

# Lexicographic Orders of Well-Orderings of the Surreal Numbers

Set approximations, the singular birthday transition, set-length words,  
class orders, and higher-order structure

Research report merged from twenty-eight independent manuscripts  
prepared for Vladimir Reshetnikov (sources 08, 09, 11 and 12 of batch 80;  
sources 13–18 of batch 81; sources 19–30 of batch 83; source 31 of batch 89;  
sources 32–35 of batch 96; source 36 of batch 97)

Sources dated 2 October 2026 (source 11: 3 October 2026, UTC), 3 October 2026 (sources  
13–30), 4 October 2026 (sources 31–34; source 31 UTC), 5 October 2026 (source 35) and  
October 2026 (source 36); merged 2–5 October 2026

## Abstract

The phrase *all well-orders of the surreal numbers* has several inequivalent meanings. Well-orders of a fixed birthday fragment form a set; well-orders of arbitrary set-sized subsets form an ordinary class; well-orders of the whole surreal line are themselves classes, and their totality belongs to a higher logical level. We develop these settings and distinguish set-like from unrestricted class well-orders.

For an infinite set-sized alphabet  $X$ , the existing ProveIt theory gives  $|\mathcal{W}(X)| = 2^{|X|}$  and the exact ordinal embedding spectrum  $\beta < (|X|)^+$ . We apply it to surreal birthday fragments. For arbitrary set-length surreal words, we give an explicit sign-sequence embedding into **No**, with birthday bounds, and identify the one-sided cuts created by limit-length words.

For the whole surreal line, we define lexicographic comparison directly on labeled class well-orders, without assuming ordinal enumerations or a class of class order types. Every such well-order has a canonical initial segment of type Ord; its remaining tail determines a convex fiber. In the set-like fragment, bounded-support permutations of one global enumeration form an ordinary class isomorphic to **No**, and interpolate every uniformly set-indexed strict cut of the entire fragment. The fragment contains every class linear order, admits binary class-word coding, and cannot have an exhaustive uniform class of set-codes. The unrestricted order has adjacent pairs, all arising from finite residual alphabets. An omitted-range construction exhibits a proper-class cut filled by a non-set-like well-order. In a full inaccessible-universe interpretation, the unrestricted order does not embed into its set-like fragment.

The proofs use ZF, ZFC, or GBC, as specