut property are already covered by [Proposition 82.14](#). The remaining cases should be parameterized by genuine cofinality and endpoint data, not by the numerical value of a threshold that translation removes.

**Research question 113.217** (The dense quotient of numerical class carriers). Classify the shorter-first numerical class-carrier order after contracting the adjacent pairs of [Theorem 83.2](#). Which properties of the upper cones  $U(A)$  survive in this quotient? Can the range of available final-segment orders be encoded as a canonical family of decorations on it?

[Theorem 83.6](#) supplies every possible numerical final class segment as an available-letter order after an increasing prefix. A classification must therefore address arbitrary class cuts, rather than only bounded-support or set-prefix data.

**Research question 113.218** (The exhaustive-branch stabilizer). Characterize the uniform systems of local increasing residual bijections that preserve every exhaustive class branch of the injection tree. Are there useful generators or closure operations for the resulting subgroup?

[Proposition 96.11](#) gives a substantial explicit family of such automorphisms. [Theorem 96.7](#) and [corollary 96.12](#) show that prefix coherence and every single fixed set-height restriction are insufficient tests. The condition must express global coverage of labels, not just local successor-order behavior.

**Research question 113.219** (Comparability versus stronger recursion). Investigate the relation of CWO, and therefore CTH, to ETR, continuous rankings, and weak comparability by arbitrary suborder embeddings.

Hamkins–Woodin formulate these comparisons in their Question 7 [27]. The present article supplies a new equivalent presentation of the strong comparability principle; it does not settle the converses involving stronger recursion. Finite normal forms from a history may make that boundary easier to study, because they identify what a condensation-specific construction can provide without a universal truth recursion.

[merge] (4 October 2026, batch 96.) Not settled by Part XVI. Over GB, sources 34 and 35 add equivalent forms of CWO: canonical histories and initial embeddings into  $P(W)$  ([theorem XVI.5.8](#) and [note XVI.5.19](#)), and source 35’s fixed-point extension principle FPE ([corollary XVI.6.19](#), over GB by [theorem XVI.6.21](#)).

**Research question 113.220** (Alternative condensation limits). How do different limit conventions compare with the nested least-representative rule used here? Which retain finite normal forms or the equivalence with strong comparability?

For the present rule, [Corollary 108.14](#) proves that the induced equivalence relation at a limit is the union of the earlier equivalences. This removes one ambiguity. Conventions that choose new representatives or form an external quotient without retained anchors can have different existence requirements.

**Research question 113.221** (Recovering a class realization from an expanded order). Which additional predicates on the global enumeration order, its core, or its ordered prefix tree determine the available class collection up to an appropriate isomorphism?

The bare external set-like enumeration order of a countable two-sorted class model can be  $\mathbb{Q}$ . Naming heights and successor orders still permits the branch changes of [Theorem 96.7](#). Literal label evaluation is sufficient to rule out those particular changes, but whether a substantially smaller invariant family of predicates recovers the intended realization remains open in this analysis.

**Research question 113.222** (Scan equivalence for relation encodings). Classify the order types obtained from different well-ordered scans of relation tables on a fixed surreal carrier or birthday set. Identify natural hypotheses under which two scans induce isomorphic, equimorphic, or provably different orders of well-orders.

The existing endpoint examples already rule out scan-independence in general. A useful next theorem should specify a structural class of scans and compare their effects without silently replacing relation-bit comparison by enumeration comparison.

**Research question 113.223** (A certified mathematical core). Implement the set-sized first-difference, binary fusion, birthday spectrum, and canonical word-factorization results in Lean on top of the inspected sign-sequence foundation. Then formalize the normal-form theorem from a supplied history in an explicitly chosen class or universe-relative framework.

The native spectrum is a particularly focused first target: its statement is exact at every ordinal cutoff, its proof is independent of Global Choice, and its delicate limit invariant is explicit. Success there would provide a reusable library for the later permutation and class-level constructions.

[merge] Status of source 29's questions, 3 October 2026. [Research question 113.212](#) is open (with [research questions 113.94](#) and [113.224](#)). [Research questions 113.213](#) to [113.215](#), [113.217](#), [113.219](#) and [113.220](#) are open. [Research question 113.216](#) is open; source 27 computes the point characters ([proposition 82.8](#)). [Research question 113.218](#) is answered in part ([theorem 96.4](#)). [Research question 113.221](#) is answered in part: literal label evaluation suffices ([theorem 102.3](#) and [notes 102.5](#) and [102.16](#)), and label-edge equality makes the core-and-cylinder structure rigid ([theorem 93.3](#)). [Research question 113.222](#) is answered in part at set level ([theorems 84.2](#) and [84.4](#)) and for one scan on **No** ([theorem 84.13](#)). [Research question 113.223](#) is a proposal.

### 113.24 Source 30: research questions after the new results

The following are proposed research tasks for this program. Where a problem is inherited, its remaining scope is narrowed by the theorems above. The list is not a claim that every item is an independently established open problem throughout the literature.

#### 113.24.1 Residual coding beyond the classified cases

**Research question 113.224** (Singular residual cardinals that are not strong limit). Suppose  $\nu \leq \kappa$ ,  $\nu < 2^{<\kappa}$ , is singular and not strong limit. Determine the exact equimorphism type of  $\mathcal{W}_{\mu\gamma+\nu\delta+n}(\mathbf{No}_{<\kappa})$  in ZFC.

The present proof gives a concrete interval of possibilities: pair orientations give a lower binary factor of length  $\nu\delta$ , while padding the entry codes gives an upper factor of length  $\nu^2\delta$ , appended after  $\rho_\kappa\gamma$ . The strong-limit lower construction cannot simply be reused because  $\mathbf{No}_{<\nu}$  may contain more than  $\nu$  labels. A productive approach is to identify which  $\nu$ -sized residual alphabets can replace its disjoint sign cones. The aim is a coding-capacity theorem for arbitrary residual alphabets, not just a cardinality estimate.

**Research question 113.225** (Dependence on cardinal arithmetic). Which additional cardinal-arithmetic hypotheses, weaker than GCH, guarantee the full fixed-type classification? Can two models with the same relevant cardinalities have different residual binary coding lengths?

The mixed-block theorem already gives one sufficient condition: every singular cardinal at most  $\kappa$  actually encountered in the finite cardinal descent is strong limit; larger residual cardinals are covered by the native padded code. No hypothesis about unrelated cardinals is needed. The next step is to decide whether this condition is necessary or merely sufficient.

#### 113.24.2 Topological classification beyond invariants

**Research question 113.226** (The positive finite-prefix spaces). Are  $E_n$  and  $E_m$  homeomorphic for all positive finite  $n, m$ ? What about their doubled orders and the spaces  $P_n$  for  $n \geq 3$ ?

All  $E_n$  for  $n > 0$  share the proper  $\Delta_3^0$  description and meagreness proved here. These invariants do not classify their homeomorphism types. ([merge] Source 30's  $P_n$  is  $P_{\omega+n}$  here.) The doubled-space Borel formula adds a precise constraint: any candidate homeomorphism has to respect the countable-exception structure of measurable separation of fibers.

**Research question 113.227** (Later countable ordinal types). For arbitrary countable  $\alpha > \omega + 2$ , determine the Cantor–Bendixson derivative sequence and Baire-category behavior of  $\mathcal{W}_\alpha(\mathbb{Q})$ .

The non-Borel ranking obstruction is already known from [corollary 68.17](#); that should not be left as the main unresolved question. What remains is a structural analysis of the order topology itself, especially at limit remainders, where finite fibers no longer describe the whole local geometry.

**Research question 113.228** (Reverse coding at later countable types). For which countable  $\alpha \geq \omega + \omega$  is the map from lexicographic enumerations to relation tables Borel measurable? What structural feature of the terminal order determines its failure or success?

The opposite-direction ranking map already fails to be Borel at every  $\alpha \geq \omega + 3$ . The reverse direction requires a separate analysis. At  $\omega + 2$ , one binary endpoint-orientation predicate repairs the measurable presentation exactly ([proposition 68.18](#)); that case is settled. For  $n \geq 3$ , the lexicographic Borel structure contains too many sets to be contained in any standard Borel structure on the same carrier. An appropriate standard presentation must therefore change which sets are measurable, rather than simply add predicates to all existing order-open sets.

### 113.24.3 Global scans and reconstruction

**Research question 113.229** (Arbitrary scans and non-set-like jumps). Is relation-table lexicography on all class well-orders dense for every set-like scan? If not, characterize a scan and a pair of non-set-like orders producing a jump.

Theorem [84.11](#) settles the set-like suborder, and Theorem [84.13](#) settles the explicit max-index scan even on all class orders. Neither proof alone settles every scan on all orders. A counterexample would have to exploit proper-class predecessor structure that cannot be closed into the common initial set used in the set-like proof.

**Research question 113.230** (Topologies determined by scans). Classify when a scan’s support topology and its order topology agree. Determine which changes of scan preserve the intrinsic local-character description of bounded inversion support.

Our canonical scan already separates these topologies and identifies one-sided set coinitality with bounded inversion support. A general classification should explain how much of this asymmetry is a scan artifact and how much is forced by well-foundedness.

**Research question 113.231** (How much named core suffices?). Find intermediate named structures between a unary predicate for the support core and its pointwise embedding that recover the class realization.

The endpoints are now precise: [proposition 102.19](#) shows that even a baseline point and the whole core named setwise can lose ETR, while fixing the core pointwise recovers all labels through its represented cuts. Candidates include prefix cylinders, the evaluation map on a structured subfamily, or the pair-swap Boolean operations. The distinction between a countable external language and an internal uniform family must be preserved.

**Research question 113.232** (Uncountable realizations and common baselines). Which analogues of the universal-baseline theorem hold for uncountable set models? Which external order invariants of their admitted enumeration spaces detect more than the cardinality of the class collection?

The countable argument uses both Cantor back-and-forth and Williams’s countable minimum-realization theorem. Removing countability is not a routine restatement. The labelled inclusion theorem itself does not need it and provides a useful comparison standard.

#### 113.24.4 Foundational and formal priorities

The most concrete next formalization target is the prefix-free code together with the regular block-length lemma. It is self-contained, uses already available small-cut foundations, and supports every regular residual case. The next difficult target is the singular scheduler. The most compact class-theoretic target is pair coding and its decoder; the most informative local-to-global target is partial-table extension.

A broader foundational question asks how much choice follows from universality of the surreal *numerical* order for all class linear orders, without assuming a global well-order of its labels. That is a different question from [note 111.27](#); it was posed explicitly by Hamkins [21]. Nothing in the present proof settles that question, and the global baselines used here cannot be assumed in an argument attempting to derive global choice.

[merge] Status of source 30's questions, 3 October 2026. [Research question 113.224](#) is open (with [research questions 113.94](#) and [113.212](#)); the cube spectrum of these strata is settled by [theorem 64.11](#). [Research questions 113.225](#) to [113.230](#) and [113.232](#) are open; source 29's [corollary 68.7](#) bears on [research question 113.226](#). [Research question 113.231](#) is answered in part: a core fixed pointwise recovers the class part ([note 102.5](#)). Hamkins's question on universality and choice [21] is not settled ([section 1.7](#) (f)).

#### 113.25 Earlier questions answered by sources 19–30 (dated notes, 3 October 2026)

[merge] Dated notes in the form of [section 50](#); where the question indexes of [section 113](#) and [section 113.5](#) say otherwise, these notes supersede them. The “What this Part answers” sections of Parts X–XIV give the same status with the theorems in context.

- (a) *Source 12's [research question 113.11](#), all fixed enumeration types* (with source 08's question 4, Part VI status (e) and [section 31.3](#), and sources 15–18's [research questions 113.46](#), [113.58](#), [113.69](#) and [113.83](#)): answered in part. For every type  $\alpha = \mu\gamma + \sum_{i < k} \lambda_i \eta_i + n$  of  $\mathbf{No}_{<\kappa}$  the embedded binary-cube spectrum is exact, and the least coding length is determined whenever the two weighted bounds agree, in particular for every type when every residual cardinal is regular, a singular strong limit or above  $\kappa$  (source 19, [theorems 64.7](#) and [64.11](#)); hence every type is classified when  $\kappa < \aleph_\omega$  in ZFC, and every type under GCH (source 30, [corollary 64.20](#) and [note 64.18](#)). Open: singular non-strong-limit residual cardinals at most  $\kappa$  ([research questions 113.94](#), [113.212](#) and [113.224](#)). The infinite-remainder case that Part VI left open ([section 31.3](#)) is covered.
- (b) *Source 12's [research question 113.12](#), noncardinal birthday bounds* (with sources 15, 17 and 18's [research questions 113.47](#), [113.70](#) and [113.84](#)): answered in part. The native alphabet remembers its cutoff exactly:  $\mathbb{B}_\beta \hookrightarrow \mathbf{No}_{<\theta}$  iff  $\beta < \theta$  (source 29, [theorem 76.5](#) and [corollary 76.6](#)); the minimal slice at a noncardinal cutoff has coding rank  $\mu$ , characters and cofinalities computed, and is isomorphic to no bounded interval or ray of itself (source 21, [theorem 77.4](#)); on the countable band the permutation strata forget  $\theta$  up to equimorphism ([corollary 78.10](#)). The order type remains open.
- (c) *Source 12's [research question 113.13](#), isomorphism invariants and homogeneity*, and source 08's question 1: answered in part. At the countable cutoff the minimal slice is homeomorphic to Baire space, has the real line as Dedekind completion with a dense meagre  $F_\sigma$  of omitted points, every open interval is isomorphic to the whole order, finite partial maps extend, and prefix cylinders are not intrinsic (sources 21 and 24, [theorems 67.2](#), [67.4](#) and [67.8](#) and [corollary 67.9](#)); at regular  $\mu$  it is homeomorphic to  $(\mu^{<\mu})^\mu$  ([theorem 66.2](#)); it is completely metrizable only

- at  $\mu = \omega$  (theorem 69.18); weights and finite-tail characters of every stratum are known (theorems 63.4 and 63.9). The isomorphism type at uncountable cutoffs is open.
- (d) *Source 12's research question 113.17, automorphisms and finite condensation*: answered in part for countable models (source 21, note 109.30 and corollary 109.31); the finite-tail blocks are first-order definable in the pure order of every set-sized model (source 19, proposition 109.7).
  - (e) *Source 11's research question 113.8, source 12's research question 113.18, source 08's question 12, and Part VIII's item (e) "What the unlabelled external order type remembers"*: answered further. The admitted labelled global enumerations recover the whole class part over the same sets (sources 22, 27 and 30, theorem 102.3 and notes 102.5 and 102.16); the external pure order of a countable model is one of two shuffles, according as the model is  $\omega$ -standard or not, and all set-sized models have the same complete theory (source 19, theorems 109.1 and 109.9); naming the core setwise and the baseline still loses the realization, and ETR is invisible to the pure order (source 30, propositions 102.19 and 102.20). Uncountable models are open. Source 17's research question 113.75 (recovering a class realization) is **answered** with fixed coding parameters by source 22, and source 14's research question 113.43 in part.
  - (f) *Source 12's research question 113.19, compatibility between cutoffs* (with sources 14, 15, 17 and 18's research questions 113.42, 113.54, 113.79 and 113.85): answered in part. Restriction is monotone only in three degenerate cases (source 19, theorem 73.1); append-tail maps form a coherent direct system whose limit is the bounded-support core (source 20, theorem 74.8); fixed-slot embeddings compose exactly within a cardinality band (source 21, theorem 75.1). Preservation of condensation, coding ranks or cylinders, and coherence across a change of cardinality, remain open.
  - (g) *Source 11's research question 113.3, iterated residual decomposition* (with sources 13, 15, 16 and 18's research questions 113.30, 113.48, 113.64 and 113.86): answered for the canonical-history formulation over GBC: every class well-order has its canonical terminating condensation history exactly when strong comparability of class well-orders holds (source 29, theorem 108.19); a supplied history terminates (source 20, theorem 108.1); limits are unions (corollary 108.14). Whether ETR is necessary (Hamkins–Woodin's Question 7) and the theory over GB remain open. *Dated note, 4 October 2026 (batch 96)*: the theory over GB is answered by sources 34 and 35 (section 113.29 (b)); Question 7 remains open.
  - (h) *Source 11's research question 113.4 and research question 113.5; Part VIII's item (c)*: answered further. Exhaustive branches are not recognized by the core with all its unranked cylinders and any set of parameters (source 25, theorems 91.1 and 91.2), nor by the ordered prefix tree (theorems 96.2 and 96.7); equality of labels across extension edges suffices and makes the structure rigid (theorems 93.1 and 93.3 and note 96.5); this answers the "extra predicates" item and source 14's research question 113.34. An increasing relabelling makes two cores disjoint (proposition 97.9). The stabilizer of the exhaustive cuts is still undescribed, with partial families (theorem 96.4 and corollary 96.12).
  - (i) *Part VIII's item (f), ordinal support bounds*, and source 17's research question 113.78: the ordinal half is **answered**: a partial injection completes with support below  $\beta$  exactly when the stated cardinal criterion holds, and the least such  $\beta$  is given in closed form (source 27, theorems 101.1 and 101.2). Birthday bounds and the forced-prefix length remain open.
  - (j) *Part VII's open items on centered increasing words and interior terminators*, and source 18's research question 113.91: answered in part. The centered order is  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ , with all zero conventions identified (sources 27 and 29, corollary 82.5 and notes 82.11 and 82.13); no fixed marker makes increasing words set-cut saturated (source 23, theorem 82.1); actual thresholds

reduce to zero and gaps with two large sides are classified ([proposition 82.14](#)); characters at a general gap are computed ([proposition 82.8](#)). Gaps with a small side and a cut classification remain open.

- (k) *Part VII's item on two scans, source 08's question 9 and source 09's fifth direction*: the scan question is answered negatively at set level: two scans of one countable carrier can give a real-embeddable order and an order with continuum many disjoint intervals, with the same ordinal spectrum (source 27, [theorems 84.2 to 84.4](#)). Source 09's "natural set-coded dense core" exists: the bounded-support core is dense in the relation-table order for every set-like scan (source 27, [theorem 84.5](#); source 30, [theorem 84.11](#)). The representation of its cuts, and scans on all of **No**, remain open.
- (l) *Source 18's research question 113.89,  $\omega$ -nonstandard class models*: **answered**, three times independently: the external order is the shuffle of the factorial colours together with one further block type, and it has the same complete theory as the standard shuffle, which is decidable (sources 19, 20 and 21, [theorem 109.1](#), [notes 109.13](#) and [109.33](#), and [corollary 109.22](#)).
- (m) *Source 17's research question 113.72, complete metrizable when  $q = \omega$* : **answered**: the minimal slice is completely metrizable exactly when  $\mu = \omega$  (source 24, [theorem 67.2](#); source 26, [theorem 69.18](#)). The dense-open threshold is open ([research questions 113.155](#) and [113.183](#)).
- (n) *Source 15's research questions 113.50 and 113.51* (completion with residual data; automorphisms across residual fibres) *and source 14's research question 113.39*: **answered** in the external formulation by source 19 ([theorems 98.2](#) and [98.5](#)).
- (o) *Source 17's research question 113.77, the condensed unrestricted order*: answered in part (source 20's local-size blocks, [theorem 107.5](#); the countable models of item (l)).
- (p) *Source 13's research question 113.28* (termination cuts): already answered by source 16; source 23's criterion is a second route ([theorem 36.1](#)). *Source 13's research question 113.20* (extra structure for recognizing branches): answered as in item (h).
- (q) *Questions not affected*: [research questions 113.2](#), [113.14](#) and [113.16](#) (source 23's [theorem 108.23](#) bears on [research question 113.14](#) but does not answer it), [research questions 113.9](#) and [113.10](#), and Hamkins's question on universality and choice.

### 113.26 Source 31's research questions (batch 89)

[merge] (3 October 2026.) Source 31's Section 13, "Further research questions", printed whole; its questions 1–12 are numbered here in this section's sequence and labelled `swo:gcz:n1–swo:gcz:n12`.

The following questions are proposed directions. Except where explicitly identified as repository questions, they are formulated here and are not being advertised as a catalog of established open problems. Each distinguishes a specific missing step from results proved above.

**Research question 113.233** (Global selection from finite sets). Is ZC with a selector on all nonempty finite sets and expanded Separation nonconservative over ZC? What changes with Foundation?

The present proof uses selection on every nonempty subset of a countable carrier. Finite-input selection does not supply that operation. Enayat's global finite choice principles provide relevant background, but do not by themselves settle this Zermelo conservativity question.

**Research question 113.234** (Pairs and bounded finite cardinalities). For a fixed integer  $m \geq 2$ , what pure set-theoretic consequences follow from a class selector on  $m$ -element sets, with expanded Separation? Can these consequences distinguish different  $m$ ?

A proof would require either a different obstruction model or a new reduction from finite-input choices to a useful uniform presentation. Arbitrary countable-set enumeration cannot simply be assumed.

**Research question 113.235** (The Separation complexity needed by the refinement). Which finite collection, or syntactic fragment, of Separation instances involving the selector suffices for [theorem XV.5.1](#)?

The proof gives explicit containing sets, but its defining formulas include well-order tests and unbounded quantification over class labels. Boundedness of the output is not a claim that every defining formula is  $\Delta_0$ . Tracking the actual formulas is a feasible formalization project.

**Research question 113.236** (Reducing ordinary Choice). How much of ordinary AC can be removed from the localized nonconservativity theorem?

The positive uniformization proof only asks for well-orders of  $D$  and  $\mathcal{C}_D$ ; for  $D = \omega$ , the latter can be coded by a fixed set of reals. A complete weakening must also recheck the base countermodel and the final cardinal obstruction, rather than dropping Choice from the proof statement alone.

**Research question 113.237** (Fragments that restore conservativity). Which Replacement or Collection fragments suffice to restore conservativity for countable-input global selection with expanded Separation?

Collecting every definable  $\omega$ -family destroys the particular class-family obstruction used here. That observation does not establish a general conservativity theorem, which would require an expansion or forcing argument for arbitrary models of the chosen base.

**Research question 113.238** (Selectors beyond the countable threshold). For well-ordered sets  $D$  and  $E$ , when do restricted global selection on  $D$ -small and on  $E$ -small sets have the same original-language consequences over a fixed weak base?

Every bound containing  $\omega$  already gives our nonconservativity witness. The uniform presentation theorem supplies a common method of comparison but does not collapse the full hierarchy of consequences.

**Research question 113.239** (Definable-class versions of the spectra). What replaces the rank-model classification when the admitted classes are  $\text{Def}(V_\lambda, p)$ , rather than all external subclasses?

External cardinal equality then need not produce an admitted bijection, and a cofinal witness to Replacement failure need not be definable from the permitted parameter. The full-class answers provide bounds and test cases, not an answer to this definability problem.

[merge] (4 October 2026, batch 96.) Answered in part, for the external order types at a strongly inaccessible height: for the classes definable over  $V_\kappa$  in a fixed finite language with set parameters the realized types form an interval  $[0, \Theta_L)$  with  $\kappa < \Theta_L < \kappa^+$ , of countable cofinality under a named global well-order, closed under ordinal arithmetic, and raised by a truth predicate, which represents the old ceiling exactly (sources 32–35; [section XVI.12](#) (e)). The analogues of the thresholds of Part XV for definable classes remain open.

**Research question 113.240** (Abstract weak-theory equivalences). Find a natural two-sorted extension of ZC over which particular surreal coding principles characterize ordinal abstraction, an image-bounding scheme, or a restricted class-choice principle.

Our exact equivalences are semantic statements about  $\mathcal{M}_\lambda$ . Turning one into an abstract equivalence requires a proof for arbitrary models, including models without the full external rank hierarchy or all subclasses.

**Research question 113.241** (All set-like order types at a cutoff). Classify the external order types of every internally set-like well-order of  $S_\lambda$ , especially at singular and non-strong-limit heights.

We classify whether some such order has type  $\lambda$ , and whether it can respect birthdays. A classification of all possible types requires control of the birthday bounds on every proper initial segment and may contain more information than cardinality alone.

**Research question 113.242** (The repository’s global control schemes). For each precise supported-prefix extension, small-net rigidity, and inverse-reconstruction scheme in ProveIt, identify the minimum selection, collapse, and image-bounding assumptions.

This is the remaining program behind `swo:ge:n10` ([research question 113.209](#)). The domain-size criterion can test candidate image-bounding claims, while bounded trace compression may test claims that a uniform presentation is available. No equivalence for all three schemes has been proved here.

**Research question 113.243** (A verified bounded uniformization theorem). Can a proof assistant verify [theorems XV.3.3](#) and [XV.4.1](#) over an explicit Zermelo axiom interface, with no imported theorem using Replacement?

This is a concrete near-term target. Every newly formed set can carry its containing-set witness as part of the formal construction. A separate module can then instantiate the theorem with the Glazer obstruction interface.

**Research question 113.244** (Surreal transfer and parameter-sensitive choice). Can the distinctions between uniform choice, ordinal coding, and admitted definability be used to sharpen the obstruction to definable transfer expansions of **No**?

Hamkins’s surreal transfer question and Glazer’s contribution to its discussion are a direct further intersection [76]. Our results concern weak foundations and full-class rank models. They do not settle transfer in ZFC with arbitrary set parameters; a solution would require a separate definability or forcing argument.

[merge] Status of source 31’s questions, 3 October 2026. All twelve are proposed continuations. [Research question 113.241](#) is answered at strongly inaccessible heights by source 12’s [theorem 21.1](#) (ii): there every internally set-like global well-order of  $\mathbf{No}_{<\kappa} = S_\kappa$  has external type  $\kappa$ ; elsewhere it is open. [Research question 113.242](#) restates the open remainder of source 28’s [research question 113.209](#), item (a) below. [Research question 113.243](#) is a formalization proposal. [Research question 113.244](#) concerns Hamkins’s surreal transfer question [76], not the universality question of [section 1.7](#) (f). The others are open; this write found no answer to them elsewhere in this report.

## 113.27 Earlier questions answered by source 31 (dated notes, 3 October 2026)

[merge] Dated notes in the form of [section 113.25](#); where the question indexes of [sections 113](#) and [113.12](#) say otherwise, these notes supersede them. [Section XV.15](#) gives the same status with the theorems in context.

- (a) *Source 28's research question 113.209, separating Class Replacement from uniform set choice:* answered in part, for the mechanisms rather than for the three named schemes. Countable selection with expanded Separation is nonconservative over  $ZC$  and  $ZC_F$ , conditional on the Glazer interface (theorem XV.5.1 and section XV.5.1), and conservative without expanded Separation (proposition XV.5.5); in the full-class rank models, global choice, ordinal coding and image bounding have different exact thresholds (theorems XV.7.2, XV.7.4, XV.8.2, XV.8.4 and XV.9.3, lemma XV.9.2, and corollary XV.9.4). Open: the weakest assumptions for the supported-prefix extension, small-net rigidity and inverse-reconstruction schemes themselves (research question 113.242). The sibling questions of sources 24 and 26 on the same resources, research questions 113.161 and 113.185, stay open.
- (b) *Questions not affected:* those listed in section 113.25 (q), including Hamkins's question on universality and choice.

### 113.28 The questions of sources 32–35, merged by theme (batch 96)

[merge] (4 October 2026.) The research questions of the four sources of Part XVI, with their commentary, merged into one list: source 34's agenda items R1–R12 (its Section 11), source 35's questions 10.1–10.13 (its Section 10), source 32's questions 12.1–12.11 (its Section 12) and source 33's research questions 12.1–12.14 (its Section 12). Each is printed whole, under the theme it belongs to, with its source and number in its heading; a dated [merge] paragraph at the head of each theme says which questions coincide, which are answered and by what, and what remains open. Answered questions stay on record (Vladimir's standing rule of 4 October 2026). The four introductions follow, then the themes; earlier questions of this report that sources 32–35 answer are in section 113.29.

**Source 34's introduction to its agenda.** The following agenda distinguishes a localized extension from a published foundational question. The first three items are especially suitable continuations because their input objects and proof obligations are already explicit.

**Source 35's introduction to its program.** The results give several directions with different levels of risk. The first group concerns formal verification and relatively local extensions of the proofs. The second asks reverse-mathematical questions that remain substantially harder. The third concerns systematic notation design. An answer in one group should not be advertised as settling a stronger question in another.

**Source 32's introduction to its questions.** The following questions distinguish repository continuations from broader published questions. A question described as published was posed in the cited source; that description does not assert an exhaustive verification that its status has remained unchanged through every later publication.

**Source 33's introduction to its questions.** The questions below are a proposed program. Except where an explicit published source is named, “question” means a direction not settled by this manuscript, not a claim that the problem is known to be open worldwide.

#### 113.28.1 Verifying the choice-free core and proof-carrying notation

[merge] Source 34's R1, source 35's questions 10.1 and 10.2, source 32's question 12.11 and source 33's question 12.13 ask for the same first formalization: the two-sorted class interface, the choice-free power theorem and the capped normal-form reconstruction; source 34's R12 and source 33's

question 12.12 ask for proof-carrying notation. All open: no statement of Part XVI is formalized (section 1.5). This report's earlier formalization plans for the class orders are in section 59 and section 111.

**Research question 113.245** (Source 34, R1: kernel-check the GB refinement). Formalize [Theorem XVI.4.2](#) and the canonical-history equivalence in a two-sorted encoding that records comprehension instances. The key deliverable is an axiom audit showing that no Choice or ETR axiom entered either proof. A full-model ordinal calculation alone would not meet this objective.

### Verify the choice-free core first

**Research question 113.246** (Source 35, Question 10.1: Formalize the finite-support minimization theorem). Can the greedy proof of [note XVI.4.4](#) be formalized in a two-sorted theory whose set axioms are precisely ZF, with all uses of class comprehension and Replacement recorded?

This is the most immediate verification target. A successful formalization should use the original subclass of candidate polynomials and a finite prefix as parameters, rather than postulating a sequence of newly formed tail classes. Its termination argument should explicitly construct the uniquely specified sequence of exponent labels in the nonterminating case. Checking this point also provides a reusable pattern for other finite-support functors.

**Research question 113.247** (Source 35, Question 10.2: Verify the complete normal-form argument). Can one give a machine-checked proof of the GB fixed-schedule criterion, including the capped reconstruction establishing that the polynomial image is an *initial* subclass?

An ordinary order embedding would not suffice for the equivalence with strong comparability. The finite reconstruction with a retained upper cap is the most important part to preserve. A formal library should then separate the choice-free result for arbitrary carriers from the Global-Choice-dependent reduction to the whole surreal carrier. The inspected repository has not already supplied a machine verification of this later manuscript development.

**Research question 113.248** (Source 32, Question 12.11: A verified presentation library). Can the weak presentation theorems, the ETR-dependent existence theorem, and the external spectrum theorems be formalized in one library without identifying their notions of well-foundedness or smallness?

A successful implementation should expose a theorem's class-admissibility assumptions in its type, and should make it impossible to import an external well-foundedness proof into an arbitrary internal model without an explicit absoluteness bridge. This is a substantive design constraint, not merely a namespace convention.

**Research question 113.249** (Source 33, Research question 12.13: Formal reverse mathematics). Implement the two-sorted class-model interface and verify the distinction between the GBC theorems and the ETR-dependent existence theorems. A particularly focused first milestone is a complete formal proof of the uniform-family diagonal, followed by a bounded-satisfaction compiler for one fixed complexity level.

**Research question 113.250** (Source 34, R12: a proof-carrying notation interface). Design a syntax whose constructors carry certificates of class well-ordering and whose conversions carry explicit initial embeddings. The goal is an extensible and checkable family, not a final catalog. The uniform diagonal theorem proves that the latter goal is too strong.

**Research question 113.251** (Source 33, Research question 12.12: Proof-carrying notation systems). Construct useful finite-expression languages with verified evaluation and well-foundedness proofs for long fragments beyond  $\Omega$ . Which fragments have decidable equality or comparison? The no-uniform-cofinal-family theorem gives a precise reason not to promise one self-contained system covering all definable well-orders in its own language.

### 113.28.2 Comparison, recursion, and the strength of histories

[merge] Source 34's R5, source 35's question 10.3, source 32's question 12.8 and source 33's question 12.10 are Hamkins and Woodin's Question 7, which this report records as source 29's [research question 113.219](#): **open**. Over GB it is now a question about any of the equivalent principles CWO, CTH and FPE ([theorems XVI.5.8](#) and [XVI.6.21](#) and [corollary XVI.6.19](#)). Source 34's R6 and source 35's question 10.5 ask the weak-versus-strong part of the same question: **open**. Source 32's question 12.1 and source 33's question 12.6 ask for the strength of the existence of condensation hierarchies or towers: **answered**, and kept on record: it is CWO, over GBC by source 29 ([theorem 108.19](#)) and over GB by sources 34 and 35, because hierarchies and towers are nested histories ([remark XVI.5.24](#)); only  $\text{CWO} \Rightarrow \text{ETR}$  remains open. Source 35's question 10.4 is source 15's [research question 113.48](#): **open**. Source 34's R7 is **open**. Source 32's question 12.10, on removing global choice, is answered for the arguments it names: the descending-sequence test is replaced over GB by [lemma XVI.2.2](#) for linear orders, support localization and least-representative division need no choice ([theorems XVI.3.3](#) and [XVI.4.2](#)), and the diagonal of an already well-ordered uniform family is a GB theorem ([theorem XVI.7.2](#)); global choice remains for ordering arbitrary index classes ([corollary XVI.7.3](#)), and how much set theory each argument needs is **open**.

**Research question 113.252** (Source 34, R5: comparability versus elementary transfinite recursion). Investigate the converse to  $\text{ETR} \Rightarrow \text{CWO}$ , and its relationship with continuous ranking. This is Hamkins–Woodin's published Question 7, not resolved by the present history equivalence [27]. The GB refinement isolates an additional equivalent formulation that may be useful for building separating models or extracting recursion.

### The remaining recursion and comparison boundary

**Research question 113.253** (Source 35, Question 10.3: Does comparability yield elementary transfinite recursion?). Determine whether strong class-well-order comparability implies ETR over the usual base theories, or construct a separating model.

This is a classical open-question direction, not a problem solved by the choice-free improvement. The results here add an equivalent fixed-point extension formulation over GBC: every class well-order has an initial extension admitting an isomorphism with its own  $\Omega$ -power. One may therefore try to recover iterated truth from the completion witnesses, or show that those witnesses can exist without all elementary recursion solutions. A bare order isomorphism need not provide a truth predicate; the missing reduction must be proved rather than inferred from the height of the order.

**Research question 113.254** (Source 32, Question 12.8: Comparison and recursion). What are the reverse implications between ETR, existence of continuous class rankings, initial class-order comparability, and arbitrary-suborder comparability?

This is the family of comparison questions posed by Hamkins and Woodin [27]. Our diagonal theorem uses neither comparison principle and therefore does not answer those reversals. Condensation existence may provide a new intermediate principle to test, rather than a presumed equivalence.

## Connections to published problems and formal systems

**Research question 113.255** (Source 33, Research question 12.10: Comparison versus recursion: a published interface). Hamkins–Woodin ask whether ETR, continuous rankings, initial comparison, and weak comparison of class well-orders are equivalent over  $\text{GBC}^-$  [27, Question 7]. Can the diagonal and condensation methods isolate new implications or separating model constructions? This article proves no reversal. The targeted search located the published question but did not establish a complete up-to-date resolution of its status; a project pursuing it should begin with a renewed specialist literature check.

**Research question 113.256** (Source 34, R6: weak versus strong comparison). Determine the exact strength of arbitrary-suborder comparability relative to initial-segment comparability. The diagonal theorem does not settle this question. A reversal must produce an initial range or a genuine countermodel, rather than appeal to set-order intuition.

**Research question 113.257** (Source 35, Question 10.5: Weak comparison and ranking principles). Which of the implications among ordinary suborder comparability, initial-segment comparability, continuous class rankings, and ETR reverse over GB or GBC?

The successor-sum bound proved here uses ordinary suborder embeddings and needs no universal comparison principle. By contrast, fixed-point completion uses an initial embedding certificate. This distinction may help formulate intermediate principles. The relevant established implications and the original Hamkins–Woodin question should remain explicit when constructing models or proposed reductions [27].

**Research question 113.258** (Source 32, Question 12.1: Exact strength of condensation existence). Over GBC, what is the strength of the assertion that every class well-order  $W$  admits the set-interval condensation hierarchy along  $W + 1$ ? Is it weaker than full ETR, equivalent to a recognizable fragment, or equivalent to a natural class-order comparison principle?

The termination part is settled by [note XVI.5.20](#); hierarchy existence is the remaining issue. A productive separation test would construct a GBC realization closed under this one elementary operator but not under arbitrary elementary recursions.

## Condensation, ranks, and recursion

**Research question 113.259** (Source 33, Research question 12.6: The exact recursion strength of exhaustion). Determine the weakest theory proving the existence and exhaustion of the condensation tower for every class well-order. [Note XVI.5.32](#) gives a sufficient order-dependent ETR assumption. Does an appropriately uniform exhaustion principle recover a substantial recursion principle?

**Research question 113.260** (Source 35, Question 10.4: Uniform finite condensation). For every supplied class well-order  $W$ , does GB prove the existence of one class coding all finite iterates of its set-interval condensation operator?

Each externally fixed finite iterate is elementary. The uniform assertion is different, as the repository correctly emphasizes. The finite-trace proof for repeated  $P$  does not answer this question:  $P$  acts by local transformations of finite supports, whereas set-interval condensation contains a global set-existence test. A promising approach is to analyze whether a single input order can make its successive condensations encode increasingly complex partial truth. A negative result must construct such an input and recover the truth information explicitly.

**Research question 113.261** (Source 34, R7: restricted history principles). Study histories only for orders of a specified definability complexity, only on a specified family of code carriers, or only on specified schedules. Track the existence of a well-order on each carrier explicitly, so a restriction cannot become vacuous when Choice fails. Determine when these fragments recover full comparability and when they measure a weaker principle. The whole-surreal-carrier reduction in the repository uses its separate Global Choice analysis and is not a new open problem here.

**Research question 113.262** (Source 32, Question 12.10: Reducing choice and background strength). Which arguments can be carried out without Global Choice, given well-ordered input domains? How much set theory is needed for support localization, least-representative division, and diagonal domination of an already well-ordered uniform family?

The direct least-element proof for sums is choice-free once the orders are supplied. Global Choice was used in the descending-sequence test and in ordering arbitrary parameter-index classes. Separating these uses may yield versions suited to choiceless GB or weaker set fragments.

### 113.28.3 Condensation lengths, quotients, and normal forms

[merge] Source 33's question 12.7 is **answered** for its first part, and kept on record: the digit map of every supplied tower has initial image, and needs only GB and the tower ([remark XVI.5.29](#)). Source 32's question 12.2 and source 33's question 12.8 are answered in part in full inaccessible models by source 20's exact heights  $\min\{\alpha : \theta \leq \kappa^\alpha\}$  ([corollary 108.3](#)); the internal classification is open. Source 35's questions 10.12 and 10.13 continue source 18's [proposition 52.15](#) and source 20's [research question 113.112](#), which is answered in part by [corollary 108.14](#); open. Source 32's question 12.3 and source 33's question 12.9 are open.

**Research question 113.263** (Source 33, Research question 12.7: Sharper canonical digit representations). For which supplied towers is the canonical map  $\Phi$  of [Theorem XVI.5.27](#) already initial? Can one give an intrinsic criterion on tower fibers that proves initiality without invoking general class comparison? A separate question is whether a different canonical compression map has a weaker axiom bound.

**Research question 113.264** (Source 32, Question 12.2: Optimal bounds for individual orders). Given a supplied hierarchy, can its first universal stage be characterized from intrinsic structural data of  $W$ ? Which invariants yield better bounds than  $W$  itself, while distinguishing the genuinely changing quotient maps in [corollary XVI.5.22](#)?

The explicit examples realize every supplied class length as an exact collapse length. A classification therefore has to retain more information than the external cardinality of the domain or the repeated quotient's isomorphism type.

**Research question 113.265** (Source 33, Research question 12.8: Minimal condensation lengths). Under which hypotheses can one assign a minimal exhaustion length to an arbitrary class well-order, compare these lengths, and do so uniformly across a supplied family? The coherent-relation requirement must be kept; the repeated quotient-type example  $P(\omega)/E_n \cong P(\omega)$  rules out a classification using quotient types alone.

**Research question 113.266** (Source 32, Question 12.3: Normal forms after repeated  $\Omega$ -division). For which presentations does iteration of [theorem XVI.3.6](#) yield a useful canonical normal form? Can one recognize the finite-support powers and hereditary term orders directly from their block structure? What hypotheses ensure uniqueness of more elaborate normal-form expansions?

The one-step division theorem is unconditional in GBC. Neither a universal Cantor normal form for all class well-orders nor a uniformly admitted iteration through all possible class lengths has been established here.

### Condensation beyond finite polynomial forms

**Research question 113.267** (Source 35, Question 10.12: Classify isomorphism-level condensation fixed points). Which class well-orders are isomorphic to their set-interval quotient, and which can occur in nontrivial isomorphism-level cycles?

The example  $P(\omega)$  already shows that one-step condensation can preserve the order type. It does not show that the actual retained subclass is unchanged. Nor does it prevent a specified transfinite history from terminating. Any classification should retain the quotient map, the literal retained representatives, and the isomorphism type as distinct data. This avoids the false inference that every quotient must have a strictly smaller abstract length.

**Research question 113.268** (Source 35, Question 10.13: Alternative limits with an explicit universal property). What genuinely different class-order theories arise when limits of condensation systems are defined by other universal properties or additional completion operations?

The nested-representative limit and the union of its induced equivalence relations already describe the same canonical process. A new theory must change something substantive, such as the admitted maps, the identifications made at limit stages, or the ambient type level. The benefit should be an exact theorem or a preserved invariant, rather than an alternative spelling of the same construction.

**Research question 113.269** (Source 33, Research question 12.9: Other smallness ideals). Replace “is a set” by a specified smallness ideal or by internal cardinality below a cutoff. Which analogues of canonical division and finite-digit representation survive? Singular cutoffs require particular care because the rank-bounding and replacement arguments used at an inaccessible  $\kappa$  may fail.

### 113.28.4 Notation systems, fixed points, and support conditions

[merge] Source 35’s question 10.6 is **answered** positively by this write ([theorem XVI.6.21](#)), and kept on record. Source 34’s R4 and source 35’s question 10.8 ask for the same Veblen-style hierarchy of class-order fixed points; with source 35’s question 10.7 (completion for other functors), source 34’s R2 and R3, and source 33’s question 12.14, they are open.

### Fixed-point completions and their functorial behavior

**Research question 113.270** (Source 35, Question 10.6: A choice-free completion theorem). Can the local fixed-point completion theorem itself be lowered from GBC to GB in full generality, with a completely uniform proof of well-ordering for the finite-trace direct limit?

The explicit finite-support constructor is now known to preserve well-ordering without Choice. The remaining point is the internal uniformity of the iterated stages for an arbitrary supplied seed embedding. Proving each externally fixed stage is not by itself a proof of the needed uniform assertion in a weak base. This article keeps the stated GBC hypothesis for the completion theorem instead of using a metatheoretic iteration as an unstated class-existence axiom.

**Research question 113.271** (Source 35, Question 10.7: Completion as a universal construction). For which class-order functors  $F$  does a supplied initial embedding  $W \preceq_{\text{init}} F(W)$  yield a least fixed-point extension by an elementary finite-trace construction?

For  $F = P$ , finite support guarantees preservation of the direct limit, while preservation of initial embeddings guarantees that every predecessor of a point lies in a single stage. These two properties suggest sufficient hypotheses. They should be phrased for one uniformly supplied functor on codes and maps, without quantifying over a nonexistent class containing all classes as elements. Normal dilators are a natural source of examples, but a claim about every dilator must specify its coding and axioms separately.

**Research question 113.272** (Source 34, R4: iterated fixed-point notation). Develop a Veblen-style hierarchy of class-order constructors with finite support and local certificates. State a well-foundedness theorem for the complete proposed syntax before assigning it a large symbolic ordinal name. Compare the resulting theory with the support-based constructions used in ordinal analysis [86].

[merge] (4 October 2026, batch 97.) Advanced by source 36: its finite-support transfer theorem turns a finite-support term operator that preserves set well-orders into one that preserves class well-orders, over GB without choice ([theorem XVII.6.2](#)), and the epsilon-term functor  $\mathbf{Ep}$  is such an operator, with set-case type  $\varepsilon_\beta$  ([theorem XVII.6.4](#)) and an order of type  $\zeta_{\kappa+1}$  from its iterates ([theorem XVII.6.7](#)). The hierarchy itself, here and in source 35's [research question 113.273](#), stays open (source 36's [research question 113.299](#); [section 113.31](#) (d)).

**Research question 113.273** (Source 35, Question 10.8: Successive fixed points and Veblen-style systems). Construct explicit hereditary notation systems for successive  $P$ -fixed points, their common fixed points with other constructors, and suitable Veblen-style closures. Identify the exact comparison and well-ordering proofs for each system.

The classical use of class epsilon notation shows that such growth is a legitimate proof-theoretic direction. The contribution needed here is a coherent class-presentation semantics and verified constructor laws. A symbol resembling a familiar ordinal notation is not enough to establish a class well-order. Bounded specialization and finite-support direct limits offer two complementary proof methods.

**Research question 113.274** (Source 34, R2: support conditions beyond finite trees). Determine which families of set-sized supports admit a coherent replacement for greatest-disagreement comparison while preserving class well-foundedness. An unrestricted infinite support need not have a greatest differing coordinate. The finite-support proofs identify exactly where such a replacement must supply additional structure; a proposed extension should include counterexamples showing why its support restrictions are needed.

**Research question 113.275** (Source 34, R3: normalization of arithmetic inside the hereditary system). Construct certified algorithms for addition, multiplication, and exponentiation of the initial-segment notations represented by finite trees, with an explicit interface for ordinal coefficients. Prove the algorithms against class-order isomorphisms, not only against a few specializations  $\Omega \mapsto \kappa$ . Determine precisely which operations preserve finite normal forms.

[merge] (4 October 2026, batch 97.) **Answered for addition and multiplication** by source 36's [theorems XVII.5.1](#) and [XVII.5.2](#), proved against class isomorphisms of the represented initial segments, relative to the ordinal arithmetic of the coefficients ([section 113.31](#) (b)). Exponentiation, and which operations preserve finite normal forms in general, stay open (source 36's [research question 113.300](#)).

**Research question 113.276** (Source 33, Research question 12.14: Higher-order extension without a final universe). Which useful ordinal operations and comparison principles can be expressed on unrolled or hyperclass order codes, and what are their exact collection and recursion requirements? A satisfactory extension should reproduce the appropriate diagonal obstruction at its own level rather than postulate an absolute final ordinal of every universe.

### 113.28.5 Diagonals and definability complexity

[merge] Source 35's question 10.9, source 32's question 12.6 and source 33's question 12.1 ask the same thing: the least complexity of an order escaping a fixed definability level; open. Source 35's question 10.11 is open. Source 33's question 12.2 asks to remove the named global order: for orders on Ord with ordinal parameters source 35 removes it ([theorem XVI.7.11](#)); for arbitrary carriers and set parameters it is open. Source 34's R8 is the same distinction between ordinal and set parameters, which source 35's  $\delta_{\text{ord}} \leq \delta_{\text{set}}$  measures ([theorem XVI.8.6](#)); open.

### Definability spectra and uniform bounds

**Research question 113.277** (Source 35, Question 10.9: Quantitative complexity of escape orders). For a fixed finite  $n$ , what is the smallest definability complexity of a class well-order that strictly dominates all  $\Sigma_n$  ordinal- parameter presentations in the sense of the successor-sum theorem?

Our construction proves an escape at some finite higher complexity. It does not identify the least possible increase, and it does not prove that every adjacent level of a chosen syntactic hierarchy has a particular canonical representative. Establishing sharp upper and lower bounds would turn a qualitative nonuniformity theorem into a finer ordinal-analysis tool.

**Research question 113.278** (Source 32, Question 12.6: Syntactic complexity of diagonal bounds). Given formulas of fixed quantifier complexity, how complicated must a formula defining a diagonal upper bound be? Can the valid-fiber filter and the global index order be optimized to produce a sharp complexity hierarchy?

The proof uses only a fixed finite list and an elementary well-foundedness test. Making the syntactic transformations explicit would both sharpen the mathematics and provide a suitable finite verification target for the repository's formula calculus.

### Definability and order-height spectra

**Research question 113.279** (Source 33, Research question 12.1: Sharp complexity of the diagonal). For a fixed syntax convention, what is the best explicit upper bound on the complexity of the formulas defining  $D_n$ ? [Theorem XVI.7.20](#) proves that no isomorphic  $\Sigma_n(G)$  presentation exists. Can a matching small additive increase in the Levy hierarchy be obtained, and can optimality be shown for natural coding schemes?

**Research question 113.280** (Source 35, Question 10.11: Optimal uniform-family bounding). Given a uniform family, can one construct a more canonical or smaller strict bound than its successor-sum, while staying in the same weak theory and preserving useful functorial properties?

The successor-sum depends on an ordering of the index class and makes no claim to be a least upper bound. Removing that dependence may require comparison witnesses or higher-order selection. The problem is therefore a useful test case for the difference between explicit bounding and canonical classification.

**Research question 113.281** (Source 33, Research question 12.2: The role of a definable global order). Which weaker hypotheses suffice for parameter-free cofinality in the pure language  $\{\in\}$ ? Can the global-order parameter be removed in models without a parameter-free definable global well-order, perhaps for selected families of carriers or selected formula complexities?

**Research question 113.282** (Source 34, R8: ordinal parameters versus arbitrary set parameters). The spectrum theorem permits all set parameters. Characterize models in which ordinal parameters already give the same spectrum, and models in which the two differ. Under an appropriate definable global coding of sets by ordinals the distinction disappears; without such coding it should be treated as a real restriction.

### 113.28.6 Definability ceilings and truth

[merge] Source 34's R9, source 32's question 12.4, source 33's questions 12.3 and 12.4, and source 35's question 10.10 ask for the same invariant, the definable ceiling  $\Theta_L$  (source 32's  $\delta_A$ , source 33's  $\delta_G$ , source 35's  $\delta_{\text{set}}$ ; [section XVI.12](#) (e)): open beyond the necessary conditions  $\kappa < \Theta_L < \kappa^+$ ,  $\text{cf} = \omega$  under a named global order, and closure under ordinal arithmetic, including  $\kappa^{\Theta_L} = \omega^{\Theta_L} = \Theta_L$ . Source 32's question 12.7 is answered in part: with a named global order, parameter-free definitions are cofinal ([theorem XVI.8.3](#) and [corollary XVI.7.21](#)); in the pure language source 35 bounds the three suprema ([theorem XVI.8.6](#)); initiality of the parameter-free spectrum fails at  $V_\kappa$  (the remark after [proposition XVI.8.2](#)). Source 34's R10, source 32's question 12.5 and source 33's question 12.5 ask how large a truth jump is: source 32 shows that truth represents the old ceiling exactly ([theorem XVI.8.12](#)); the size of the new ceiling is open.

**Research question 113.283** (Source 34, R9: the invariant  $\Theta_{A,G}$ ). Analyze the dependence of the external definable-order cutoff on the model and named predicates. Countable cofinality is now fixed under the stated hypotheses, but the exact cutoff need not be. Compare it with admissible structures, unrolling heights, and definable closure. A theorem should specify whether it concerns an external ordinal or an internally definable object.

[merge] (4 October 2026, batch 97.) Advanced by source 36: the cutoff over any transitive model of ZFC is a fixed point of  $\xi \mapsto \varepsilon_\xi$  above  $\zeta_{\kappa+1}$  ([proposition XVII.6.11](#)); it is bounded by the height of every admissible set containing the model ([S36.6.2](#)); and the full model over  $V_\kappa$  unrolls to  $H_{\kappa^+}$ , of height  $\kappa^+$  ([proposition XVII.8.1](#)). The exact cutoff stays open (source 36's [research questions 113.295](#) and [113.302](#); [section 113.31](#) (e)).

**Research question 113.284** (Source 32, Question 12.4: Classifying definability ceilings). For fixed inaccessible  $\kappa$  and global predicate  $G$ , which ordinals occur as  $\delta_A$ ? Are there natural sufficient conditions supplementing

$$\kappa < \delta < \kappa^+, \quad \text{cf}(\delta) = \omega, \quad \kappa^\delta = \delta?$$

Closure under hereditary finite term formation gives further necessary restrictions. It would be valuable to compare the ceiling with heights arising from admissibility, definable well-founded relations, or an appropriate unrolling, but no identification of these invariants is assumed in the proofs above.

[merge] (4 October 2026, batch 97.) Advanced, not answered: source 36 proves that these ceilings satisfy  $\varepsilon_\delta = \delta$  and  $\delta > \zeta_{\kappa+1}$  ([theorem XVII.7.5](#) and [proposition XVII.6.11](#)), which implies  $\kappa^\delta = \delta$  and makes the remark above on hereditary term formation precise; it bounds them by admissible heights ([S36.6.2](#)); and varying  $G$  instead of  $A$  gives the same supremum  $\kappa^+$  ([theorem XVII.7.11](#)). Which ordinals occur is open (source 36's [research question 113.295](#); [section 113.31](#) (c)).

**Research question 113.285** (Source 33, Research question 12.3: Identifying the external ceiling). Can  $\delta_G$  be characterized in admissibility, fine-structural, or unrolling terms for canonical choices of  $G$  over  $V_\kappa$  or constructible rank models? The manuscript proves countable cofinality, arithmetic closure, and the epsilon-number property, but not an exact ordinal notation for this ceiling.

[merge] (4 October 2026, batch 97.) Advanced, not answered:  $\delta_G$  is a fixed point of  $\xi \mapsto \varepsilon_\xi$  above  $\zeta_{\kappa+1}$ , not only an epsilon number (source 36's [theorem XVII.7.5](#) and [proposition XVII.6.11](#)), and it is bounded by the height of every admissible set containing  $V_\kappa$  (S36.6.2); no exact characterization is known (source 36's [research questions 113.295](#) and [113.302](#); [section 113.31](#) (c)).

**Research question 113.286** (Source 33, Research question 12.4: Dependence on the global-order predicate). How much can  $\delta_G$  vary as  $G$  ranges over set-like global well-orders of one fixed  $V_\kappa$ ? What information can be coded into such a  $G$  while preserving its order-theoretic role, and what external heights can occur? Distinguish a change of predicate from a change of the set model.

[merge] (4 October 2026, batch 97.) **Answered** by source 36 ([lemma XVII.7.10](#) and [theorem XVII.7.11](#); [section 113.31](#) (a)). As  $G$  ranges over the bijections  $\kappa \rightarrow V_\kappa$ ,  $\delta_G = \mathfrak{H}_G$  is unbounded in  $\kappa^+$ ; any  $A \subseteq \kappa$  can be coded into  $G$  by adjacent swaps so as to be parameter-free  $G$ -definable; and every  $\alpha \in [\kappa, \kappa^+)$  is the type of a parameter-free  $G$ -definable class well-order for some  $G$ . The set model is fixed throughout. Which ordinals occur is source 36's [research question 113.295](#).

**Research question 113.287** (Source 35, Question 10.10: Characterize the definability-sensitive cutoffs). For inaccessible  $\kappa$ , analyze the external suprema of the well-order types definable over  $V_\kappa$  with no parameters, ordinal parameters, real parameters, or arbitrary set parameters. Which equalities between these suprema are forced by structural properties of  $V_\kappa$ ?

The counting argument gives strict bounds below  $\kappa^+$ , and successor closure gives no maximum. It does not calculate the suprema. These are external invariants of a specified structure and language. They should not be presented as internally definable ordinals of  $V_\kappa$ , since many lie above its entire ordinal class. Models with a definable global well-order may behave differently from models where arbitrary set parameters carry information unavailable from ordinal parameters.

**Research question 113.288** (Source 32, Question 12.7: Parameter-free and restricted-parameter spectra). What replaces [theorem XVI.8.9](#) when set parameters are forbidden, restricted to ordinals, or restricted to a specified set of parameters? Which closure and initiality properties survive?

Downward closure in the proof used the arbitrary point parameter  $x$  of a presentation. Without that parameter, the spectrum need not be justified as an initial segment by the same argument. The first task is to specify the parameter class before comparing ceilings.

**Research question 113.289** (Source 34, R10: how large is a single truth jump?). Our sum construction gives an explicit upper bound beyond every old definable order. Find sharper external bounds on its order type and determine how much the indexing well-order affects it. There is no reason to assume that the chosen diagonal sum is the least possible representative of the new definability gap.

**Research question 113.290** (Source 32, Question 12.5: Quantitative truth jumps). Can  $\delta_{T_A}$  be bounded or characterized in terms of  $\delta_A$  and a natural additional invariant of  $(V_\kappa, G, A)$ ? How do successive truth predicates and uniformly admitted limit truth predicates affect the spectrum?

The present exact result is that the first truth extension represents the old ceiling, not a formula for the new one. Distinguishing a finite tower of individual predicates from one admitted sequence of all stages remains essential.

**Research question 113.291** (Source 33, Research question 12.5: Iterated truth growth). How large is the gap  $\delta_{G,T} - \delta_G$  in an appropriate ordinal sense, and how does the hierarchy behave under finite, set-length, or class-length iterated truth predicates? [Theorem XVI.8.19](#) provides strictness for one truth expansion, not a quantitative classification of the iterated spectrum.

### 113.28.7 Changes of class realization and forcing

[merge] Source 34's R11, source 32's question 12.9 and source 33's question 12.11 ask how ceilings and notation systems behave under changes of the class realization and under forcing; open. This report's questions on changes of class realization are indexed in [section 113.12](#) (row "Changes of the class realization").

**Research question 113.292** (Source 34, R11: forcing and new class-order types). Hamkins and Woodin establish preservation results under specified forcing hypotheses and formulate more general questions [27]. Study preservation of the explicit notation systems and of  $\Theta_{A,G}$  separately from preservation of all class-order types. Old orders can remain well-founded while new isomorphisms or new presentations become available.

**Research question 113.293** (Source 32, Question 12.9: Changes of class realization and forcing). How does the definability ceiling change when one enlarges the admitted predicates while retaining the same set universe? Which analogous invariants behave well when the set universe also changes by forcing?

The first situation includes the truth extension proved here. The second must be kept distinct: preservation results for class well-orders and ETR in the forcing literature impose their own hypotheses [27]. A useful starting point is to formulate comparison maps between two explicitly specified spectra instead of presuming that all externally identical ordinal types have admitted isomorphisms.

**Research question 113.294** (Source 33, Research question 12.11: Preservation of definability heights). How do  $\delta_G$  and the truth-expanded heights behave under forcing or changes of class realization? Known class-order preservation results [27] concern carefully specified hypotheses. Equality of set ordinals does not, by itself, settle preservation of a *definability* spectrum in a changed language.

**Source 34's closing remark and source 35's practical sequence.** The immediate mathematical deliverable is the choice-free history theorem. The fixed-point and definability results supply two distinct ways to extend the project: one builds increasingly expressive finite syntax, while the other measures how the available class language changes the range of order types.

**A practical sequence of next steps** A sensible implementation sequence starts with the choice-free finite-support lemma and explicit map laws, then verifies the normal-form theorem, and finally formalizes fixed-point completion. These steps have short dependencies and precise acceptance criteria. The full reverse-mathematical separation problems should be pursued after these constructive foundations are checked, because they rely on subtler model existence and truth considerations.

For the repository, the immediate mathematical changes would be to replace the polynomial well-order proof, lower the assumptions of the specific canonical-history theorems, add the local fixed-point criterion, and attach an explicit status note to each theorem. A separate module should

contain the notation interface and its constructor certificates. This article and its archive are a standalone deliverable; no repository mutation or publication is part of the present work.

The resulting picture is precise: class-order arithmetic has many explicit, arbitrarily extensible constructions; the canonical histories available for all inputs are governed by strong comparability; and uniform definability imposes its own barriers even when individual presentations are elementary. These three facts give distinct, testable directions for further work.

### 113.29 Earlier questions answered by sources 32–35 (dated notes, 4 October 2026)

[merge] Dated notes in the form of [section 113.27](#); where the question indexes of [sections 113](#), [113.5](#) and [113.12](#) say otherwise, these notes supersede them, and the cells concerned carry dated notes. [Section XVI.12](#) gives the same status with the theorems in context.

- (a) *Source 20's research question 113.111, the strength of complete condensation histories “over GB or GBC”*: answered over GBC by source 29 ([theorem 108.19](#)) and now over GB by sources 34 and 35 ([theorem XVI.5.8](#) and [note XVI.5.19](#)): the existence of the histories for all inputs is equivalent to CWO, and to source 35's FPE ([corollary XVI.6.19](#) and [theorem XVI.6.21](#)). Whether CWO implies ETR stays open ([research question 113.219](#)).
- (b) *Source 11's research question 113.3 and the related questions of sources 13, 15, 16 and 18 (research questions 113.30, 113.48, 113.64 and 113.86)*, whose status after Part XIV left “the theory over GB” open ([section 113.25](#) (g)): the canonical-history formulation is now answered over GB as in (a). Source 15's first question, whether GB codes all finite condensations uniformly ([research question 113.48](#)), stays open; source 35 asks it again ([research question 113.260](#)).
- (c) *Source 31's research question 113.239, definable-class versions of the spectra*: answered in part, for external order types at an inaccessible height ([section XVI.12](#) (e)); its classification of global choice, enumeration, coding and Class Replacement for  $\text{Def}(V_\lambda, p)$  stays open.
- (d) *Source 29's research question 113.219*: not answered; sources 34 and 35 add equivalent forms of CWO over GB ([theorem XVI.5.8](#) and [corollary XVI.6.19](#)).

### 113.30 The questions of source 36 (batch 97)

[merge] (4 October 2026.) Source 36's ten research questions (its Section 9; Section XVII.9), printed whole with its commentary after its introduction to them, with the renamings of Part XVII (horizons  $\mathfrak{H}$ , the hereditary order  $E$ ). Each question is followed by a dated [merge] paragraph naming the questions of [section 113.28](#) it coincides with and its status. All ten are open; the second is answered in part by Part XVI. Questions of this report that source 36 answers or advances are in [section 113.31](#).

The first group below consists of questions suggested by the proved structure. They are an agenda for further investigation, not claims that each is a newly identified open problem in the literature. The final comparison question has an explicit published antecedent.

**Research question 113.295** (Source 36, Research question 1: Which horizons are realizable?). For fixed inaccessible  $\kappa$ , characterize

$$\mathcal{H}_\kappa = \{\mathfrak{H}_G : G \text{ codes a bijection } \kappa \rightarrow V_\kappa\}.$$

The article proves this set is unbounded in  $\kappa^+$ . Every member has cardinality  $\kappa$ , cofinality  $\omega$ , is fixed by epsilon enumeration, and exceeds the explicit zeta bound. These are necessary conditions, not a sufficient characterization. Further finitary notation operators may force additional closure

conditions. A useful first objective is to identify a nontrivial sufficient condition, or to exclude a candidate satisfying all conditions established here.

[merge] Open. It is the question of the theme “Definability ceilings and truth” of [section 113.28](#) (source 34’s [research question 113.283](#), source 32’s [research question 113.284](#), source 33’s [research questions 113.285](#) and [113.286](#), source 35’s [research question 113.287](#)) with the predicate  $G$  varying instead of an additional predicate  $A$ . The necessary conditions now known for one  $\mathfrak{H}_G$ :  $\kappa < \zeta_{\kappa+1} < \mathfrak{H}_G < \kappa^+$ ,  $\text{cf} = \omega$ ,  $\varepsilon_{\mathfrak{H}_G} = \mathfrak{H}_G$  ([theorem XVII.7.5](#) and [proposition XVII.6.11](#)), closure under the finite-support constructors and  $\text{Ep}$ ; unboundedness of the set is [theorem XVII.7.11](#). The sentence “Further finitary notation operators may force additional closure conditions” is a conjecture of source 36, not proved.

**Research question 113.296** (Source 36, Research question 2: Parameter-free versus parameter-allowing horizons). For which transitive set models  $M$  does  $\mathfrak{H}_0(M) = \mathfrak{H}(M)$ , and when can there be a strict gap?

The equality is proved here in the inaccessible-height setting after a global enumeration is named. The unrestricted transitive-model case lacks the same uniformly sound well-order filter and may lack a definable global enumeration. A classification should identify separately the roles of these two issues. Merely observing that there are countably many parameter-free formulas does not settle the question.

[merge] Answered in part by Part XVI. Source 34’s [theorem XVI.8.3](#) proves  $\sup \mathcal{S}_0^L = \Theta_L$  for every transitive  $\beta$ -model of GBC whose language names a global well-order  $G$ , and its last sentence removes  $G$  from the language when  $G$  is parameter-free definable from the other predicates; so  $\mathfrak{H}_0(M) = \mathfrak{H}(M)$  whenever  $(M, \text{Def}(M))$  is a  $\beta$ -model with a parameter-free definable global well-order (source 33’s [corollary XVI.7.23](#) is the internal form of the same elimination, by embeddings). Open without the  $\beta$ -hypothesis or without such a well-order: the two issues source 36 separates. The question is source 32’s [research question 113.288](#) and source 33’s [research question 113.281](#) for the pure language, and source 34’s [research question 113.282](#) concerns the related comparison of ordinal and set parameters.

**Research question 113.297** (Source 36, Research question 3: The complexity profile). For a fixed nested hierarchy of first-order formulas, calculate the bounded-complexity heights  $h_n$  and sharpen the effective bound  $h_n < h_{f(n)}$ .

The proof gives an effective increase without optimizing quantifier alternations. An audited coding might yield a small constant shift. This is a concrete syntactic project: fix the representation of domains, relations, partial truth, and validity, then count the actual complexity of the diagonal formula. Numerical shifts should be conclusions of that audit, not guesses.

[merge] Open. It is the question of the theme “Diagonals and definability complexity” of [section 113.28](#): source 35’s [research question 113.277](#), source 32’s [research question 113.278](#), source 33’s [research question 113.279](#). “An audited coding might yield a small constant shift” is a conjecture of source 36, not proved.

**Research question 113.298** (Source 36, Research question 4: The size of truth promotion). How much information about  $\mathfrak{H}_{G,T}$  is determined by  $\mathfrak{H}_G$ , when  $T$  is truth for  $(V_\kappa, \in, G)$ ?

We prove that  $\mathfrak{H}_G$  acquires a presentation and that the horizon strictly increases. We do not calculate the new endpoint from the old one. One can first examine finite iterates of truth in a fixed external full model, then ask which features depend on the predicate’s content rather than merely the previous horizon.

[merge] Open. It is source 34's [research question 113.289](#), source 32's [research question 113.290](#) and source 33's [research question 113.291](#). Known about  $\mathfrak{H}_{G,T}$ : it exceeds  $\mathfrak{H}_G$  and is presented exactly at  $\mathfrak{H}_G$  ([theorem XVII.7.9](#); source 32's [theorem XVI.8.12](#)), it has cofinality  $\omega$  (source 33's [theorem XVI.8.19](#)), and, since [theorem XVII.7.5](#) applies to the expanded language as source 36 says before [theorem XVII.7.9](#),  $\varepsilon_{\mathfrak{H}_{G,T}} = \mathfrak{H}_{G,T}$ .

**Research question 113.299** (Source 36, Research question 5: Higher finitary notation functors). Develop and compare class versions of Veblen and other well-order preserving finite-term operators, with exact predecessor semantics.

The support-localization theorem gives a method once a valid set-order operator and its support invariance are supplied. The task is to provide those data and prove the resulting class theorems. The Veblen constructions of [97] are a precise starting point. One should not infer that every ordinal function admits such a finite-support realization.

[merge] Open. It is source 34's [research question 113.272](#) and source 35's [research question 113.273](#), with source 35's [research question 113.271](#) for functors with a supplied initial embedding. Source 36's transfer theorem ([theorem XVII.6.2](#)) and epsilon-term functor ([theorem XVII.6.4](#)) are its first step (dated note at [research question 113.272](#)).

**Research question 113.300** (Source 36, Research question 6: Normalizing general powers of point-cuts). Extend the explicit arithmetic on hereditary  $\Omega$ -terms to a fully proved power-normalization algorithm.

The article proves direct addition and multiplication of represented point-cuts and supplies arbitrary class exponentiation as a presentation. It does not prove an algorithm converting every such power back into a term of E. A complete treatment should handle zero, successors, limit tails, and the exact distinction between a point and its predecessor class. This is a proof and implementation objective, rather than a claim that the corresponding set-ordinal algorithms are unknown.

[merge] Open. It is the exponentiation part of source 34's [research question 113.275](#), whose addition and multiplication part source 36 answers ([theorems XVII.5.1](#) and [XVII.5.2](#); dated note at [research question 113.275](#)).

**Research question 113.301** (Source 36, Research question 7: Weaker set theories). Which localization and finite-term transfer results survive without Power Set or with weaker forms of Collection?

The choice-free localization proof uses rank sets. A global enumeration can sometimes supply alternate set bounds. The appropriate question is which bounding and replacement principles are sufficient for each construction, not whether the displayed GB proof can be copied unchanged into a weaker theory.

[merge] Open. It is the set-theoretic half of source 32's [research question 113.262](#) ("how much set theory is needed for support localization . . ."), whose choice half is answered over GB ([section 113.28](#), theme "Comparison, recursion, and the strength of histories"). Part XV studies Zermelo set theory without Replacement, a related weakening ([part XV](#)).

**Research question 113.302** (Source 36, Research question 8: Admissible and definability bounds). Give sharper model-sensitive bounds for  $\mathfrak{H}(M)$ , and identify when the admissible upper bound is attained.

The existence of equality examples is already discussed in the historical sources [100, 101]; it should not be posed again as an unanswered existence question. A more informative objective is a classification by closure properties, class well-foundedness correctness, and the available parameter regime.

[merge] Open. It is the comparison with admissible structures asked by source 34’s [research question 113.283](#), by source 32 after [research question 113.284](#) and by source 33’s [research question 113.285](#); source 36’s bound (S36.6.2) and [proposition XVII.8.1](#) are first steps (dated note at [research question 113.283](#)). The MathOverflow discussions cited were not checked by this write.

**Research question 113.303** (Source 36, Research question 9: Stability under extensions). How do the spectra and horizons change under forcing, under changes of class realization, and under expansions by specific predicates?

Changing a class realization with the same sets preserves well-foundedness of a shared relation under the relevant base axioms, but can add comparison maps and new presentations. The truth and coding theorems give two sharply controlled expansion mechanisms. A forcing analysis must account for both new predicates and potentially new externally well-founded presentations. The broader forcing questions about ETR have a separate literature [27].

[merge] Open. It is the theme “Changes of class realization and forcing” of [section 113.28](#): source 34’s [research question 113.292](#), source 32’s [research question 113.293](#), source 33’s [research question 113.294](#).

**Research question 113.304** (Source 36, Research question 10: Class comparison and recursion strength). What are the exact reverse implications among ETR, continuous rankings, initial comparability, and weak class-order comparability over the relevant weak class theories?

This is the question posed in [35, 27]. No solution is claimed here, and no later resolution was verified by the targeted search. The explicit finite-code orders offer a controlled test family: their comparison maps can be constructed directly, which helps separate the strength of specific notation systems from the strength of comparison for every class well-order.

[merge] Open. It is Hamkins and Woodin’s Question 7, source 29’s [research question 113.219](#), and the theme “Comparison, recursion, and the strength of histories” of [section 113.28](#) (source 34’s [research questions 113.252](#) and [113.256](#), source 35’s [research questions 113.253](#) and [113.257](#), source 32’s [research question 113.254](#), source 33’s [research question 113.255](#)).

### 113.31 Earlier questions answered or advanced by source 36 (dated notes, 4 October 2026)

[merge] Dated notes in the form of [section 113.29](#); the questions concerned carry dated notes of their own in [section 113.28](#), and [section XVII.11](#) gives the same status with the theorems in context.

- (a) *Source 33’s [research question 113.286](#), dependence of  $\delta_G$  on the global-order predicate: answered.* As  $G$  ranges over the bijections  $\kappa \rightarrow V_\kappa$ , the ceilings  $\delta_G = \mathfrak{H}_G$  are unbounded in  $\kappa^+$ ; every  $A \subseteq \kappa$  can be coded into some  $G$  so that  $A$  is parameter-free  $G$ -definable; and every  $\alpha \in [\kappa, \kappa^+)$  is the type of a parameter-free  $G$ -definable class well-order for some  $G$  ([lemma XVII.7.10](#) and [theorem XVII.7.11](#)). The change is of the predicate only, with the set model fixed, as the question asks to distinguish. Which ordinals occur as  $\mathfrak{H}_G$  is source 36’s [research question 113.295](#).
- (b) *Source 34’s [research question 113.275](#), normalization of arithmetic inside the hereditary system: answered for addition and multiplication by [theorems XVII.5.1](#) and [XVII.5.2](#), proved*

- against class isomorphisms of the represented initial segments. Exponentiation, and the question which operations preserve finite normal forms, stay open ([research question 113.300](#)).
- (c) *Source 32's research question 113.284 and source 33's research question 113.285, classifying or identifying the definability ceiling*: advanced, not answered. New necessary conditions:  $\varepsilon_\delta = \delta$  and  $\delta > \zeta_{\kappa+1}$  ([proposition XVII.6.11](#) and [theorem XVII.7.5](#)), which proves source 32's remark that closure under hereditary finite term formation gives further necessary restrictions.
  - (d) *Source 34's research question 113.272 (and source 35's research question 113.273), a Veblen-style hierarchy of class-order constructors*: advanced by the finite-support transfer theorem and the epsilon-term functor on class well-orders ([theorems XVII.6.2, XVII.6.4 and XVII.6.7](#)); the hierarchy itself is open ([research question 113.299](#)).
  - (e) *Source 34's research question 113.283, the invariant  $\Theta_{A,G}$  and its comparison with admissible structures and unrolling heights*: advanced by the admissible bound ([S36.6.2](#)), the unrolling height  $\kappa^+$  of the full model ([proposition XVII.8.1](#)) and the closure properties of (c); open ([research question 113.302](#)).
  - (f) *Source 31's research question 113.239, definable-class versions of the spectra*: advanced for the external order types at heights that are not inaccessible: for every transitive  $M \models \text{ZFC}$  the definable spectrum is an interval  $[0, \mathfrak{H}(M))$  with  $\mathfrak{H}(M) < |\kappa|^+$ , its proper-carrier part is  $[\kappa, \mathfrak{H}(M))$ , and  $\varepsilon_{\mathfrak{H}(M)} = \mathfrak{H}(M)$  ([theorem XVII.6.9](#) and [propositions XVII.6.10 and XVII.6.11](#)). The thresholds for global choice, enumeration, coding and Class Replacement stay open, as in [section 113.29](#) (c).
  - (g) *Not answered*: Hamkins and Woodin's Question 7 (source 29's [research question 113.219](#); source 36's [research question 113.304](#)).

## 114 The sources' conclusions

[merge] Source 11 has no conclusion section; its summary is [section 115](#). The conclusions of sources 12, 09 and 08 are printed whole.

### 114.1 Source 12's conclusion

There is a rigorous full lexicographic order of all global surreal well-orders, provided it is understood as a relation on class objects, not as an ordinary class containing those objects. Its comparison needs no universal enumeration of abstract class order types: the largest common *labelled* prefix is elementary and sufficient.

The set-like suborder has a particularly uniform geometry. It fills set-indexed cuts, contains every class linear order even locally, and is equimorphic with binary classes on Ord. The unrestricted order adds new proper-class prefix phenomena, including finite adjacent blocks. The diagonal theorem prevents either construction from being exhausted by a same-level class of set codes.

At set-sized birthday bounds the theory becomes quantitative. The full well-order space of a carrier of cardinality  $\mu$  has exact ordinal spectrum below  $\mu^+$  and binary rank  $\mu^+$ . The minimal surreal slice has rank  $\mu$ , except at singular strong-limit cutoffs, where it has rank  $\kappa \cdot \kappa$ . This is an order-theoretic effect of cofinal blocks of code lengths, invisible to cardinal counting alone.

The inaccessible-rank interpretation shows exactly how these facts can coexist: internal classes and the external collection of all such classes occupy different levels. Respecting those levels removes the apparent paradox without weakening the embedding and universality questions into trivialities.

## 114.2 Source 09’s conclusions

The lexicographic well-ordering problem has three different answers, depending on its carrier. On a fixed set of surreals of size  $\kappa$ , the exact ordinal spectrum stops at  $\kappa^+$ . Allowing arbitrary set-length words gives a class-universal dictionary order, but prefix limits give it local order properties different from those of **No**. For set-like global well-orders, first disagreement again defines a linear comparison. Existence of a global enumeration is equivalent to global choice over **GB** with set choice, and all global enumerations cannot be collected into an ordinary class of set codes.

The eventual-agreement core resolves the constructive side of the global problem: it is a genuine class, it is isomorphic to the surreal line, it realizes every uniformly set-sized cut of global enumerations, and it is dense in every global interval. Bounded reflection explains why set-indexed configurations can always be studied in a suitable bounded permutation stage. The explicit missing branch and binary diagonal identify two independent boundaries: arbitrary class-sized cuts need not have solutions, and no single uniform class-indexed coding covers all global enumerations.

These boundaries are not paradoxes. They are the information needed to state theorems at the correct logical level.

## 114.3 Source 08’s conclusion

The global enumeration problem has a particularly clean answer once the types of objects are separated. Set-like well-orders of **No** are represented by class bijections from **Ord**, and numerical first-disagreement gives a rigorous virtual linear order. That order is large enough to encode every class binary word, yet its set-cut geometry is already witnessed by a single class of set-supported perturbations. This code class is another copy of the surreal line.

At a fixed set carrier, the structure is different: its exact ordinal spectrum stops at the successor of the carrier cardinal, and finite permutation tails account for every jump. At varying set carriers, termination introduces new local cofinalities. For non-set-like well-orders, a further index convention or relation code is necessary. None of these distinctions is optional bookkeeping: each changes a mathematical conclusion.

The principal proofs are elementary in their stated foundations. Their formalization should begin with bounded objects and the repository’s existing sign-sequence cut theorem, and only then pass to the uniform class formulation. The dense-skeleton theorem provides a concrete target: it combines first-disagreement combinatorics, controlled set support, small-cut filling, and universe-aware back-and-forth without requiring a paradoxical collection of all classes.

[merge] (3 October 2026.) The conclusions of sources 13, 14 and 17 follow; source 13’s includes its result ledger. Sources 15, 16 and 18 end with status tables instead, printed with the ledgers in the next section. In source 13’s ledger, the row “No full two-point split embedding” is a further statement whose proof is source 11’s ([note 55.6](#)).

## 114.4 Source 13: conclusions and result ledger

The strongest organizing principle is not that a single enormous well-order has been discovered. It is that different notions of “all” and different representations produce distinct linear orders, while a small collection of explicit tools connects them safely.

The fixed-set layer has its own cardinal and ordinal spectra. The ordinary class of set words depends decisively on termination. The full set-like enumeration domain has a surreal-sized dense core but no exhaustive uniform class of set codes. The raw order domain expands individual branch fibers, not the entire cut space of that core. A higher-level product can exceed the dense core’s

capacity even though ordinary class-indexed sums are absorbed. Finally, pure order isomorphisms can change the prefix presentation itself.

| New Lean proofs                                      | Not supplied                                                                        | Formalization plan only                            |

The follow-up therefore gives explicit answers to several concrete questions raised by the repository while leaving stronger classification and minimal-axiom problems clearly identified. The proofs and their stated size hypotheses are the basis on which these conclusions should be evaluated.

### 114.5 Source 14: conclusion

The strongest organizing distinction is not between large and small cardinalities alone. It is between set-coded presentations, class-valued branches, and raw class relations with further tails. Prefix cylinders make that distinction mathematically visible.

Every normalized class cut of the set-supported core either stops at a cylinder edge, stops at a genuine numerical gap, or follows an injective branch through all ordinals. Exhaustive well-orders are exactly the branches that cover the alphabet. Because this criterion reconstructs a graph using only set quantifiers and old parameters, it yields a no-new-realization theorem for old cuts. Raw well-orders have the same trace precisely when their canonical initial branches agree, leaving an explicit residual well-ordering problem in each fiber.

Support restrictions provide a different axis of complexity. Allowing support of cardinality  $< \kappa$  gives exactly the cut-filling threshold of  $\kappa$ , and the failure beyond it has an attained support cost. All these layers still contain a copy of the full surreal order. Thus class universality, density in an ambient comparison order, and saturation are genuinely different properties.

The resulting theory remains paradox-free because each “all” has a specified sort, each prefix has a specified size, and each use of surreal cut filling has set option families. The automorphism-orbit theorem sharpens this distinction: bare-order symmetries can exchange exhaustive traces with nonbranch boundaries. The principal open targets are now the exhaustive-trace stabilizer, finer support invariants, and the interaction between raw tail structure and higher class realizations.

## 114.6 Source 17: conclusion

The lexicographic ordering problem separates into several mathematically substantial structures. On the minimal birthday-cutoff slice, the relevant parameters are the cardinality  $\mu = 2^{<\kappa}$  and two different cofinalities  $r = \text{cf } \kappa$ ,  $q = \text{cf } \mu$ . Point characters are  $(q, q)$ , cylinder cofinalities are  $r$ , and three distinct cut mechanisms give the exact gap spectrum. Exhaustiveness is also the key issue in fusion: a coherent full-length injection need not be a permutation.

The same distinction persists at class scale. A single lower class cut of a supported core determines an injective global word exactly when its labelled cylinders straddle at every ordinal length. A separate coverage condition distinguishes exhaustive words. Reconstruction is elementary, but exhaustion is invisible to the bare core order: a core automorphism can carry an exhaustive branch gap to a nonexhaustive one. The represented- cut predicate is therefore genuine additional structure, and same-set class extensions change it while leaving the code carrier unchanged.

For unrestricted class well-orders, a proper-class prefix can leave a finite residual alphabet. The resulting maximal adjacency components are exactly the factorial blocks of a finite final segment; their condensation is dense without becoming an ordinary class of all class orders. Across all these conclusions, typing the objects and bounding the recursion histories are part of the mathematics, not merely notational cautions.

[merge] (3 October 2026, batch 89.) Source 31 has no conclusion section; its closing section, on the consequences for this report’s questions and for formalization, is printed in Part XV ([section XV.12](#)).

## 115 Results, assumptions, and verification status

| Result                                                                   | Foundation used here                                              |
|--------------------------------------------------------------------------|-------------------------------------------------------------------|
| Fixed-alphabet cardinality and ordinal spectrum                          | ZFC; existing repository theorem                                  |
| Explicit set-length word compression                                     | ZF, as a definable class construction                             |
| Local word characters and set-cut arguments                              | Surreal set cuts; ZFC for cardinal-valued characters              |
| Any class well-order of <b>No</b> implies global choice                  | GB with ZF set part                                               |
| Raw comparison, canonical initial part, finite-jump criterion            | GB, with the given class orders                                   |
| Bounded-support completion and interpolation                             | GBC, with a fixed global enumeration                              |
| $\mathcal{P}_{\text{bd}} \cong \mathbf{No}$ and class-order universality | GBC, by set-valued back-and-forth                                 |
| Binary class coding and no exhaustive uniform evaluator                  | GBC, interpreted with class parameters                            |
| Unrestricted order does not embed into its set-like fragment             | Full inaccessible universe; or KM + GC for definable uniform maps |
| All higher-order collections treated as actual objects                   | An explicitly chosen higher-order or containing-universe setting  |

The proof dependencies are short. Set cuts yield fresh coefficients after deleting a set. Fresh coefficients and bounded-support completion yield strong interpolation. Strong interpolation yields density, local cofinality statements, the **No**-isomorphism, and cut coding. Independently, the

predecessor comparison yields convex cones, the canonical initial-part decomposition, and the finite-residual jump theorem. Pair swaps supply both positive binary embeddings and the diagonal obstruction.

The bundled Python script checks finite instances of the two comparison rules and of the sign encoding. It checks 465 coefficient-code comparisons, 79,800 word-code comparisons, and 266,272 pairs of finite permutations, with the predecessor rule checked in both directions and the adjacency criterion compared with the finite lexicographic order. These checks help detect a reversed delimiter or an incorrect finite comparison. They do not verify an ordinal induction, a class comprehension argument, or a cardinal nonembedding theorem.

The article contains full mathematical proofs for the claims it promotes to theorems. It does not claim that the new results have been checked in Lean, that the whole repository has been audited, or that every research question listed here is a previously published open problem.

[merge] The other sources' ledgers follow; each records the hypotheses its source used, not that each is necessary.

### 115.1 Source 12's proof-dependency and assumption ledger

| Result                                             | Stated setting                         | Essential input                                                                                     |
|----------------------------------------------------|----------------------------------------|-----------------------------------------------------------------------------------------------------|
| Common labelled prefix and full lexical comparison | GBC; comparison is elementary          | Existing well-orders; class minima; ambient linear order.                                           |
| Global-choice equivalence                          | GB + set AC                            | Ordinal coding of transitive closures; restriction of a surreal well-order to a set of codes.       |
| No exhaustive class-coded family                   | GBC                                    | A baseline Ord-bijection; elementary diagonal pair orientation.                                     |
| Set-like cut interpolation                         | GBC                                    | Set-sized discrepancy bound; surreal small-cut filling; prefix extension.                           |
| Local class universality                           | GBC                                    | Set-valued forth and back-and-forth recursions; global enumeration.                                 |
| Finite-tail adjacency                              | GBC                                    | Label transpositions; finite residual cylinders; no infinite order well-ordered in both directions. |
| Set-sized full spectra                             | ZFC                                    | Pair coding; regularity of $\mu^+$ ; cylinder-fusion nonembedding.                                  |
| Minimal-slice singular transition                  | ZFC                                    | Cone partition; scheduler; ordinal block sums; regularity or singular cofinality as appropriate.    |
| Full-class rank model                              | Ambient ZFC + an inaccessible $\kappa$ | Closure of $V_\kappa$ ; all external classes; regularity for descending sequences.                  |

### 115.2 Source 09's theorem-status ledger

| Result           | Logical setting and proof input                | Status here                                 |
|------------------|------------------------------------------------|---------------------------------------------|
| Surreal set cuts | Set options; standard sign-sequence simplicity | Classical; repository primitives inspected. |

| Result                                                      | Logical setting and proof input                       | Status here                                    |
|-------------------------------------------------------------|-------------------------------------------------------|------------------------------------------------|
| Class universality and back-and-forth                       | GBC; set-valued recursion                             | Classical mechanism, proved in full.           |
| Global baseline $\Leftrightarrow$ GC                        | GB plus set choice; well-founded ordinal codes        | Standard coding argument, proved here.         |
| Fixed-set cardinality and ordinal spectrum                  | ZFC; pair switches and regular-cardinal stabilization | Generalization/reproof of the set-sized route. |
| Limit-prefix character of $\mathcal{I}$                     | ZFC schema or GBC class statement                     | Written proof.                                 |
| Bounded-support extension                                   | GBC with fixed $b$ ; set cardinal arithmetic          | Written proof; finite mechanism tested.        |
| Core interpolation and $\mathcal{P}_s(b) \cong \mathbf{No}$ | GBC; uniform families, small cuts, extension          | Main construction; written proof only.         |
| Bounded reflection                                          | GBC; Replacement for a uniform set family             | Written proof.                                 |
| Missing (Ord, Ord) branch                                   | GBC; ordinal prefixes and uniform completions         | Explicit counterexample with proof.            |
| Uniform no-coding                                           | GBC; pair switches and diagonal class                 | Written proof; finite diagonal tested.         |
| Inaccessible model                                          | ZFC plus a strongly inaccessible cardinal             | Conditional set-sized theorem, proved here.    |
| Proposed Lean modules                                       | Explicit universes, smallness, and baseline parameter | Plan only; not compiled or verified.           |

### 115.3 Source 08's assumption and proof-dependency ledger

| Result                                      | Assumptions                                  | Main dependencies                                         |
|---------------------------------------------|----------------------------------------------|-----------------------------------------------------------|
| Fixed-carrier cardinality and universality  | ZFC, $ X  = \kappa$ infinite                 | Pair blocks and lower-cut bits                            |
| Exact ordinal spectrum                      | Same                                         | Regularity of $\kappa^+$ , not of $\kappa$                |
| Adjacency classification                    | Same                                         | Extreme residual enumerations, two-sided well-foundedness |
| Regular cutoff theorem                      | $\kappa$ regular, $2^{<\kappa} = \kappa$     | Birthday bounds, terminal coding, active-row cuts         |
| Pairwise global comparison                  | Class parameters, elementary comprehension   | A least disagreement below one witness                    |
| Orbit prefix extension                      | Baseline $b$ , class replacement, set Choice | Enlargement to a bigger set cardinal                      |
| Orbit interpolation                         | Baseline and uniform set families            | Cross-disagreement bound, fresh entry, prefix extension   |
| Skeleton isomorphism and class universality | GBC                                          | Global enumerations, uniform set-valued recursion         |
| Virtual binary equimorphism                 | Baseline, elementary class operations        | Pair blocks and ordinal concatenation                     |
| No exhaustive class-uniform list            | GBC for arbitrary class indices              | Pairwise diagonalization                                  |
| Full-class model example                    | External strongly inaccessible $\kappa$      | Relative sets versus external sets                        |

The ledger records the hypotheses actually used in the supplied proofs. It does not claim that every hypothesis is logically necessary. In particular, the foundational optimization questions in [section 113.4](#) remain distinct from the sufficiency results.

[merge] (3 October 2026.) The ledgers and status tables of sources 14, 15, 16, 17 and 18 follow (source 13's is with its conclusions in [section 114](#)). Each records what its source proved in writing

and what it inherited; “new” there means new relative to this report at the source’s pin, not new relative to the sibling sources, which proved several of the same theorems independently (section 4.5). Source 18’s table is printed whole, as is its remark that its review corrected the arbitrary-alphabet density construction to include isolated global endpoints (the correction is in the printed theorem, theorem 27.9). Source 16’s last subsection describes its delivered package; the shipped names are listed in appendix B.

#### 115.4 Source 14: result ledger and verification status

| Result                                                       | Status in this package                                                                                                                  |
|--------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| Fixed-set cardinality, ordinal spectrum, adjacency           | Inherited from the pinned ProveIt report; stated with source, not newly established here.                                               |
| Birthday minimal-slice dichotomy                             | Inherited; ordinal multiplication and mutual embeddability explicitly retained.                                                         |
| Core cylinders and prefix completion                         | Reproved as prerequisites; basic constructions already present in the predecessor.                                                      |
| Boundary trichotomy, Theorem 43.3                            | Main continuation result; complete written proof, relative to named cylinders.                                                          |
| Character table, Theorem 44.1                                | Written derivation from the trichotomy, including the principal-cut correction.                                                         |
| Exhaustive recognition, Theorem 45.1                         | Answers the prefix-enriched version of a predecessor research question.                                                                 |
| Class-model absoluteness, Theorem 48.1                       | Written proof using the elementary reconstruction formula and fixed old parameters.                                                     |
| Cut automorphism orbits and nonrecognizability, Theorem 47.2 | Written proof by set homogeneity and two-sided back-and-forth; distinguishes order-invariant classification from prefix classification. |
| Support compression and exact threshold, Theorem 49.3        | Main continuation result; finite kernel checked computationally, infinite/cardinal proof supplied in text.                              |
| Core isomorphism with <b>No</b> ; diagonal non-coding        | Inherited statements; proofs or recovery arguments included for context.                                                                |
| Direct raw comparison and canonical branch                   | Inherited constructions; short proofs given to support the trace analysis.                                                              |
| Trace fibers, Theorem 54.6                                   | New synthesis of the canonical branch with cut recognition; written proof.                                                              |
| Historical priority of continuation results                  | Not established; no claim of a first result in the published literature.                                                                |
| Lean verification of continuation results                    | Not performed. Proposed module names and pseudocode are not compiled artifacts.                                                         |

The entire manuscript is an unrefereed research contribution. The ledger separates what is proved in writing, what is inherited, and what remains unverified; a finite diagnostic is never substituted for a class theorem.

#### 115.5 Source 15: what is settled here and what remains

| Topic                       | Result and boundary                                                                                                               | Foundation                           |
|-----------------------------|-----------------------------------------------------------------------------------------------------------------------------------|--------------------------------------|
| Set-sized spectra           | Cardinality and ordinal universality are inherited background, with proof reproduced                                              | ZFC                                  |
| Native class comparison     | Direct first unequal labels; no abstract class-type comparison required                                                           | GB with given class well-orders      |
| Canonical block quotient    | All first-level blocks defined simultaneously; any class index can occur                                                          | GB for quotient; GBC for realization |
| Long condensation histories | Explicit polynomial histories for every given class well-order; no arbitrary-input equivalence to ETR                             | GBC                                  |
| Represented cuts            | Persistence at every set prefix level is necessary and sufficient; all first failures classified                                  | GBC with fixed core                  |
| Abstract reconstruction     | An automorphism of the core can destroy representability                                                                          | GBC                                  |
| Bounded local geometry      | Local character $\text{cf}(2^{<\kappa})$ , global cofinality $\text{cf } \kappa$ , and exact $\eta_{\text{cf } \kappa}$ threshold | ZFC                                  |
| Longer fixed types          | Exact cube and finite-factor classification for $\mu \cdot \gamma + n$ ; not all smaller infinite residual tails                  | ZFC                                  |
| Alternative codes           | Rank endpoints, table endpoint classification, quotient and restriction obstructions                                              | ZFC or GBC as stated                 |
| Formal verification         | Concrete interfaces proposed; finite examples checked; new transfinite proofs not machine-verified                                | Explicit status, not an added axiom  |

The research questions below are proposed extensions of this development. Except for a cited historical question, they are not claims that a named problem has an independently verified current open status in the literature.

### 115.6 Source 16: proof status, assumptions, and reproducibility

| Result                                                                    | Assumptions                                            | Status relative to the inspected report                   |
|---------------------------------------------------------------------------|--------------------------------------------------------|-----------------------------------------------------------|
| Set-alphabet cardinality and ordinal spectrum, <a href="#">Note 32.1</a>  | ZFC                                                    | Existing result, reproved.                                |
| All-stratum density and cellularity; countable incompleteness             | ZFC                                                    | New extension here, with full proofs.                     |
| Exact regular-stage gap spectrum                                          | ZFC; regular $\mu$ ; $\eta_\mu$ alphabet of size $\mu$ | New extension here.                                       |
| Endpoint word-tree isomorphisms; complete termination type classification | GBC                                                    | New extension here; explicit embeddings need less choice. |

| Result                                                             | Assumptions                               | Status relative to the inspected report                        |
|--------------------------------------------------------------------|-------------------------------------------|----------------------------------------------------------------|
| Direct raw comparison and GC equivalence                           | GB; given class well-orders               | Existing result, explained and reproved.                       |
| Simultaneous set-interval block decomposition and largest set tail | GB                                        | New extension here; no ETR.                                    |
| Bounded-support completion and interpolation                       | GBC; uniform families                     | Existing result, reproved.                                     |
| Represented-cut recognition and first-failure classification       | GBC; one available lower cut              | New extension here; elementary formulas.                       |
| Elementary uniform nonembedding                                    | GBC plus $\Sigma_1^1$ class comprehension | Sharper sufficient bound; no reversal claimed.                 |
| Full-model identification and nonembedding                         | Ambient ZFC plus an inaccessible cardinal | Existing result, rederived with additional stratum comparison. |
| Proposed Lean architecture                                         | Explicit universe and model choices       | Design only; no new Lean verification claimed.                 |

### 115.6.1 What was checked

The source audit read the merged surreal well-order article and README, the reals report README, the project agent instructions, and the specific sign-sequence and size-obstruction declarations listed above, at revision 491ed8411cccf7bd57916eb7666bbba762e92f96. The audit was targeted, rather than a proof that no overlapping statement occurs anywhere else in the repository. The new arguments were developed and checked independently within this preparation, including the set-theoretic scopes of the cut, block, topology, and termination proofs. This is mathematical review, not a kernel proof or external peer review.

The accompanying Python script checks finite relation-prefix comparison, the centered and prefix-first sign encodings, and the distinction between relation-table and enumeration comparison. It evaluates finite surreal sign strings as exact dyadic rationals, so the numerical side of the encoding check is independent of the encoded lexicographic comparator. Its successful finite tests do not establish class comprehension, transfinite well-foundedness, cardinal arithmetic, or saturation.

The PDF was compiled from the included standalone LaTeX source and checked for missing references, compilation errors, and layout defects. The archive includes the source, PDF, finite diagnostic script and its results, a short build guide, and a source/status note. A standard TeX installation with the packages named in the preamble is sufficient:

```
latexmk -pdf -interaction=nonstopmode surreal_well_orders_further.tex
python3 finite_checks.py
```

No network access is needed to compile the article or run the finite checks. The bibliography gives pinned repository locations and primary literature links for independent investigation.

## 115.7 Source 17: theorem and dependency ledger

| Result                                                    | Main dependency                                        | Foundation                            | Status here              |
|-----------------------------------------------------------|--------------------------------------------------------|---------------------------------------|--------------------------|
| Alphabet gaps,<br><a href="#">Theorem 29.4</a>            | Sign paths, set recursion, small deletion              | ZFC                                   | Proved                   |
| Minimal-slice invariants,<br><a href="#">Theorem 30.2</a> | Cylinder base, divergence bounds                       | ZFC                                   | Proved                   |
| Fusion, <a href="#">Theorem 30.5</a>                      | Dense refinement, coverage schedule                    | ZFC                                   | Proved                   |
| Gap spectrum,<br><a href="#">Theorem 30.11</a>            | Alphabet gaps, cut trichotomy, character calculation   | ZFC                                   | Proved                   |
| Exact reserve,<br><a href="#">Theorem 49.7</a>            | Cardinal deficiency balance, complement bijection      | Set choice; class notation elementary | Proved                   |
| Core interpolation and isomorphism                        | Surreal set cuts, supported completion, set histories  | GBC                                   | Source results re-proved |
| Recognition,<br><a href="#">Theorem 46.21</a>             | Unique straddlers, elementary class comprehension      | GBC                                   | Proved                   |
| Automorphism extension and failure                        | Recognition, large-gap homogeneity                     | GBC                                   | Proved                   |
| Class-extension detection                                 | Recognition, pair coding, common baseline              | Same-set GBC models                   | Proved                   |
| Finite condensation                                       | Source adjacency, no descending $\omega$ -chain        | GBC; comparison-level statement       | Proved                   |
| All-type or noncardinal classification                    | Residual alphabets not controlled by current interface | Not fixed                             | Proposed questions       |

“Proved” means that a written argument is supplied in this article. It does not mean external proof review, historical priority, or formal verification. The targeted source audit read the merged report, its README, its open-question sections, and the relevant source proofs at the pinned revision. It was not an exhaustive audit of the repository or the literature.

## 115.8 Source 18: assumptions, provenance, and verification status

| Result family                                      | Framework                                          | Status in this deliverable                                |
|----------------------------------------------------|----------------------------------------------------|-----------------------------------------------------------|
| Set ordinal spectra                                | ZFC                                                | Repository result, proof supplied                         |
| Bounded cardinal invariants and exact gaps         | ZFC                                                | Proved here; independent mathematical audit               |
| Elementary labelled class comparison               | GB with supplied well-orders                       | Repository method, proof supplied                         |
| Canonical set-interval decomposition               | GB with supplied well-order                        | Proved here; no ETR used                                  |
| Block-index realizations on <b>No</b>              | GBC                                                | Proved by explicit construction and transport             |
| Core interpolation and exhaustive-code obstruction | GBC                                                | Repository methods, proofs supplied                       |
| Represented-cut criterion                          | GB with a fixed baseline                           | Proved here; surjectivity distinguishes the set-like case |
| Countable factorial shuffle                        | Externally countable, $\omega$ -standard GBC model | Proved here; external classification                      |
| Centered word cut theorems                         | GB/definable-class formulation                     | Proved here; isomorphisms additionally use GBC            |
| Full-class nonembedding model                      | Ambient ZFC with inaccessible cardinal             | External interpretation and cardinal proof supplied       |
| Lean realization of new results                    | Future work                                        | Not claimed or built                                      |

The repository audit was targeted to the surreal well-order report, the reals precursor, their source-status documents, and four relevant sign-sequence foundation files. It was not an audit of the whole repository. We fixed a revision so that subsequent repository changes cannot silently change the basis of this article. The mathematical proof review checked the cutoff hypotheses, singular-cardinal steps, class replacement and comprehension uses, finite terminal fibers, and external-model assumptions. It also corrected the arbitrary-alphabet density construction to include possible isolated global endpoints.

The complete source is self-contained LaTeX with an embedded bibliography. The PDF was compiled from that source and its rendered pages inspected. Those checks establish document consistency and layout; the mathematical validation remains the conventional proofs and their independent review. The attached package makes no claim of a formal kernel certificate or a literature-priority result.

[merge] (3 October 2026, batch 89.) Source 31’s axiom ledger and its status of the principal assertions close Part XV ([sections XV.13](#) and [XV.14](#)).

## A Source crosswalk and reproducibility

The immutable sources used in the targeted audit are recorded in the accompanying source audit. For convenient verification, the most relevant mappings are:

| Source | Relevant content                                                                                                                                                                                                                               |
|--------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| [1]    | Labels <code>lwo:lem:prefix-free</code> , <code>lwo:lem:cylinder</code> , <code>lwo:prop:cardinality</code> , <code>lwo:thm:no-long</code> , <code>lwo:thm:ordinal-spectrum</code> ; bounded sign orders in <code>lwo:sp:thm:surreals</code> . |
| [3]    | Set-coded surreals and bounded birthdays; unrestricted cut obstruction; class-quantification and universe distinctions; set-valued recursion.                                                                                                  |
| [7]    | Actual sign carrier, ordinal embedding, smallness obstruction, and bounded fragments.                                                                                                                                                          |
| [9]    | Small cut operation, separator properties, and birthday bounds.                                                                                                                                                                                |
| [5]    | A nearby use of a set-like global well-order and ordinary class-parameter recursion.                                                                                                                                                           |

To compile the delivered standalone source, run `latexmk -pdf surreal_well_orders.tex` from its directory. All article sections and the bibliography are included in that single file; no separate bibliography processor is needed. Run `python3 finite_checks.py` for the finite checks. The supplied PDF was compiled from the included sources and inspected after rendering.

[merge] *Delivery names.* The paragraph above describes source 11’s delivered package. Its `surreal_well_orders.tex` is shipped as `article.tex`, which this merged text replaces; its PDF is not shipped (`article.pdf` is a build of this text); its `finite_checks.py` and `finite_checks_results.txt` are `code/11-raw-orders-finite_checks.py` and `data/11-raw-orders-finite_checks_results.txt`; the “accompanying source audit” is `11-raw-orders-repository_audit.md`. Build this report with `latexmk -pdf -interaction=nonstopmode -halt-on-error article.tex`, and rerun the checks as in [appendix B](#). The same applies to the reproducibility records of the other sources that follow.

## A.1 Source 12: reproducibility and inspection record

The package contains `article.tex`, the compiled `article.pdf`, a build script, an exact finite-check program, its recorded JSON output, and a research-status and source-audit file. The Python program uses only the standard library. The recorded run passed all 180,905 finite comparison cases. Its comparisons are exact; there are no floating-point tolerances or inferred transfinite results. The PDF was compiled and rendered for visual inspection.

The repository audit directly inspected the merged real-well-order README and the sign-sequence simplicity Lean source at the stated commit. It did not independently compile the repository or verify the predecessor report’s proofs. The needed predecessor patterns have therefore been reproved in the present manuscript. Literature checking was focused on surreal foundations, Kanovei–Shelah indexing, and class recursion and well-orders; it was not sufficient to certify historical originality.

## A.2 Source 09: repository and source audit

The repository was inspected through its GitHub connector. All cited repository files are pinned to

63bb8b1d99359e7188abf0a33fb152e121858150.

A later search surfaced a newer commit; the cited foundational files were fetched at the earlier pinned snapshot rather than mixing versions. No repository file was changed.

The targeted inspection covered the merged real well-ordering report’s README and the relevant returned source of the sign-sequence and cut-operation modules. The real report identifies itself as unrefereed and not formalized. Its README describes a merged 54-page report and separates its results from nearby Lean developments. That report is used as research context, not as a kernel-certified dependency.

The sign-sequence file provides actual Lean declarations for the universe-indexed carrier, order, ordinal embedding, and smallness properties; the cut file provides the small-cut operation and its birthday bound. Their source statements were read, but this project did not rebuild the repository or audit all transitive dependencies. No claim of independent kernel verification is made.

The primary literature checked includes Kanovei–Shelah’s original index definition, Rangel–Mariano’s explicit set/class framework, and the class-recursion distinctions in Gitman–Hamkins–Holy–Schlicht–Williams. The Kanovei–Shelah index page was also visually inspected. The literature search was targeted rather than exhaustive. General universality and back-and-forth arguments are classical; the support-core organization and the accompanying obstruction statements are proved here without a priority claim.

### A.3 Source 09: verification and reproducibility

The accompanying `code/finite_checks.py` uses only Python’s standard library. It checks finite versions of the pair-switch lexicographic embedding, partial-prefix permutation completion, the forced-prefix separator algorithm, support extension preserving first disagreements, and the diagonal switch construction. Exact rational arithmetic is used for the separator tests. A deterministic random seed makes the sampled checks reproducible; other suites exhaust their specified finite ranges.

**These checks do not verify any transfinite theorem.** Their role is to detect indexing, orientation, and extension mistakes in the finite combinatorial mechanisms. Proofs of the infinite statements are the written arguments in the article. The recorded run passed 164,560 assertions, including 1,101 separator-family cases. The test report is `data/finite_checks.json`. The archive also contains a build script and a theorem-status ledger.

To compile the article, run `bash build.sh` in the archive’s root directory. It makes three passes with `pdflatex`, resolves the internal bibliography and cross-references, and writes build products into `build/` before copying the finished PDF to the root.

### A.4 Source 08: finite regression checks

The package includes `verify_finite.py`, requiring Python 3.10 or later and only its standard library. Running it writes `verification_results.json`. The supplied run passed:

| Check                                                          | Instances |
|----------------------------------------------------------------|-----------|
| Consecutive permutation pairs, sizes 1 through 7               | 5,906     |
| All increasing pairs of distinct permutations, sizes through 5 | 7,432     |
| Pair-code order comparisons, bit lengths 0 through 7           | 21,845    |
| Sign words of lengths 0 through 6                              | 127       |
| All sign-code order and prefix-free comparisons                | 16,129    |

The permutation test checks both directions of the adjacency rule on all manageable pairs, not just a few positive examples. The sign test compares the numerical convention  $- < 0 < +$  with the

binary blocks  $00 < 01 < 11$ , including pairs in which one sign word is a proper prefix. The pair-code test checks that every output is a permutation of the correct finite alphabet and that comparisons agree with the input binary order.

These tests can detect a reversed pair orientation, a wrong terminal block, or a mistaken finite-tail rule. They cannot prove regularity arguments, transfinite stabilization, set/class separation, or the existence of a global isomorphism. Those depend on the mathematical proofs in the text.

## A.5 Source 08: source audit and reproducibility

Two mathematical source files were inspected. One is `SignSequence.lean`; the other is `SignSequenceCut.lean`. Both were read at the pinned ProveIt commit. The project’s README was used only for its stated organization and audit policy. No build was run, and no claim was imported merely because a research report’s title suggested it. The source files have blob hashes

|                              |                                                       |
|------------------------------|-------------------------------------------------------|
| <code>SignSequence</code>    | <code>e2c093860f29b0b9ea312d50099fc4aa89a76a99</code> |
| <code>SignSequenceCut</code> | <code>c5c35afd98a5ad293687367ee9fb0244f94cc91c</code> |

The Kanovei–Shelah preprint was inspected directly, including the page defining its index. The class-recursion references were consulted through the author’s research summaries. Classical book and journal references provide background attribution; no claim of an exhaustive literature or priority search is made. The prior continuum manuscript was identified in the user’s file library and used as a contextual predecessor, not as a formally certified dependency.

The package contains a self-contained L<sup>A</sup>T<sub>E</sub>X source with an embedded bibliography, the compiled PDF, a build script, the finite verification script and its output, and a README. No external figure or private font file is needed. Compile with a standard TeX Live installation using `latexmk -pdf surreal_well_orders.tex`, or run `pdflatex` sufficiently many times to resolve cross-references.

[merge] (3 October 2026.) The audit and reproducibility records of sources 13, 14, 15 and 17 follow; source 16’s is the last subsection of its status section and source 18’s is part of its status table (both printed with the ledgers). They describe the delivered packages, whose layout differs from this directory: the shipped names of every delivered file are in [appendix B](#), and none of the six manuscripts or their PDFs is shipped. Their checksum manifests (sources 13, 14, 16, 17) and source 13’s build logs are not shipped either. Source 15 ships no checksums; source 18 ships no code or data.

## A.6 Source 13: repository and literature audit

### A.6.1 Pinned source and scope of inspection

The current main branch was resolved through the connected GitHub interface to

`0ecd158fd163bc4aca0ee40ccf6479ca6cf5f2a8`

with commit timestamp 3 October 2026, 17:15:49 UTC. The working tree was not modified. The audit was targeted, not an exhaustive review of every proof in the repository or a rebuild of the Lean project.

The merged surreal report’s introduction, guide, selected dense-core and cylinder proofs, raw omitted-range and model sections, formalization plan, and research-question index were inspected. Retrieval targets included source ranges around 5000–5600, 5730–6205, and 6800–7120; these describe the targeted portions, not a claim that the entire 115-page report was independently certified. The real well-ordering report’s guide was inspected for provenance and conventions.

| Source                | Path or Git blob identity                                                                                              |
|-----------------------|------------------------------------------------------------------------------------------------------------------------|

The mathematical claims newly developed here were checked by reviewing their proofs and by finite tests of the code-level constructions. No independent referee report or machine verification is implied. The literature search was targeted to primary sources on the surreal continuum, class well-orders and recursion, higher-class foundations, and the Kanovei–Shelah index. It was not a complete priority search for every abstract order-theoretic lemma.

### A.6.2 Specific dependency choices

The fresh-value lemma uses an already constructed small-cut interface. The dense-core interpolation argument is written out rather than attributed only to a theorem name. The global product obstruction explicitly reuses the earlier report’s density and inverse-evaluator method. The cut and automorphism theorems do not require its singular-cardinal classification, and the central-word theorem does not require surreal arithmetic. Thus a later correction in a nonessential prior theorem would not automatically affect the main new proofs.

## A.7 Source 13: reproducibility and finite checks

The archive contains the standalone `article.tex`, its compiled PDF, a build script, a standard-library Python checker, its recorded JSON output, and a status note. No external image or private font file is required. The bibliography is internal to the TeX source.

The finite checks cover the following distinct mechanisms. First, they build well-order relations on finite alphabets and compare the common-predecessor formula with direct permutation lexicography. Second, they test convexity of every finite prefix cylinder and the uniqueness and coherence of crossing prefixes at all finite cut positions. Third, they test finite prefix completion. Fourth, they compare the central-word sign code with independent rational values of finite surreal sign sequences.

The test alphabets for the last group are  $-2, -1, -\frac{1}{2}, \frac{1}{2}, 1, 2$ , with all words of length at most three, including repeated-letter words. Finite signs are evaluated as dyadic rationals, not merely re-compared by a second copy of the same lexicographic function. The reserved-marker condition is also checked by exhibiting the collision that would result from admitting a trailing zero as a letter.

These tests do not establish class comprehension, ordinal-limit coherence, global choice, the back-and-forth theorem, or a transfinite birthday bound. They are reproducible checks of finite instances and independent representations, with the logical trust boundary stated explicitly.

```
# Run from the extracted archive directory.
python3 code/finite_checks.py --output data/finite_results.json
bash build.sh
```

The build script runs three LaTeX passes to settle cross-references and the table of contents. A PDF inspection record and checksums are included in the delivery’s status files.

## A.8 Source 14: finite diagnostics and reproducibility

The accompanying `verification.py` uses only Python’s standard library. It checks finite instances of the following kernels: relation-based common prefixes versus enumeration prefixes; convexity of prefix cylinders; the chain property of crossing prefixes at every finite cut; extension of partial injections on a finite support; preservation of all comparisons under support compression; finite self-delimiting sign and word codes; and pair-orientation coding. The exact tested ranges, case counts, and pass/fail results are written to `verification_results.json` by the delivered execution. The delivered run passed every diagnostic. Its principal counts are:

| Kernel                                             | Tested cases or comparisons |
|----------------------------------------------------|-----------------------------|
| Labelled common-prefix comparison                  | 15,018                      |
| Prefix cylinders / proper finite cuts              | 2,371 / 867                 |
| Finite partial injections                          | 15,126                      |
| Compressed candidates / retained comparisons       | 3,868 / 66,873              |
| Numerical sign-code pairs                          | 16,129                      |
| Outer word-code pairs, two termination conventions | 320,000                     |
| Pair-orientation comparisons                       | 21,844                      |

Finite alphabets have endpoints and adjacent labels, unlike the residual surreal alphabet. Therefore the finite crossing-prefix test checks the chain lemma, not the full boundary trichotomy. The buffer argument for infinite partial injections, cofinality at singular cardinals, Global Choice, and class-model absoluteness are not experimentally verified. Those assertions stand on their written proofs and remain appropriate subjects for independent mathematical and formal review.

To reproduce the package locally:

```
python3 verification.py
bash build.sh
```

The build script compiles the standalone source twice with `pdflatex`; the bibliography is internal, so no external database or network access is needed for compilation. Standard TeX packages named in the preamble must be installed. `SHA256SUMS.txt` records the delivered source, PDF, scripts, status files, and diagnostic output. The archive does not include fonts, repository clones, or LaTeX auxiliary files. The repository itself has not been modified.

## A.9 Source 14: source audit and bibliographic scope

The primary repository inputs were read through the GitHub connector at the pinned revision below. The targeted mathematical ranges were the opening status and abstract, the core/interpolation and binary-coding sections, the universe and formalization discussion, and the continuation questions. The actual Lean simplicity file was separately inspected. The metadata in the README distinguishes four source manuscripts from their merged report. We did not treat their statements as kernel-verified results or as established published literature.

External sources were used to check the Kanovei–Shelah indexing construction, the distinction between elementary comparison and class-valued recursion, and standard surreal background. The consulted version of the class-recursion paper is explicitly dated in the bibliography. No unresolved question quoted from it is asserted here to remain open as of the present date. The new arguments in this article are self-contained relative to the stated surreal set-cut theorem, GBC, and explicitly marked inherited set-spectrum results.

### A.10 Source 15: source provenance and reproducibility

The repository inputs were read through the GitHub connection at the pinned revision stated in [Section 4.8](#). The main paths are the surreal well-orders report, the real well-orderings report, and `Algebra/SurrealNumbers/Surreal/Foundations/SignSequence.lean`. The new results are deductions in this article, not changes committed to the repository. No claim of source-wide novelty follows from this targeted audit.

The primary literature was checked for the precise Kanovei–Shelah index, surreal order versus simplicity, global choice, class well-foundedness and ETR, and the standard interval-condensation mechanism. In particular the countable condensation studied by Brown and Suárez is related methodology, not the same as the model-relative set-interval condensation used here [34]. The final journal and arXiv versions of a source may have different pagination; theorem references specify the version where needed.

The accompanying `examples.py` regenerates the three-label table, checks the explicit restriction reversal and the Boolean restriction bound, and checks the finite predecessor-comparison formula. These calculations are reproducibility aids for finite examples only. They do not validate cardinal arithmetic, class comprehension, transfinite recursion, or the new proper-class theorems.

The source is a standalone L<sup>A</sup>T<sub>E</sub>X document with an internal bibliography and no external figures. Build it with

```
latexmk -pdf -interaction=nonstopmode -halt-on-error
surreal_lexicographic_orders.tex
```

The PDF was compiled and inspected for unresolved references, overflowing formulas, and page-layout defects. Mathematical review and layout review are separate from formal proof checking.

### A.11 Source 17: finite checks and reproducibility

The package contains `finite_checks.py`, which requires only the Python standard library. Its deterministic recorded run is in `finite_checks.json`. The run passed all of the following checks:

| Finite mechanism checked                                              | Instances |
|-----------------------------------------------------------------------|-----------|
| Predecessor-signature comparison against tuple lexicography           | 533,418   |
| Exact adjacency condition against consecutive finite permutations     | 266,272   |
| Convexity of prefix cylinders, carriers of size at most 7             | 16,072    |
| Uniqueness and coherence of straddlers at finite cut levels           | 852       |
| Finite partial-injection extension on its necessary support           | 15,126    |
| Prefix-free coefficient-code comparison                               | 961       |
| Variable-length word-code comparison (400 words, repetitions allowed) | 160,000   |

The empty carrier and empty word are included where appropriate. The coefficient tests use all sign sequences of length at most four. Word tests use an alphabet of seven sign sequences of length

at most two, and words of length at most three. Finite partial injections are tested on carriers of size at most six, including partial maps with fixed points.

These tests do not verify singular cardinals, limits of prefix chains, class comprehension, large-gap homogeneity, or the necessity of an infinite reserve. They are consistency checks on the finite mechanisms used by the proofs, not experimental evidence for an unproved theorem.

To reproduce the checks and build the PDF from a TeX Live installation, run the supplied `build.sh`. The bibliography is internal to the LaTeX source, so no external bibliography database is required. The ZIP includes a README and a research-status note, with SHA-256 checksums of its payload. It does not bundle fonts or claim to reproduce the separate source report.

## A.12 Source 31: delivery and reproducibility

[merge] (3 October 2026.) Source 31 was delivered as `global_choice_surreal_coding.zip` (arrival `7c0f2d9f9`) with three files: the manuscript `global_choice_surreal_coding.tex` (1,547 lines, 70,676 bytes), its 21-page PDF (400,246 bytes) and `README.txt` (2,590 bytes). None is shipped; the placement `23adb85f9` staged nothing, and all three are recoverable with `git show 7c0f2d9f9:docs/incoming/global_choice_surreal_coding.zip`. Source 31 ships no program and no data, by design (section XV.12.3). Its README lists the main results, builds the article with `latexmk -pdf -interaction=nonstopmode -halt-on-error global_choice_surreal_coding.tex` (no images, bibliography database, download or shell escape), says that the supplied PDF was built with pdfTeX, checked for unresolved references and layout warnings and visually reviewed, records the inspected commit and path of this report, and states that “No repository files were modified”. Rebuilt from a fresh extraction with MiKTeX on 3 October 2026, the delivered manuscript gives 21 pages with no warning. Part XV is that manuscript with the changes listed in section 1.10.

## A.13 Sources 32–35: delivery and reproducibility

[merge] (4 October 2026.) The four archives (arrival `e3839ad2c`) were placed in `111c38012`. Staged, byte-identical to the delivery (13 files, 39,802 bytes, LF only): source 32’s `code/32-ceilings-Makefile`, `code/32-ceilings-finite_checks.py`, `data/32-ceilings-finite_checks.json` and `32-ceilings-PROOF_STATUS.md`; source 33’s `code/33-heights-build.sh`, `code/33-heights-finite_checks.py`, `data/33-heights-verification_results.json`, `data/33-heights-BUILD_REPORT.json`, `33-heights-PROOF_STATUS.md` and `33-heights-SOURCE_AUDIT.md`; source 34’s `34-choicefree-PROOF_STATUS.txt`; source 35’s `code/35-completion-finite_notation_check.s.py` and `data/35-completion-finite_notation_results.json`. Not shipped (they survive in the arrival commit): the four manuscripts and PDFs, the four delivery READMEs, source 32’s `SHA256SUMS` (7 of 7 hashes verified at placement) and source 33’s `MANIFEST.sha256` (9 of 9). Part XVI is the text of the manuscripts.

*The checks, rerun for this write on copies* (Python 3.14): source 32’s script with `-output` passes 689,808 assertions (seed 20261004); source 33’s passes 155,530; source 35’s passes 1,825 splitting, 21,993 flattening and 2,700 comparison cases (30 terms, bases 5, 7 and 11). Each output equals the shipped record as JSON and byte for byte up to line endings (Windows writes CRLF). All three check finite coding conventions only, as each says.

*Delivery names.* The shipped build files name unshipped sources: `code/32-ceilings-Makefile` compiles `beyond_ord.tex` and writes `finite_checks.json`; `code/33-heights-build.sh` compiles `article.tex` into `.build/` and copies `article.pdf`; both build nothing here. Source 35’s script writes `finite_notation_results.json` beside itself (in `code/`), and source 32’s program defaults to `finite_checks.json` in the working directory; source 32’s status file names `finite_checks.json`,

source 33's names `article.tex` and its “generated package manifest”; the printed appendices name the delivery files and are annotated in Section XVI.11. The archives can be recovered with `git show e3839ad2c:docs/incoming/<archive>.zip`. The README gives rerun commands that write only to a copy.

### A.14 Source 36: delivery and reproducibility

[merge] (4 October 2026.) The archive `Beyond_Ord_Research_Package.zip` (715,002 bytes, arrival `d7cf7d554`) holds nine files under `Beyond_Ord/`. The placement `6571ee1af` staged five of them, byte-identical to the delivery (24,944 bytes, LF only): `36-horizons-SOURCE_AUDIT.txt` (from `SOURCE_AUDIT.txt`), `code/36-horizons-build.sh` (`build.sh`), `code/36-horizons-notation_demo.py` (`code/notation_demo.py`), `data/36-horizons-verification.json` (`code/verification.json`) and `data/36-horizons-DOCUMENT_CHECKS.json` (`DOCUMENT_CHECKS.json`). Not shipped (they survive in the arrival commit): the manuscript `beyond_ord.tex`, its 40-page PDF, the delivery `README.txt` and the demonstrator's `code/README.md`, whose scope and limitations are reproduced in this report's README. Part XVII is the text of the manuscript. The four SHA-256 values in `DOCUMENT_CHECKS.json` (manuscript, PDF, demonstrator, report) match the delivered files.

*The demonstrator, rerun for this write on a copy* (Python 3.14.4, 4 October 2026, with `PYTHONUTF8=1`): `-examples-only` prints the examples, and `-report` passes with 994 distinct terms, 493,521 unordered and 2,000 ordered comparisons against the independent base-7 evaluator, 994 reflexive checks, 16 malformed inputs rejected and 8 tower boundaries, as recorded; the regenerated report equals `data/36-horizons-verification.json` except for `python_version` (3.14.4 against the delivered 3.12.14) and its CRLF line endings. Without `PYTHONUTF8=1` the program stops with `UnicodeEncodeError` under the Windows code page, and the report run leaves a 0-byte file; this is disclosed, not patched.

*Delivery names.* `code/36-horizons-build.sh` compiles `beyond_ord.tex`, which is not shipped, and builds nothing here. The source audit and `DOCUMENT_CHECKS.json` name `beyond_ord.tex`, `beyond_ord.pdf` and `code/...` delivery paths; Section XVII.10 is annotated with the shipped names. The demonstrator's documented command `-report code/verification.json` overwrites its argument; the README gives a rerun that writes only to a copy. The archive can be recovered with `git show d7cf7d554:docs/incoming/Beyond_Ord_Research_Package.zip`.

## B The finite checks as shipped

[merge] All four programs use only the Python standard library and check finite instances; they verify no transfinite, class-theoretic or cardinal statement. Rerun on 2 October 2026 on copies, with Python 3.14.4 on Windows, each reproduced its recorded output exactly apart from line endings: on Windows all four write CRLF, while the records have LF, so compare with `diff -strip-trailing-cr`.

| Source | Program and record                                                                                           | Checks                                                                                                                                                    | Output                    |
|--------|--------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------|
| 11     | <code>code/11-raw-orders-finite_checks.py</code> ; <code>data/11-raw-orders-finite_checks_results.txt</code> | 465 sign-code pairs; 79,800 word-code pairs; predecessor comparison and adjacency on all 266,272 pairs of permutations of at most 6 points (867 adjacent) | prints to standard output |

| Source                                                                                 | Program and record                                                                            | Checks                                                                                                                                                                                                                                                                  | Output                                                                                                                                                            |
|----------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 12                                                                                     | <code>code/12-singular-finite_checks.py; data/12-singular-finite_checks.json</code>           | 180,905 cases: sign code, pair orientation, common prefix and adjacency, larger adjacent pairs, row scheduler                                                                                                                                                           | writes the file named by <code>-output</code>                                                                                                                     |
| 09                                                                                     | <code>code/09-core-finite_checks.py; data/09-core-finite_checks.json</code>                   | 164,560 assertions, 1,101 separator families, seed 20261002: pair switch, prefix completion, forced separator, bounded reflection, diagonal switch                                                                                                                      | default <code>-output</code> is <code>data/finite_checks.json</code> beside <code>code/</code> , an unprefixed new file; always pass <code>-output</code>         |
| 08                                                                                     | <code>code/08-skeleton-verify_finite.py; data/08-skeleton-verification_results.json</code>    | 5,906 consecutive and 7,432 ordered pairs of permutations; 21,845 pair-code comparisons; 16,129 sign-code comparisons on 127 words                                                                                                                                      | writes <code>verification_results.json</code> beside itself                                                                                                       |
| <i>[merge] Batch 81 (sources 13–17; source 18 ships no code), added 3 October 2026</i> |                                                                                               |                                                                                                                                                                                                                                                                         |                                                                                                                                                                   |
| 13                                                                                     | <code>code/13-products-finite_checks.py; data/13-products-finite_results.json</code>          | 533,417 relation-versus-lexicographic pairs of permutations of at most 6 points; 2,371 convex cylinders and prefix completions; 5,885 cut-level uniqueness checks; 867 successor-failure partitions; 2,044 transitivity triples; 67,081 central-word pairs on 259 words | default <code>-output</code> is <code>data/finite_results.json</code> relative to the working directory, an unprefixed new file; always pass <code>-output</code> |

Run them on copies, never in the report directory. From the report directory, with an empty scratch directory `$$`:

```
cp code/08-skeleton-verify_finite.py "$S/"
python "$S/08-skeleton-verify_finite.py"          # writes $$/verification_results.json
python code/09-core-finite_checks.py --output "$S/09.json"
python code/11-raw-orders-finite_checks.py > "$S/11.txt"
python code/12-singular-finite_checks.py --output "$S/12.json"
```

and compare with the four records in `data/`. The delivered build scripts build nothing in this layout: `code/08-skeleton-build.sh` runs `verify_finite.py` and compiles `surreal_well_orders.tex` beside itself, `code/09-core-build.sh` compiles an `article.tex` in `code/`, and `code/12-singular-build.sh` changes into `code/` and then calls `code/finite_checks.py`. They are kept as delivered.

[merge] (3 October 2026, batch 81.) The five programs of sources 13–17 also use only the Python standard library and check finite instances only. Rerun on 3 October 2026 on copies, with Python 3.14.4 on Windows, each reproduced its recorded output apart from line endings and, for sources 13 and 14, the recorded `python_version` (3.13.5). From the report directory, with an empty scratch directory `$$`:

```
python code/13-products-finite_checks.py --output "$S/13.json"
cp code/14-trichotomy-verification.py "$S/"
python "$S/14-trichotomy-verification.py"          # writes $$/verification_results.json
python code/15-blocks-examples.py > "$S/15.txt"
python code/16-strata-finite_checks.py --output "$S/16.json"
python code/17-gaps-finite_checks.py --output "$S/17.json"
```

and compare with the records in `data/` using `diff -strip-trailing-cr`. The delivered build scripts build nothing in this layout: `code/13-products-build.sh` and `code/14-trichotomy-build.sh` compile an `article.tex` in `code/` (the first writes `build-pass-1.log` there before failing), `code/15-blocks-build.sh` and `code/18-shuffle-build.sh` run `latexmk` on the unshipped manuscripts `surreal_lexicographic_orders.tex` and `surreal_lexicographic_orders_further_study.tex`, and `code/17-gaps-build.sh` first runs `python3 finite_checks.py`, absent under that name. They are kept as delivered.

*Delivery names.* The reproducibility records printed in [appendix A](#) and the ledgers name the delivered files. Source 13's `code/finite_checks.py`, `data/finite_results.json`, `data/pdf_inspection.json`, `build.sh` and `RESEARCH_STATUS.md` are `code/13-products-finite_checks.py`, `data/13-products-finite_results.json`, `data/13-products-pdf_inspection.json` (it records the layout check of source 13's 33-page PDF, which is not shipped), `code/13-products-build.sh` and `13-products-RESEARCH_STATUS.md`; source 14's `verification.py`, `verification_results.json`, `build.sh` and `RESEARCH_STATUS.md` are `code/14-trichotomy-verification.py`, `data/14-trichotomy-verification_results.json`, `code/14-trichotomy-build.sh` and `14-trichotomy-RESEARCH_STATUS.md`; source 15's `examples.py`, `finite_examples.txt` and `build.sh` are `code/15-blocks-examples.py`, `data/15-blocks-finite_examples.txt` and `code/15-blocks-build.sh`; source 16's `finite_checks.py`, `finite_check_results.json` and `SOURCE_STATUS.txt` are `code/16-strata-finite_checks.py`, `data/16-strata-finite_check_results.json` and `16-strata-SOURCE_STATUS.txt`; source 17's `finite_checks.py`, `finite_checks.json`, `build.sh` and `research_status.md` are `code/17-gaps-finite_checks.py`, `data/17-gaps-finite_checks.json`, `code/17-gaps-build.sh` and `17-gaps-research_status.md`; source 18's `build.sh` is `code/18-shuffle-build.sh`. The six manuscripts, their PDFs, their delivery READMEs and the checksum manifests are not shipped; they remain in the arrival commits ([section 1.8](#)).

[merge] (3 October 2026, batch 89.) Source 31 ships no program ([appendix A.12](#)).

[merge] (4 October 2026, batch 97.) Source 36's natural-coefficient demonstrator is `code/36-horizons-notation_demo.py`, with its recorded report `data/36-horizons-verification.json`; its scope and the rerun for this write are in Section XVII.10 and [appendix A.14](#).

## C The other sources' title pages and abstracts

[merge] The results these summaries announce are printed in the body; the summaries are kept for the record.

### Source 12

**Title-page summary. Main distinction.** An arbitrary class well-order of **No** need not have order type  $\text{Ord}$ . Nevertheless, two such well-orders have an *elementarily definable largest common labelled initial segment*, possibly a proper class. This supplies a lexicographic comparison in GBC without invoking general class well-order comparability or ETR.

**Principal quantitative result.** Put  $\mathbf{No}_{<\kappa} = \{s : \alpha \rightarrow \{-, +\} : \alpha < \kappa\}$  and  $\mu = |\mathbf{No}_{<\kappa}| = 2^{<\kappa}$ , for an infinite initial cardinal  $\kappa$ . The minimal-length permutation order satisfies

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \simeq_e \begin{cases} \mathbb{B}_{\kappa \cdot \kappa}, & \mu = \kappa \text{ and } \text{cf } \kappa < \kappa, \\ \mathbb{B}_\mu, & \text{otherwise,} \end{cases}$$

where  $\mathbb{B}_\gamma = (2^\gamma, <_{\text{lex}})$  and  $\simeq_e$  means mutual order-embeddability, not isomorphism.

**Status.** This is an AI-assisted, unrefereed research manuscript. Proofs are supplied for the stated results; historical priority is not claimed. The accompanying exact finite tests do not verify the transfinite arguments. No new Lean formalization is claimed.

**Abstract.** We study the lexicographic order of well-orderings of the surreal numbers, carefully distinguishing bounded sets of surreals, set-like global well-orders, and arbitrary global class well-orders. For the full class problem, ordinal-indexed enumerations are insufficient. We construct the largest common labelled initial segment of two well-orders directly from their relations, prove that comparison of their next elements defines a linear order, and show that this construction needs only elementary class comprehension once the well-orders exist. Over GB with set choice, the existence of any class well-order of the surreals is equivalent to global choice. The collection of all these well-orders is not itself an ordinary class of GBC or Kelley–Morse theory; a diagonal theorem rules out any uniform exhaustive coding by a class of sets.

For set-like global well-orders we prove density, interpolation for set-indexed cuts, local universality for class linear orders, and mutual embeddability with the lexicographic comparison of binary classes on  $\text{Ord}$ . For unrestricted global well-orders we classify adjacent pairs: they arise precisely from finite residual permutations after a common, necessarily proper-class, prefix. At a birthday cutoff  $\kappa$ , we obtain an exact regular/singular dichotomy for the binary coding rank of minimal-length enumerations. We also establish the exact ordinal and binary-cube embedding spectra for the full set-sized order. Finally, a full-class model based on an inaccessible rank explains exactly how the bounded and global theories fit together, and provides a rigorous example in which the full order and the set-like order have the same cardinality and ordinal spectrum but different coding ranks. Explicit proof-assistant interfaces and further research questions are included.

## Source 09

**Abstract.** The phrase “the lexicographic order of all well-orders of the surreal numbers” has several mathematically different interpretations. We develop three: exhaustive enumerations of a fixed set of surreals; all set-length injective surreal words; and class bijections from the ordinals onto the surreal numbers, representing set-like global well-orders. For an infinite set  $X$  of cardinality  $\kappa$ , we give a self-contained proof that its lexicographic well-ordering space has cardinality  $2^\kappa$ , contains every linear order of size at most  $\kappa$ , and contains an ordinal precisely when that ordinal is below  $\kappa^+$ .

For the global problem, we work in Gödel–Bernays set theory with global choice and do not pretend that a collection of proper classes is itself an ordinary class. Fix a global enumeration  $b$ . Its eventually-equal perturbations admit canonical set codes. We prove that their lexicographic order is isomorphic to the surreal line, meets every set-prefix cylinder, and interpolates every uniformly set-indexed separated pair of families of arbitrary global enumerations. Thus every class linear order embeds into this genuine class core. We also prove bounded reflection for set-indexed families, construct an explicit unfilled  $(\text{Ord}, \text{Ord})$ -configuration, and diagonalize against every uniform class-indexed list of all global enumerations.

A strongly inaccessible truncation gives a fully set-sized model of the size distinction: the core has cardinality  $\kappa$ , whereas all length  $\kappa$  enumerations have cardinality  $2^\kappa$ . The article includes foundational and Lean formalization plans, a repository audit, finite verification code, and a focused research agenda.

**Title-page status.** Status: AI-assisted research manuscript; complete written arguments are provided for the stated results. Not peer-reviewed or Lean-verified. Classical ingredients and repository results are distinguished from the constructions developed here. No claim of historical priority is made.

## Source 08

**Abstract.** There is no single unqualified object called “the lexicographic order of all well-orders of the surreal numbers.” We distinguish well-orderings of a fixed set of surreals, well-orderings of varying set-sized subsets, set-like well-orderings of the whole surreal class, and arbitrary class well-orderings. For an infinite ordered set  $X$  of cardinality  $\kappa$ , the exhaustive-enumeration order  $\mathcal{W}(X)$  has size  $2^\kappa$ , contains every linear order of size at most  $\kappa$ , and contains an ordinal  $\beta$  exactly when  $\beta < \kappa^+$ . Its adjacent pairs arise precisely from finite permutation tails.

For the whole surreal class, work in Gödel–Bernays set theory with Global Choice. The numerical first-disagreement comparison of class bijections  $\text{Ord} \rightarrow \mathbf{No}$  is meaningful without treating classes as elements of classes. Fix one such bijection  $b$ . We prove that every set-sized separated family of global enumerations has a strict separator obtained from  $b$  by a permutation of set support. The class of canonical codes for these perturbations is therefore order-isomorphic to  $\mathbf{No}$ . It is a dense, set-cut-realizing skeleton inside the much larger virtual enumeration order, and every class linear order embeds into it. The full virtual order is equimorphic with the lexicographic order of class binary sequences, but admits no class-uniform exhaustive parametrization. We supply proofs, cutoff versions, counterexamples to tempting identifications, a universe-sensitive Lean implementation plan tied to inspected ProveIt sources, and a research agenda.

### Status box.

**Status and scope.** The results below are mathematical derivations with explicit proofs, not claims of historical priority. The manuscript has not been independently refereed, and its new results have not been checked by a proof assistant. Repository declarations are identified separately from proposed extensions. The accompanying executable checks cover finite coding and adjacency examples only. All uses of “class” are relative to the stated foundational model.

[merge] (3 October 2026.) The title pages of sources 13–18 follow, with their abstracts and status statements; layout commands are omitted.

## Source 13

**Title page.** “Further research report”. *Lexicographic Orders of Surreal Well-Orderings: Cut reconstruction, asymmetric products, prefix non-rigidity, and size-safe foundations* (PDF metadata: “Further Structure”). Research manuscript prepared for Vladimir Reshetnikov, 3 October 2026.

**Abstract.** We further investigate the lexicographic comparison of well-orderings of the surreal numbers, separating set-sized alphabets, set-length words, set-like global enumerations, unrestricted class well-orders, and code-dependent alternatives. The central new result is an exact prefix-cylinder criterion for a normalized class cut of a surreal-sized dense core to be represented by an injective ordinal-class word. Exhaustive words are characterized by an additional label-coverage condition. Cuts that fail the criterion have a first failure of one of two precisely described kinds: a next-label cut or a limit-prefix boundary.

We prove an asymmetric product phenomenon. The global enumeration order absorbs a surreal left factor, and more generally admits every ordinary class-indexed lexicographic sum of copies of itself. Its two-point split, however, does not embed back in the full inaccessible-universe interpretation, nor by a definable uniform transformation in Kelley–Morse theory with global choice. Externally countable models give the opposite answer for unrestricted external maps. A finite-block recoding automorphism shows that the pure linear order does not recover its prefix

cylinders. Finally, replacing end-first dictionary comparison by a central termination convention on the nonzero alphabet makes both arbitrary and injective set-length word orders isomorphic to the surreal line.

The proofs specify their logical size levels. An implementation plan uses the repository’s actual universe-indexed sign-sequence and small-cut interfaces, without claiming a new Lean formalization.

**Title-page status. Research status.** AI-assisted, unrefereed mathematical manuscript. The proofs are presented for scrutiny; historical priority and kernel verification are not claimed. This is a follow-up to the repository’s merged report, not a replacement or a certification of all its results. The inspected repository snapshot is pinned in [Appendix A.6](#). Finite checks accompany the article, but do not establish transfinite or class-theoretic theorems.

## Source 14

**Title page.** “Research continuation”. *Lexicographic Well-Orders of the Surreals II: Cut classification, support thresholds, and class-model absoluteness*. Prepared for Vladimir Reshetnikov, 3 October 2026.

**Abstract.** The earlier ProveIt reports identify a set-coded dense skeleton of the lexicographic order of global surreal enumerations, but leave open which cuts of that skeleton come from exhaustive enumerations. We answer the prefix-structured version of that question. Every proper normalized class cut of the skeleton has exactly one of three forms: an edge of a set-prefix cylinder, a nonprincipal numerical gap after a set prefix, or a coherent injective branch of length  $\text{Ord}$ . The last form is realized by a global well-order of set-like type exactly when its branch covers every surreal. Reconstruction is elementary; a separate orbit theorem shows that bare-order automorphisms can destroy exhaustive representability.

This yields an absoluteness theorem: enlarging the class part of a model while retaining its sets and a fixed baseline enumeration cannot newly realize an old skeleton cut by a global enumeration. New enumerations have genuinely new trace cuts. For unrestricted labelled class well-orders, the trace map forgets exactly the tail after the canonical  $\text{Ord}$ -long initial segment; its fibers are described explicitly.

A separate support analysis gives a sharp hierarchy. If  $\kappa$  is an infinite set cardinal, the permutations of a baseline with support of cardinality  $< \kappa$  form an  $\eta_{\text{cf } \kappa}$ -order, but not an  $\eta_{(\text{cf } \kappa)^+}$ -order. A separated pair of  $\text{cf } \kappa$ -long families forces at least  $\kappa$  moved coordinates, and this support cost is attained in the full skeleton. Thus universality for ordinary class linear orders can coexist with sharply limited saturation.

We distinguish fixed carriers, variable set domains, increasing subclasses, global set-like orders, unrestricted class relations, relation-code lexicography, and order-type quotients. The exposition includes proofs, exact quantifier conventions, a repository audit, universe-relative and Lean formalization plans, finite regression tests, and a focused research agenda.

**Title-page status. Research status.** The new results below are proved in this manuscript, not machine-verified. They are unrefereed and no claim of historical priority is made. The cut classification is relative to the named prefix cylinders; it is not a classification in the language of bare linear order alone. The repository is unchanged.

## Source 15

**Title page.** *Lexicographic Orders of Surreal Well-Orders: Interpretations, canonical blocks, represented cuts, and fixed-type spectra.* “A continuation of the ProveIt research report”. Research article prepared for Vladimir Reshetnikov, 3 October 2026.

**Abstract.** There is no single unqualified object called the lexicographic order of all well-orders of the surreal numbers. The carrier, representation, comparison alphabet, indexing order, prefix convention, and foundational size level all affect the answer. We give a systematic account of the principal interpretations and develop three extensions of the existing ProveIt report. First, the relation that a closed interval in a class well-order is a set produces its entire canonical block decomposition by an elementary formula; every class well-order can occur as the block-index order. Explicit ordinal polynomials realize arbitrarily long class-indexed condensation histories. Second, a cut of the bounded-support surreal core is represented by an injective ordinal-class word exactly when every set-length level has a cylinder meeting both sides. First failure gives an exhaustive description of terminal cuts, including repeated-label obstructions and limit-prefix boundaries. The lower-core-cut map forgets exactly the residual well-order after the first proper block. Third, for birthday cutoffs we extend the minimal-slice dichotomy to enumeration types consisting of any admissible set number of full cardinal blocks followed by a finite tail, with exact binary coding lengths. Exact local characters and the saturation threshold are computed for every cardinal birthday cutoff. Complete proofs, counterexamples, foundational assumptions, source provenance, and a prioritized research program are included.

**Title-page status. Status.** This is an AI-assisted, unrefereed research exposition. “Extension” means a deduction beyond the audited repository report, not a claim of historical priority. Its new theorems have written proofs and independent mathematical review within this task. They have not been checked by Lean or another proof assistant. Finite calculations check only the explicit finite examples.

Repository revision inspected: 0ecd158fd163bc4aca0ee40ccf6479ca6cf5f2a8.

## Source 16

**Title page.** “Order theory and foundations”. *Lexicographic Orders of Surreal Well-Orders: Cuts, Canonical Blocks, and the Limits of Set-Sized Coding.* “A further study of the ProveIt research program”. Research article prepared for Vladimir Reshetnikov, 3 October 2026.

**Abstract.** The phrase “the lexicographic ordering of all well-orders of the surreal numbers” describes several substantially different objects. We separate well-orders on a fixed set, ordinal-length words, numerically increasing subsets, set-like global well-orders, arbitrary class well-orders, and relation-table encodings. Building on the ProveIt report, we establish several extensions. For every infinite alphabet we compute the density and cellularity of every fixed enumeration stratum, including a transition at three terminal positions, and prove that every stratum fails conditional Dedekind completeness. At regular saturated stages we determine the complete cofinality spectrum of unfilled cuts. For global enumerations we give an exact prefix-cylinder criterion for the cuts represented by injective ordinal-class branches, with an additional criterion for exhaustiveness. Every failure has a first coordinate or limit-prefix obstruction. For an arbitrary class well-order, the elementary relation “the interval between these points is a set” simultaneously extracts all its canonical ordinal-class blocks, without elementary transfinite recursion. We also classify alternative

termination conventions, sharpen a comprehension bound for uniform nonembedding, and give a formalization plan that distinguishes smallness, Lean universes, and internal class semantics. All new results are presented with ordinary mathematical proofs; no claim of historical priority or machine-checked verification is made.

**Title-page status. Repository snapshot.** 491ed8411cccf7bd57916eb7666bbba762e92f96.

The source audit is targeted. The article is independent of later changes to the repository, and its new theorems are not additions to the Lean library.

## Source 17

**Title page.** *Lexicographic Well-Orders of the Surreal Numbers, II: Exact cut spectra, branch recognition, optimal support reserves, and automorphism-extension obstructions.* Research manuscript prepared for Vladimir Reshetnikov, 3 October 2026.

**Abstract.** We continue the ProveIt report on lexicographic well-orders of surreal numbers, separating set-sized enumeration spaces, set-length words, set-like global well-orders, unrestricted class well-orders, and relation-code orders. For every infinite cardinal  $\kappa$ , put  $X = \mathbf{No}_{<\kappa}$ ,  $\mu = 2^{<\kappa}$ ,  $r = \text{cf } \kappa$ , and  $q = \text{cf } \mu$ . For the minimal-length enumeration order  $P = \mathcal{W}_\mu(X)$  we prove that every point has two-sided character  $(q, q)$ , that  $\text{cf } P = \text{ci } P = r$ , and that density, weight, and cellularity are  $\mu^{<\mu}$ . Its nonprincipal cut-character spectrum is exactly

$$\{(r, r), (q, q)\} \cup \{(\theta, r), (r, \theta) : \theta \in \text{Reg}, \theta < \mu\}.$$

Here  $\text{Reg}$  denotes the infinite regular cardinals. These statements require neither regularity of  $\kappa$  nor  $2^{<\kappa} = \kappa$ . We also establish an exact saturation threshold and a fusion theorem for dense open sets.

In *GBC*, we give a necessary-and-sufficient cylinder criterion for a class cut of a bounded-support surreal core to represent an injective Ord-word; a separate coverage condition characterizes exhaustive words. The reconstruction is elementary and needs no ETR. This yields an exact criterion for extending core automorphisms to the full global enumeration order and an obstruction: some core automorphisms do not extend. Proper extensions of the available classes necessarily add new represented cuts while leaving the set-coded core unchanged. A cardinal deficiency formula gives the optimal number of additional moved positions needed to extend a set partial injection to a supported permutation. We also identify maximal finite adjacency components in the unrestricted order and show that their quotient is dense. All higher-order statements are formulated without a same-level class of classes.

**Title-page status. Status.** The new assertions have ordinary mathematical proofs in this manuscript. They are not claimed to be historically first, peer-reviewed, or Lean-verified. The repository was read at the pinned revision stated in [Section 4.10](#); it was not modified or built. Finite checks supplied with this article test finite mechanisms, not the transfinite theorems. The remaining questions are explicitly distinguished from the results proved here.

## Source 18

**Title page.** *Lexicographic Well-Orders of the Surreal Numbers: Cuts, canonical class blocks, and changes of interpretation.* Research article prepared for Vladimir Reshetnikov, 3 October 2026.

**Abstract.** The phrase “the lexicographic ordering of all well-orders of surreal numbers” describes several different objects. We give a common framework for well-orders of fixed sets, fixed enumeration types, set-length words, numerically increasing words, ordinal-indexed global enumerations, and arbitrary class well-orders. We retain the repository’s elementary comparison by common labelled prefixes and develop its unresolved topological and foundational questions.

For  $X = \mathbf{No}_{<\kappa}$  and  $\mu = 2^{<\kappa}$  we compute the density, cellularity, point characters, saturation threshold, and complete Dedekind-gap character spectrum, including exact multiplicities, of the minimal permutation order  $\mathcal{W}_\mu(X)$ . A third terminal position causes its density and cellularity to reach  $2^\mu$ . For arbitrary class well-orders, an elementary set-interval equivalence yields a canonical decomposition into Ord blocks and a final set ordinal, without ETR. The quotient can be isomorphic to the original order. An exact prefix criterion recognizes which class cuts of a dense core are represented by global well-orders; a repeated-label cut gives an explicit obstruction. We also classify the external full lexicographic order of every countable  $\omega$ -standard GBC model as a dense shuffle of finite chains of factorial sizes, and show that its pure order does not define the set-like fragment. Finally, termination conventions distinguish word orders isomorphic to  $\mathbf{No}$  from orders with limit-prefix obstructions and even adjacent pairs.

All new claims are supplied with conventional proofs. Their status is relative to a pinned repository snapshot, without a claim of literature priority or machine verification. Explicit size boundaries and a staged formalization plan accompany a revised research agenda.

**Title-page status. Repository basis.** <https://github.com/VladimirReshetnikov/ProveIt> Snapshot: 83befe707f2840c2b53e0606701d8a2b28598e47. This is an AI-assisted research manuscript with mathematical proof review; it is not a refereed paper or a Lean certificate.

## Sources 19–30

[merge] The title pages and abstracts of the twelve batch-83 sources, with the status statements on their title pages. The results they announce are printed in Parts X–XIV; the summaries are kept for the record, with this report’s notation (section 1.3.2). Each title page names Vladimir Reshetnikov as the person the manuscript was prepared for and is dated 3 October 2026.

**Source 19.** *Lexicographic Orders of Surreal Well-Orders: Residual spectra, decorated completions, and model invariants.*

There is no single object called the lexicographic order of all well-orders of the surreal numbers. The answer changes with the carrier, enumeration type, termination rule, coding convention, and foundational universe. We give a common framework for the principal interpretations and continue the repository’s analysis beyond its set-sized spectra, canonical class blocks, and dense set-like core.

The main developments concern infinite residual tails, explicit completion codes, and the structure visible in an external model. We determine the embedded binary-cube spectrum for every fixed enumeration type, and the least coding length whenever two explicit ordinal bounds coincide. A cylinder-fusion argument reduces long fixed-type embeddings to residual alphabets. We describe the Dedekind completion of the global order by retaining the entire residual well-order fiber over each core cut, and obtain an exact automorphism-extension criterion. For general residual alphabets, at most two initial ordinal words can have the same trace, and an exact greedy-tail criterion detects this ambiguity; an equivalent numerical criterion uses deletion of a set. For countable models, nonstandard finite tails produce a second, exactly determined shuffle order; nevertheless the pure orders arising from all externally set-sized models have the same first-order theory. We also classify

all monotone restriction maps and give a canonical bounded completion description, including the topology at the first infinite birthday cutoff.

The proofs separate ordinary set recursion from elementary transfinite recursion with class-valued stages, and distinguish admitted classes from external subsets. A practical formalization plan and a revised research agenda record both the results obtained and the remaining problems.

**Source 20.** *Lexicographic Orders of Surreal Well-Orders: Coherent Limits, Nonextendible Symmetries, and Countable Models.*

The phrase “the lexicographic ordering of all well-orders of the surreal numbers” combines several different mathematical objects. We separate fixed set carriers, variable domains, ordinal enumeration strata, numerical well-ordered subclasses, set-like global enumerations, arbitrary class well-orders, and characteristic-relation codes. A common toolkit makes their size boundaries and comparison rules explicit.

Building on the ProveIt investigation and its recent continuations, we develop further results in five directions. Restriction-coherent birthday orders glue to class well-orders; their native lexicographic comparisons stabilize despite nonmonotone restriction maps, and minimum local types on a club of birthday cutoffs detect set-likeness. Automorphisms of the surreal-sized bounded-support core can destroy representability of cuts, even while fixing any prescribed set of core points. A local coding dichotomy identifies exactly when intervals of the full order admit uniform set or class codes. Iterated condensation has a termination bound under an explicitly stated recursion principle. Finally, the full order in a countable model with nonstandard natural numbers has a universal shuffle description involving both finite factorial chains and one additional infinite interval type. The two countable orders are elementarily equivalent and their common pure-order theory is decidable. A countable-alphabet example connects the theory with Baire space and Dedekind completion.

The article supplies conventional proofs, counterexamples, a theorem dependency ledger, and a revised research agenda. The results are research claims with internal mathematical review, not machine-checked theorems or claims of priority in the literature.

**Repository basis.** <https://github.com/VladimirReshetnikov/ProveIt>; pinned revision d5bd4a67b41b89688a079997574a94bcd855bb83. The repository was read through its GitHub interface. This is an independent AI-assisted continuation, not a modification of the repository.

**Source 21.** *Lexicographic Orders of Surreal Well-Orders: Further Structure, Automorphism Obstructions, and Model Dependence.*

There is no single unqualified object called the lexicographic order of all well-orders of the surreal numbers. A well-order of a fixed set of surreals, an ordinal-length injective word, a numerically well-ordered subset, a set-like global enumeration, and an arbitrary class well-order live at different logical levels and have different order-theoretic properties. We organize these interpretations and continue the corresponding ProveIt research program with explicit proofs and a careful size discipline.

The principal further result concerns automorphisms. A fixed global enumeration has an ordinary class of bounded-support modifications, order-isomorphic to the surreal line. Some order automorphisms of this dense core cannot extend even to order embeddings from the set-like enumeration space into the space of all class well-orders. They can move the cut of an exhaustive enumeration to a cut represented by no class well-order at all. A weaker obstruction moves an

exhaustive cut to the cut of an injective branch that omits labels. Within the set-like space, we characterize extendable automorphisms exactly by preservation of exhaustive represented cuts.

Several complementary results make the distinction concrete. For a countable dense alphabet, the minimum-length permutation order is homeomorphic to Baire space, every open interval is isomorphic to the whole order, and finite increasing partial maps extend to automorphisms; its prefix cylinders are nevertheless not intrinsic to its pure order. Its Dedekind completion is the real line, with continuum many omitted cuts, so it is not order-isomorphic to the irrational numbers. For a general set alphabet we identify the convex fibers over its first cardinality-many coordinates and compute the closure of the minimum-length stratum. We also treat noncardinal birthday cutoffs, coherent embeddings within a fixed cardinality, intrinsic finite permutation blocks, and the distinct external classifications arising from countable standard and nonstandard models.

The foundational discussion separates elementary class comprehension, ordinary set-valued recursion, elementary transfinite recursion with class-valued slices, higher-order collections, and universe-relative formalizations. A final research agenda records exactly what has been settled here and what still needs stronger classification or verification.

**Proof and provenance status.** This is an AI-assisted mathematical research manuscript with written proofs. Its principal arguments received independent internal proof checks during preparation; that is neither refereeing nor proof-assistant verification. No new Lean theorem is claimed. The ProveIt source is pinned to commit `109aaca1505c12d70ae169bdc2011f40bd476f7d`, observed on 3 October 2026. Results called extensions are extensions developed and proved in this manuscript, not claims of historical priority. Classical background and results already in the repository are identified explicitly.

**Source 22.** *Lexicographic Orders of Surreal Well-Orderings: Residual geometry, the finite-tail transition, unranked cylinders, and reconstruction of class realizations.*

The phrase “all well-orders of surreal numbers” ranges from ordinary sets of labelled enumerations to predicates on proper-class relations. We separate these interpretations and continue the ProveIt investigation in two directions.

For an infinite cardinal  $\kappa$ , let  $X = \mathbf{No}_{<\kappa}$ ,  $\mu = 2^{<\kappa}$ , and  $\Delta = \mu^{<\mu}$ . We determine the density, cellularity, and weight of *every fixed enumeration-length stratum*  $\mathcal{W}_\alpha(X)$ ,  $|\alpha| = \mu$ . At lengths  $\mu$  and  $\mu + 1$  all three invariants are  $\Delta$ . At  $\mu + 2$ , density and cellularity remain  $\Delta$ , but weight is  $2^\mu$ . At every length  $\alpha \geq \mu + 3$ , all three are  $2^\mu$ . We give exact point characters for finite tails and the tail  $\omega$ , and a general residual-fibre formula for arbitrary lengths. The ordinal embedding spectrum stays unchanged throughout.

For global enumerations, the inclusion order of the unranked prefix cylinders recovers their ordinal heights. A normalized cut represents an injective Ord-word exactly when the cylinders it crosses form a proper class; a label-coverage condition recognizes exhaustive words. Finally, a uniform pair-swap encoding and an elementary decoder show that admitted exhaustive traces, over a fixed labelled core and coding parameters, recover the entire available class realization. These arguments require no class-valued transfinite recursion and never form a same-level class of all classes.

**Status.** AI-assisted mathematical research manuscript, with complete ordinary proofs of the stated extensions. Historical priority, independent refereeing, and Lean verification are not claimed. The repository and two earlier continuation manuscripts are credited explicitly. Executable checks cover finite mechanisms only. No repository files were modified.

**Source 23.** *Lexicographic Surreal Well-Orders: Termination markers, increasing-word obstructions, and transfinite condensation.*

The expression “all well-orders of surreal numbers” encompasses several inequivalent constructions. We separate fixed-carrier enumerations, set-length words, naturally increasing well-ordered subsets, set-like global enumerations, arbitrary class well-orders, and orders on relation codes. Two extensions of the existing research are developed in detail.

First, we classify exactly which placements of a fixed termination marker make the order of all set-length words, or all injective set-length words, set-cut saturated. An interior marker works precisely when each side of its alphabet cut either has the appropriate endpoint or has no small cofinal or coinital subset. In particular, a marker immediately adjacent to an existing surreal label works: an adjacent pair in the alphabet need not produce an adjacent pair of words. We compute every point’s two-sided character. By contrast, no fixed termination marker makes the order of strictly increasing set-length surreal words set-cut saturated.

Second, we introduce set-interval condensation of raw class well-orders, using least representatives rather than proper classes as quotient elements. For every given class well-order  $\Gamma$ , a finite-support ordinal-polynomial construction supplies a class well-order with an explicitly defined condensation hierarchy indexed by  $\Gamma + 1$ , collapsing exactly at its last stage. These particular hierarchies require no elementary transfinite recursion axiom. Every interval between distinct set-like global enumerations contains raw well-orders realizing every such prescribed hierarchy. We explain why this does not classify the bare outer lexicographic order, and we give a size-explicit formalization program and further questions.

**Status.** Ordinary mathematical proofs are provided for the new statements. This is an AI-assisted, unrefereed research manuscript; historical priority and Lean verification are not claimed. The accompanying executable checks concern finite mechanisms only. The inspected repository revision and the distinction between prior results, new arguments, and open problems are recorded explicitly.

**Source 24.** *Lexicographic Well-Orders of the Surreals: Prefix completions, generalized Baire models, and the set-class boundary.*

We continue the study of lexicographic orders of labelled well-orderings of surreal numbers. The main advance is a distinction between order completion and completion by stabilization of initial segments. For an infinite alphabet of cardinality  $\mu$ , the latter completion of the minimal-length permutation space is exactly the space of injective  $\mu$ -words; failure of exhaustiveness is its entire missing boundary. For regular  $\mu$  we construct an explicit homeomorphism from the permutation space to the bounded-topology space  $(\mu^{<\mu})^\mu$ , without assuming  $\mu^{<\mu} = \mu$ .

At the countable birthday cutoff this gives a complete compatible metric and a Baire-space presentation. Nevertheless, the resulting linear order is not isomorphic to the irrationals: its Dedekind completion is the real line, but it omits continuum many points. At singular cardinalities we identify exactly when right translation and inversion are continuous in the prefix topology, and isolate the boundedness-preserving subgroup on which the usual permutation-group picture remains valid.

For global surreal enumerations, we formulate corresponding results in Gödel–Bernays class theory without forming a class of classes. Every uniformly set-indexed prefix-Cauchy net is eventually constant, whereas class-indexed approximation recovers all injective ordinal-class words. Inverse stabilization precisely repairs the loss of exhaustiveness. We also distinguish fixed and varying carriers, inherited numerical well-orders, arbitrary non-set-like class well-orders, relation-code orders, and order-type quotients. A concrete Lean plan is tied to inspected repository declarations, and the remaining singular and foundational questions are stated separately.

**Status.** This is an AI-assisted, unrefereed proof manuscript. The results are supported by

the mathematical arguments given here, not by a new Lean verification or a claim of historical priority. Finite regression checks are included but do not prove the transfinite theorems. The repository was inspected at the pinned revision recorded in Appendix 111.25; it was not changed.

**Source 25.** *Lexicographic Surreal Well-Orders: Prefix homogeneity, invisible exhaustiveness, and label rigidity.*

We continue the investigation of lexicographically ordered well-orderings of the surreal numbers, distinguishing fixed set carriers, variable-length words, naturally increasing words, set-like global enumerations, arbitrary class well-orders, and relation codes.

The principal extension concerns the set-coded, set-supported core of global enumerations. We classify the orbits of every uniformly set-indexed configuration of injective ordinal-class words under automorphisms of the core that preserve its order and all unranked prefix cylinders. The complete invariants are core membership, pairwise first-disagreement ordinals, and pairwise lexicographic comparisons. In particular, there are exactly two single-branch orbits: core branches and all other injective branches.

Consequently, even the order together with every prefix cylinder does not recognize exhaustive branches. A cylinder-preserving core automorphism can carry the trace of a global well-order to that of an injection omitting a surreal label, and therefore need not extend to the full enumeration order. This remains possible while fixing any prescribed set of core and prefix parameters. Conversely, one cross-node relation saying that two extension edges use the same label makes the core-and-cylinder structure rigid. Label coherence without the core yields exactly coordinatewise order automorphisms of the surreal alphabet.

We prove regular-cardinal set versions, including an exact automorphism-group cardinality, and a cofinality obstruction at singular lengths. All class constructions are formulated in GBC using set-valued recursion, with no same-level collection of classes and no appeal to elementary transfinite recursion.

**Status.** AI-assisted, unrefereed research manuscript. Complete ordinary proofs are supplied for the stated extensions; historical priority and Lean verification are not claimed. Earlier results are credited separately. The accompanying executable checks concern finite mechanisms, not the transfinite theorems.

**Source 26.** *Lexicographic Well-Orders of the Surreals: Non-Borel boundaries, closed universality, and safe foundations.*

We continue the investigation of lexicographic orders of labelled well-orderings of surreal numbers. The principal result answers the singular complete-metrizability question in the earlier *Prefix Completions* manuscript. For every uncountable cardinal  $\mu$  of countable cofinality, the space of bijections  $\mu \rightarrow X$ , with bounded-prefix topology, is not Borel in its completely metrizable space of injective words. Consequently it has no compatible complete metric. Together with the local-character calculation and the countable case, this gives an exact classification: for infinite minimal enumeration lengths, complete metrizability holds precisely at  $\mu = \omega$ .

The proof is an explicit omitted-label coding construction. A compact Cantor family of injections can encode any set of fewer than  $\mu$  binary branches through the omission of exactly one label. If  $\mu > 2^{\aleph_0}$ , every zero-dimensional separable metrizable space occurs as a closed subspace of the permutation space. Ordered marker labels make the construction an order embedding as well. At the unconditional birthday cutoff  $\beth_\omega$ , these results apply to the actual lexicographic order topology, yielding a metrizable Baire order with no nonempty completely metrizable open subspace.

We also distinguish fixed and varying carriers, minimal and nonminimal enumeration lengths, inherited numerical well-orders, termination conventions, relation-code lexicography, order-type

quotients, set-like global enumerations, and unrestricted class well-orders. Direct labelled comparison, bounded-support coding, diagonalization, and class-indexed approximation are formulated without a class of classes. A concrete universe-aware Lean plan, a source audit, finite regression checks, and a proposed research program complete the report.

**Status.** AI-assisted and unrefereed. The main advances are supplied with written proofs; no new Lean verification or historical-priority claim is made. Earlier repository results are identified as such. The repository was inspected at a pinned revision and was not modified.

**Source 27.** *Lexicographic Orders of Surreal Well-Orders: Further Structure from Encodings, Prefix Trees, and Support Bounds.*

There is no single order determined by the phrase “the lexicographic ordering of all well-orders of surreal numbers.” A fixed set of surreal labels, all set-length words, numerically increasing words, ordinal enumerations of the whole surreal class, arbitrary class well-orders, and well-ordered scans of relation tables produce different objects. Their differences remain substantial after their common elementary theory has been understood.

Building on the current ProveIt research corpus, we develop five further directions. First, relation-table orders on the same countable carrier can be real-embeddable or can have continuum many disjoint nonempty intervals, depending on whether the scan has order type  $\omega$  or  $\omega + 6$ ; their ordinal embedding spectra nevertheless agree. Second, an increasing word with an interior terminator splits exactly into a left part and a right part, giving a lexicographic-product description of the centered surreal construction. Third, ordered prefix trees admit automorphisms taking exhaustive ordinal branches to nonexhaustive ones: preserving levels, extensions, and the numerical ordering of siblings does not recover exhaustiveness. Fourth, every uniformly class-indexed family of arbitrary global well-orders misses a convex copy of the entire raw comparison order. A related rigidity theorem shows that a set-like enumeration order with its canonical core fixed pointwise detects the admitted class part of a model. Finally, we sharpen the existing optimum for the cardinality of permutation support to an exact least ordinal support bound.

All constructions are given with explicit size and uniformity conditions. We explain their implementation in set theory, two-sorted class theory, set models, and universe-polymorphic type theory. The proofs are conventional mathematical proofs; the accompanying finite checks test finite mechanisms, not transfinite or class-theoretic assertions.

**Status and provenance.** The repository snapshot is `7ff7736ecf3a0adc8536b2d083cf819e1ba39ace`, committed at 21:47:46 UTC on 3 October 2026. The present article is a continuation, not a replacement for the much larger merged report. Statements identified as background come from that report or the cited primary literature. The additional theorems are proved here, with no claim of historical priority or external peer review. No new Lean proof certificate is supplied.

**Source 28.** *Lexicographic Well-Orders of the Surreals: Singular permutation geometry and the canonical group envelope.*

We continue the study of lexicographic orders of labelled well-orderings of surreal numbers, with particular attention to a distinction that appears at singular enumeration cardinalities: controlling a bounded initial segment is not the same as controlling an arbitrary small set of positions. For the minimal enumeration slice, this distinction separates the numerical order topology from a canonical topology compatible with all permutation operations.

We prove that the subgroup preserving bounded sets in both directions is maximal among subgroups containing the finitary permutations and carrying the inherited topological-group structure. At every singular cardinal it is self-normalizing. We determine its forward closure and completion,

describe a dense inverse-continuity locus, and construct explicit permutations separating the one-sided boundedness conditions. The smallest group topology finer than the prefix topology is exactly agreement on arbitrary sets of size less than the enumeration cardinal. Its character is the cofinality of the small-subset poset, which is strictly greater than that cardinal in the singular case. It is complete for its two-sided group uniformity.

These results apply to surreal birthday cutoffs after verifying their thickness. We also distinguish fixed and varying carriers, inherited numerical well-orders, set-like and unrestricted global class well-orders, relation codes, and order-type quotients. Class arguments are formulated without a class of classes, and a formalization plan separates universe-indexed Lean mathematics from model-relative class semantics.

**Research status.** AI-assisted, unrefereed mathematical manuscript. The new assertions are supported by the proofs below, not by a claim of historical priority or a new Lean kernel verification. Finite regression checks accompany the text but do not prove its infinitary statements. The inspected repository revision is pinned in Appendix 111.42; the repository was not modified.

**Source 29.** *Lexicographic Orders of Surreal Well-Orders: Exact Birthday Spectra, Word Products, Topological Transitions, and Class Comparability.*

The phrase “the lexicographic ordering of all well-orders of the surreal numbers” refers to several different mathematical constructions. Some are sets, some are classes of set codes, and some are higher-order collections of class relations. We give a common framework for these interpretations and extend the corresponding ProveIt research program.

Our first result recovers the exact birthday cutoff from the numerical order: the binary lexicographic cube  $\mathbb{B}_\beta$  embeds in  $\mathbf{No}_{<\theta}$  exactly when  $\beta < \theta$ . Consequently the birthday fragments form a strictly increasing hierarchy under order embeddability, even throughout a band on which their cardinality is constant. In contrast, for every countable  $\omega < \theta < \omega_1$  and every enumeration length  $\alpha = \Lambda + n$  of cardinality the continuum, with  $\Lambda$  limit and  $n$  finite, the well-ordering stratum is equimorphic to  $\mathbb{B}_\Lambda \times_{\text{lex}} n!$ . We extend the corresponding residual-cardinal analysis to arbitrary noninitial birthday bounds and state the remaining singular upper-coding gap explicitly.

For increasing set-length words, splitting at the termination cut gives a canonical factorization. The centered surreal case has order type  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ , where  $\mathbf{T}_{\min}$  is the shorter-first order of all set-length surreal words. This identifies three previously separate zero conventions and describes the fourth by adjacent-pair expansion. If proper-class numerical carriers are admitted, shorter-first adjacency instead occurs exactly when a carrier acquires its unattained numerical supremum. The longer-first class-carrier order remains dense.

At the countable alphabet  $\mathbf{No}_{<\omega} \cong \mathbb{Q}$ , finite terminal tails produce a sharp progression in topology and measurable structure. The native lexicographic and coordinate Borel structures agree at  $\omega + 1$ , differ at  $\omega + 2$ , and are incomparable at every finite successor  $\omega + n$  with  $n \geq 3$ . We also prove that the entire ordered set-prefix tree fails to recognize exhaustive or numerically cofinal class branches. Finally, over GBC, the existence of complete terminating canonical set-interval condensation histories is equivalent to strong comparability of class well-orders. The proof supplies finite ordinal-coefficient normal forms from any such history.

Every assertion distinguishes isomorphism from equimorphism, supplied classes from collections of classes, and elementary definitions from class-recursion existence principles. The article ends with concrete formalization targets and a revised research agenda.

**Proof and provenance status.** This is an AI-assisted research manuscript with written proofs and independent internal mathematical review. It is not a refereed paper, and no new Lean verification or publication-priority claim is made. The repository audit is pinned to

commit 7ff7736ecf3a0adc8536b2d083cf819e1ba39ace, observed on 3 October 2026. Earlier project manuscripts are distinguished from the results developed here. A source manifest and a proof-status guide accompany the article.

**Source 30.** *Lexicographic Well-Orders of the Surreals: Residual Codes, Topological Transitions, and Class Reconstruction.*

The lexicographic ordering of all well-orders of the surreal numbers has several mathematically inequivalent interpretations. After separating them, we develop four continuations of the existing ProveIt reports. We determine binary-cube equimorphism types for new fixed strata with infinite remainders, including the previously isolated case  $\mu + \omega$ . Finite descent through regular and singular strong-limit cardinal blocks gives a complete fixed-type equimorphism classification under GCH. An additional bounded-birthday argument classifies every fixed type in ZFC at each infinite cutoff  $\kappa < \aleph_\omega$ . We prove a sharp topological and measurable transition between the countable strata of types  $\omega$ ,  $\omega + 1$ ,  $\omega + 2$ , and  $\omega + n$  for  $n \geq 3$ ; relation tables and enumeration codes cease to be measurably interchangeable already at  $\omega + 2$ . An exact partial-table extension theorem shows that every admitted proper-class well-order type is locally indistinguishable from every other by set-sized relation data. Finally, the admitted *labelled* global enumerations recover an entire class realization, despite the severe information loss of its external pure order. Sets, classes, and metatheoretic collections are kept distinct throughout. The article includes proofs, source and assumption audits, a formalization plan, and a prioritized research agenda.

**Status.** Conventional mathematical arguments with independent AI-assisted proof review. This is not a machine-checked formalization or an assertion of historical priority. Inherited results are identified separately from the continuations proved here.

**Source 31.** *Countable Global Choice and Surreal Coding over Zermelo Set Theory: A localized nonconservativity theorem and exact rank-model spectra.*

We investigate an intersection of Elliot Glazer's work on weak choice principles and ProveIt's research on surreal numbers and class well-orders. The first result is a refinement of Glazer's nonconservativity theorem: a global selector required to choose only from nonempty countable sets already produces new set-theoretic consequences over Zermelo set theory with Choice, provided Separation is extended to the selector. Selection on exactly countably infinite sets suffices as well. The additional argument is a bounded uniformization theorem. It converts a selector on sets embeddable into a fixed well-ordered set into a uniform assignment of injections into that set, without Replacement or ordinal collapse. A general incidence-coding theorem then connects this uniformization to Glazer's published countermodel.

The second part studies the full-class structures  $\mathcal{M}_\lambda = (V_\lambda, \mathcal{P}(V_\lambda))$ , for limit ordinals  $\lambda > \omega$ . Global choice and set-like well-orders exist at every such height. Nevertheless, ordinal enumeration of binary sign sequences, enumeration in birthday order, universal coding of sets by sign sequences, and full Class Replacement have different exact thresholds: respectively  $2^{<\kappa} = \kappa$ , strong-limit cardinality, a beth fixed point, and strong inaccessibility. We also determine replacement on each individual set domain and the external cardinalities of internal proper classes. These results isolate several

mechanisms behind the usual global-choice equivalences. Full proofs, strict separation examples, an axiom audit, and twelve further research questions are included. The article claims a proved refinement and a structural synthesis; it makes no claim of resolving unrestricted surreal transfer or of establishing historical priority for every result.

**Scope.** Conventional mathematical proofs. No Lean or Rocq verification is claimed. The nonconservativity conclusion uses Glazer’s countermodel theorem as an explicitly cited input. The rank-model classification is proved in an external ZFC metatheory.

## Sources 32–35

[merge] The title pages, abstracts and status statements of sources 32–35 (batch-96 manuscripts 08–11). The results they announce are printed in Part XVI; the summaries are kept for the record, with this report’s notation ([section 1.3.4](#)).

**Source 34 (base).** *Beyond Ord: Definable Class Well-Orders, Canonical Arithmetic, and the Limits of Notation.* “Research report prepared for Vladimir Reshetnikov”, dated 4 October 2026.

The class of all ordinals is the endpoint of set-sized ordinal notation, but it is not the endpoint of definable well-ordering. Tagged sums, lexicographic products, and finite-support powers produce well-orders such as  $\text{Ord} + 1$ ,  $\text{Ord} \cdot \text{Ord}$ , and  $\text{Ord}^{[\text{Ord}]}$  without creating a new set ordinal. We develop these constructions as relations on sets, separate their explicit arithmetic from stronger class-recursion principles, and give systematic notation by finite labelled trees.

The main refinement of the ProveIt program is a choice-free proof that finite-support powers of class well-orders are well-ordered. It lowers the repository’s equivalence between canonical terminating condensation histories and strong class-well-order comparability from GBC to GB, for arbitrary class carriers and the full subclass-minimum definition of well-ordering. This resolves the corresponding base-theory question in the inspected repository; it does not decide whether comparability implies elementary transfinite recursion. Further results give a hereditary fixed-point notation system, a uniform-family diagonal obstruction, a truth-relative construction of longer definable orders, and an external cofinality theorem for definable order spectra. In a full inaccessible-universe interpretation, all class well-order types have external lengths below  $\kappa^+$ , while the hereditary system has the exact length  $\varepsilon_{\kappa+1}$ .

Every substantive theorem is proved or explicitly attributed. The paper distinguishes repository refinements and new combinations of arguments from established literature, makes no claim of historical priority, and records a formalization plan and a focused research agenda. The proofs are mathematical proofs; no kernel-checked formalization is claimed.

**Notation convention.**  $\Omega$  denotes a presentation of  $(\text{Ord}, \in)$ , never an ordinal that belongs to the same universe.  $A^{[B]}$  denotes finite-support order exponentiation, not a power class.

**Source 35.** *Definable Class Well-Orders Beyond Ord: Arithmetic, canonical notation, fixed-point completion, and the limits of uniform definability.* “Research report prepared for Vladimir Reshetnikov”, dated 5 October 2026.

The ordinal class is the end of the set ordinals, but it is not the end of definable well-order presentations whose elements are sets. A proper-class well-order may have points with proper classes of predecessors, giving familiar-looking expressions such as  $\text{Ord} + 1$ ,  $\text{Ord} \cdot \text{Ord}$ , and  $\text{Ord}^{\text{Ord}}$  rigorous meanings. We develop their arithmetic using tagged sums, lexicographic products, and finite-support exponentiation, while keeping class presentations separate from nonexistent set ordinals beyond  $\text{Ord}$ .

The first contribution is a direct, choice-free proof that finite-support exponentiation preserves class well-ordering. It lowers the ProveIt manuscript’s equivalence between strong class-well-order comparability and complete canonical condensation histories from GBC to GB, with no use of set Choice. A second contribution, over GBC, characterizes precisely which orders have a fixed-point completion for  $P(X) = \text{Ord}^X$ : an order  $W$  initially embeds into such a fixed point if and only if  $W$  initially embeds into  $P(W)$ . For nonempty  $W$ , this is also equivalent to its canonical terminating history on  $W + 1$ . The proof uses finite traces and an explicitly coded direct limit, rather than arbitrary class-valued recursion. We also prove a strict bounding theorem for every uniformly coded family with a supplied well-ordered index class, and derive a hierarchy of definability complexities of their presentations up to admitted isomorphism.

Hereditary ordinal-coefficient terms supply a concrete exponential fixed point and a transparent comparison procedure. Full-model and definability-sensitive spectra explain the model-relative sense in which such orders can stretch farther than Ord. The final sections compare set-theoretic and type-theoretic formalizations and propose a research program. Existing polynomial and condensation results are credited to the inspected repository; classical class-epsilon notation is also credited. The extensions are proved here, but no claim of literature-wide priority or resolution of CWO versus ETR is made.

**Keywords.** Class well-order; ordinal arithmetic; elementary transfinite recursion; definability; canonical condensation; fixed point; finite-support notation; Gödel–Bernays set theory.

**Source 32.** *Beyond Ord: Definable Class Well-Orders. Explicit arithmetic, condensation, definability ceilings, and truth jumps*; headed “Foundations and order theory”. “Research manuscript prepared for Vladimir Reshetnikov”, dated 4 October 2026.

The ordinal class is the largest set-like well-order, but not the largest class well-order. We develop an explicit arithmetic of non-set-like well-orders without treating proper classes as elements of a same-level universe. Finite-support exponentiation and hereditary finite normal forms give orders far beyond Ord already in Gödel–Bernays set theory with Global Choice. A canonical division theorem expresses every class well-order as  $\Omega \cdot Q + \alpha$ , where  $\Omega = (\text{Ord}, <)$ ,  $Q$  is a class well-order presentation, and  $\alpha$  is a set ordinal.

Three further results organize the limitations of this arithmetic. First, a diagonal sum dominates every member of any one uniformly class-coded family, even without class-order comparability. Second, whenever a set-interval condensation hierarchy exists along  $W + 1$ , it collapses  $W$  by its final stage; elementary transfinite recursion supplies such a hierarchy. Explicit polynomial examples show that no set-ordinal bound suffices. Third, for an inaccessible  $\kappa$  and the classes definable over  $(V_\kappa, \in, G, A)$  with set parameters, the externally realized order types form an ordinal  $\delta_A$  satisfying

$$\kappa < \delta_A < \kappa^+, \quad \text{cf}(\delta_A) = \omega, \quad \kappa^{\delta_A} = \delta_A.$$

A full truth predicate for that structure makes  $\delta_A$  itself representable. We give proofs, isolate the relevant axioms, relate the constructions to the ProveIt repository, and propose a formalization and research program.

**Research status.** AI-assisted, unrefereed manuscript. Theorems below have written proofs; no historical-priority, peer-review, or machine-verification claim is made. Standard results and repository antecedents are identified separately. In particular, the condensation result is conditional on existence of the indicated hierarchy, not a proof of its existence in bare GBC.

**Source 33.** *Beyond Ord: Definable Class Well-Orders, Arithmetic, Condensation, and Definability Heights*; headed “Foundations / research article”. “Research manuscript prepared for Vladimir Reshetnikov”, dated 4 October 2026.

Proper-class well-orders can extend beyond the order of all set ordinals without creating new set ordinals. We develop a size-safe calculus for these orders and separate explicit constructions in Gödel–Bernays set theory with global choice from principles requiring elementary transfinite recursion. The structural results include canonical division by the order of all ordinals, an explicit condensation hierarchy for finite ordinal-coefficient polynomials, and a finite-digit embedding theorem for orders equipped with an exhausting condensation tower.

The main definability result is a uniform-family diagonal theorem. For each fixed finite formula-complexity bound, it produces a class well-order definable without set parameters, relative to a named global order, into which every well-order of that complexity with arbitrary set parameters embeds, while the constructed order embeds into none of them. Consequently, set-parameter-free presentations are externally cofinal among all set-parameter-definable presentations, but no definable uniform family can witness that cofinality. At an inaccessible rank model  $V_\kappa$ , all full-class order types are exactly the ordinals below  $\kappa^+$ ; the smaller definable spectrum has a supremum strictly between  $\kappa$  and  $\kappa^+$  of external cofinality  $\omega$ ; this supremum is an epsilon number closed under ordinal arithmetic. Adding a truth predicate strictly increases that definability height.

The article supplies proofs, an axiom ledger, repository integration guidance, and further research problems. Historical priority for the derived results is not established, and no machine verification of the class-theoretic proofs is claimed.

**Status.** AI-assisted, unrefereed research manuscript. The established literature, arguments proved here, conditional results, and open directions are distinguished throughout. The basic existence of long class well-orders and earlier condensation constructions are not advertised as new discoveries.

## Source 36

[merge] The title page, abstract and scope statement of source 36 (batch-97 manuscript 01). The results it announces are printed in Part XVII, with this report’s notation ([section 1.3.5](#)).

**Source 36.** *Beyond Ord: Definable Class Well-Orders, Finite-Support Arithmetic, and Definability Horizons*, subtitled “A constructive notation calculus with exact model-relative bounds”; “An investigation prompted by the ProveIt repository”, October 2026; no author line.

**Main result.** With a named global enumeration of an inaccessible-height universe, all first-order definable class well-orders have an external definability horizon of countable cofinality, fixed by epsilon enumeration. Presentations without set parameters already approach this horizon. Adjoining a truth predicate makes the horizon itself presentable and produces a strictly larger one.

[merge] (4 October 2026.) Apart from “fixed by epsilon enumeration”, this main result is the definability-ceiling and truth-presentation theorem that sources 32, 33 and 34 proved independently on 4 October 2026 ([notes XVII.7.D](#) and [XVII.7.G](#)); source 36 did not see Part XVI. The statement is printed as delivered.

**Scope and status.** This article gives conventional mathematical proofs, explicit constructions, source attribution, and a research agenda. Long class well-orders, their arithmetic, and the epsilon notation functor have established antecedents. The structural results are proved here as a synthesis; publication priority and a breakthrough resolution of a recognized open problem are not asserted. The accompanying finite computations check a notation demonstrator; they are not proof-assistant certification.

The class of all ordinals is the longest set-like proper class well-order, but it is far from the longest definable class well-order. We develop a systematic account with explicit carriers, arithmetic, and normal forms. Finite-support reverse-lexicographic powers define class ordinal arithmetic in

Gödel–Bernays set theory. We prove their laws, exact predecessor decompositions, and a complete criterion for set-likeness. Finite hereditary  $\Omega$ -normal forms yield a parameter-free class  $\mathbf{E} \cong \Omega^{[\mathbf{E}]}$ , with canonical strict initial segments  $\Omega, \Omega^{[\Omega]}, \Omega^{[\Omega^{[\Omega]}]}, \dots$ . Localization to set ordinals proves well-foundedness without class-valued recursion. The standard epsilon-term functor extends the notation scale to fixed points of epsilon enumeration.

For a transitive set model  $M \models \text{ZFC}$  of ordinal height  $\kappa$ , externally well-founded definable presentations with finite set parameters realize precisely  $[0, \mathfrak{H}(M))$ , where  $\mathfrak{H}(M) < |\kappa|^+$  and  $\varepsilon_{\mathfrak{H}(M)} = \mathfrak{H}(M)$ . Explicit parameter-free syntax already passes the first fixed point of epsilon enumeration above  $\kappa$ . For  $M = V_\kappa$ , with  $\kappa$  inaccessible and a named global enumeration  $G$ , we prove  $\text{cf}(\mathfrak{H}_G) = \omega$  and that presentations without set parameters are cofinal in the parameter-allowing spectrum. Each fixed formula complexity admits a definable order dominating all presentations of that complexity. Full truth makes  $\mathfrak{H}_G$  itself presentable; varying  $G$  makes the horizons unbounded in  $\kappa^+$ . With all classes available, the exact external cutoff is  $\kappa^+$ .

We distinguish formula schemas, admitted classes, external order types, unrolling, and higher-universe formalizations. A uniform diagonal theorem rules out a same-level notation system cofinal in all class well-orders. The known class-comparability and recursion-strength questions remain separate from the explicit constructions proved here.

## D Crosswalk of the sources' numbered statements

[merge] Each row gives a numbered statement of a source (numbered as in that source's own PDF), and where it is printed or recorded here. A note records a statement proved here by the same argument; a section labelled “route” prints a different argument. Labels are the source's own with its prefix, or `swo:sub:number` for unlabelled statements.

[merge] (3 October 2026.) Sources 19–30 follow, with the same conventions; their statements are numbered as in their own PDFs (source 26 numbers its research questions within sections, source 28 its questions consecutively). A row whose target is a note records a statement printed there as a duplicate of an earlier result; the note names the result and the proof that is printed.

## D.11 Source 19

| No.  | Statement in source 19                                                | Printed here as                           |
|------|-----------------------------------------------------------------------|-------------------------------------------|
| 3.1  | Lemma (Surreal set cuts and avoidance)                                | <a href="#">Note 62.16</a> , p. 354       |
| 3.2  | Lemma (A birthday-controlled insertion)                               | <a href="#">Note 62.16</a> , p. 354       |
| 3.3  | Lemma (Deletion and sign cones)                                       | <a href="#">Note 62.16</a> , p. 354       |
| 3.4  | Proposition (Fixed-carrier baseline)                                  | <a href="#">Note 62.16</a> , p. 354       |
| 4.1  | Definition (Common labelled initial segment)                          | <a href="#">Definition 111.2</a> , p. 650 |
| 4.2  | Proposition (Elementary comparison; prior result)                     | <a href="#">Note 111.3</a> , p. 650       |
| 4.3  | Proposition (First block and full block decomposition; prior results) | <a href="#">Note 111.4</a> , p. 650       |
| 4.4  | Remark (Existence and choice)                                         | <a href="#">Remark 111.5</a> , p. 651     |
| 5.1  | Lemma (A prefix-free code for any small alphabet)                     | <a href="#">Lemma 64.1</a> , p. 362       |
| 5.2  | Lemma (The main prefix and its small-deletion counterpart)            | <a href="#">Lemma 64.2</a> , p. 362       |
| 5.3  | Lemma (Fusion into one fiber)                                         | <a href="#">Lemma 64.3</a> , p. 363       |
| 5.4  | Theorem (Exact residual embedding reduction)                          | <a href="#">Theorem 64.4</a> , p. 364     |
| 5.5  | Proposition (Which small orders can occur as residual alphabets)      | <a href="#">Proposition 64.5</a> , p. 364 |
| 5.6  | Lemma (Regular-cardinal blocks over any alphabet)                     | <a href="#">Lemma 64.6</a> , p. 364       |
| 5.7  | Theorem (Uniform coding bounds for every fixed type)                  | <a href="#">Theorem 64.7</a> , p. 365     |
| 5.8  | Corollary (All regular residual layers)                               | <a href="#">Corollary 64.8</a> , p. 365   |
| 5.9  | Lemma (A constant subcylinder from a small range)                     | <a href="#">Lemma 64.9</a> , p. 366       |
| 5.10 | Lemma (The singular non-strong-limit block)                           | <a href="#">Lemma 64.10</a> , p. 366      |
| 5.11 | Theorem (Exact binary-cube spectrum for every fixed type)             | <a href="#">Theorem 64.11</a> , p. 366    |
| 5.12 | Lemma (Finite factors over a limit-length cube)                       | <a href="#">Note 64.12</a> , p. 367       |

| No.   | Statement in source 19                                                 | Printed here as                  |
|-------|------------------------------------------------------------------------|----------------------------------|
| 5.13  | Corollary (Coding bounds and exact classifications)                    | Corollary 64.13, p. 367          |
| 6.1   | Theorem (Classification of monotone restrictions)                      | Theorem 73.1, p. 448             |
| 6.2   | Remark (Finite verification)                                           | Remark 73.2, p. 449              |
| 7.1   | Theorem (Unique normal forms for the completion)                       | Theorem 65.11, p. 376            |
| 7.2   | Proposition (The exact identifications after deleting labels)          | Proposition 65.12, p. 377        |
| 8.1   | Theorem (A real completion with many omitted points)                   | Theorem 67.13, p. 389            |
| 9.1   | Definition (Completion convention for a nondense order)                | Definition 98.1, p. 567          |
| 9.2   | Theorem (Reconstruction by completed residual fibers)                  | Theorem 98.2, p. 567             |
| 9.3   | Lemma (Extrema of the residual well-order space)                       | Lemma 98.3, p. 568               |
| 9.4   | Proposition (Exactly which suborders embed into the core completion)   | Proposition 98.4, p. 569         |
| 9.5   | Theorem (The exact extension criterion)                                | Theorem 98.5, p. 569             |
| 10.1  | Lemma (Exact criterion for an unseparated pair)                        | Lemma 99.1, p. 570               |
| 10.2  | Proposition (At most two initial words over an arbitrary residual cut) | Proposition 99.2, p. 571         |
| 10.3  | Proposition (An alphabet criterion for failure of core separation)     | Proposition 99.3, p. 571         |
| 10.4  | Proposition (Different initial words with the same residual core cut)  | Proposition 99.4, p. 572         |
| 10.5  | Proposition (An explicit interior completion point)                    | Proposition 99.5, p. 572         |
| 11.1  | Theorem (Continuum many omitted amenable branches)                     | Theorem 100.1, p. 573            |
| 12.1  | Theorem (Exactly two countable GBC order types)                        | Theorem 109.1, p. 626            |
| 12.2  | Lemma (The maximal finite terminal tail)                               | Note 109.3, p. 626               |
| 12.3  | Lemma (Adjacency has finite residual carrier)                          | Note 109.4, p. 627               |
| 12.4  | Lemma (Every prescribed internal tail occurs densely)                  | Note 109.5, p. 627               |
| 12.5  | Lemma (The external shape of a nonstandard finite interval)            | Lemma 109.6, p. 628              |
| 12.6  | Proposition (Intrinsic cylinder equivalence)                           | Proposition 109.7, p. 629        |
| 12.7  | Lemma (Finite-game threshold)                                          | Lemma 109.8, p. 629              |
| 12.8  | Theorem (Uniform complete theory)                                      | Theorem 109.9, p. 629            |
| 12.9  | Corollary (A proper elementary suborder and an omitted type)           | Corollary 109.10, p. 630         |
| 12.10 | Corollary (The standard shuffle is the prime model)                    | Corollary 109.11, p. 630         |
| 12.11 | Theorem (All countable orders occur inside countable models of $T$ )   | Theorem 109.12, p. 631           |
| 13.1  | Proposition (The uniform coding obstruction)                           | Note 111.6, p. 651               |
| 14.1  | Research question (The remaining coding gap)                           | Research question 113.94, p. 919 |
| 14.2  | Research question (From equimorphism to isomorphism)                   | Research question 113.95, p. 920 |
| 14.3  | Research question (Gap arrangements in longer strata)                  | Research question 113.96, p. 920 |
| 14.4  | Research question (Noninitial birthday bounds)                         | Research question 113.97, p. 920 |
| 14.5  | Research question (Stability of first-block separation)                | Research question 113.98, p. 920 |
| 14.6  | Research question (Residual fiber isomorphism types)                   | Research question 113.99, p. 920 |

| No.   | Statement in source 19                                         | Printed here as                   |

| No.  | Statement in source 21                                                                        | Printed here as           |
|------|-----------------------------------------------------------------------------------------------|---------------------------|
| 2.1  | Example (The unlabelled quotient is incompatible with lexicography)                           | Example 61.1, p. 321      |
| 3.1  | Proposition (Cardinality and a uniform lower embedding)                                       | Note 62.13, p. 353        |
| 3.2  | Remark (A well-order of presentations need not result)                                        | Remark 62.14, p. 353      |
| 3.3  | Definition                                                                                    | Note 62.13, p. 353        |
| 3.4  | Proposition                                                                                   | Note 62.13, p. 353        |
| 4.1  | Theorem (First-cardinality decomposition)                                                     | Theorem 65.6, p. 374      |
| 4.2  | Lemma (Endpoints of a residual enumeration order)                                             | Lemma 65.7, p. 374        |
| 4.3  | Lemma (Density of exhaustive branches in the index order)                                     | Lemma 65.8, p. 374        |
| 4.4  | Theorem (Closure theorem)                                                                     | Theorem 65.9, p. 374      |
| 4.5  | Example (Finite and infinite residuals)                                                       | Example 65.10, p. 375     |
| 5.1  | Theorem (Short monotone chains in the alphabet)                                               | Theorem 77.1, p. 464      |
| 5.2  | Remark                                                                                        | Remark 77.2, p. 464       |
| 5.3  | Lemma (Finite-alphabet obstruction)                                                           | Lemma 77.3, p. 464        |
| 5.4  | Theorem (Noncardinal cutoff)                                                                  | Theorem 77.4, p. 465      |
| 5.5  | Corollary (Failure of interval self-similarity)                                               | Corollary 77.5, p. 466    |
| 6.1  | Theorem (Coherent insertion into fixed slots)                                                 | Theorem 75.1, p. 457      |
| 6.2  | Corollary (A bounded surreal system)                                                          | Corollary 75.2, p. 458    |
| 7.1  | Theorem                                                                                       | Theorem 67.6, p. 383      |
| 7.2  | Lemma (Countable sums are absorbed)                                                           | Lemma 67.7, p. 384        |
| 7.3  | Theorem (Strong finite homogeneity)                                                           | Theorem 67.8, p. 384      |
| 7.4  | Corollary (Prefix cylinders are not intrinsic)                                                | Corollary 67.9, p. 385    |
| 7.5  | Theorem                                                                                       | Theorem 67.10, p. 385     |
| 8.1  | Theorem (Largest common labelled prefix; repository baseline)                                 | Note 86.10, p. 524        |
| 8.2  | Theorem (Canonical first block)                                                               | Note 86.11, p. 524        |
| 8.3  | Theorem (Canonical set-interval decomposition)                                                | Note 86.12, p. 525        |
| 8.4  | Lemma (Uniform completion of a set prefix)                                                    | Note 86.13, p. 526        |
| 8.5  | Theorem (Uniform set-cut interpolation; repository baseline)                                  | Note 86.14, p. 526        |
| 8.6  | Lemma (The core sees exactly the first ordinal block)                                         | Note 86.15, p. 527        |
| 8.7  | Proposition (No exhaustive uniform set-code family)                                           | Note 86.16, p. 527        |
| 9.1  | Lemma (Elementary reconstruction from a core cut)                                             | Note 97.10, p. 561        |
| 9.2  | Theorem (Which core cuts are represented by words?)                                           | Note 97.11, p. 561        |
| 9.3  | Proposition (The first failed level of a cut)                                                 | Note 97.12, p. 562        |
| 9.4  | Theorem (Extension criterion)                                                                 | Note 97.13, p. 562        |
| 9.5  | Corollary (Restriction to the core)                                                           | Note 97.14, p. 563        |
| 9.6  | Definition                                                                                    | Definition 97.15, p. 563  |
| 9.7  | Lemma (Each side is an $\eta_{\text{Ord}}$ order)                                             | Note 97.16, p. 563        |
| 9.8  | Theorem (Conjugacy of large class cuts)                                                       | Note 97.17, p. 564        |
| 9.9  | Lemma (Cuts induced by nonskeleton words)                                                     | Note 97.18, p. 564        |
| 9.10 | Theorem (Nonextendable core automorphisms)                                                    | Note 97.19, p. 564        |
| 9.11 | Proposition (A large cut with no crossing first-level cylinder)                               | Proposition 97.20, p. 565 |
| 9.12 | Theorem (No extension even from $\mathfrak{W}_{\text{sl}}$ into $\mathfrak{W}_{\text{all}}$ ) | Note 97.21, p. 565        |
| 10.1 | Definition (Maximal finite terminal tail)                                                     | Definition 109.23, p. 638 |
| 10.2 | Lemma (Existence of the maximal finite tail)                                                  | Note 109.24, p. 638       |

| No.   | Statement in source 21                                                                      | Printed here as                                   |
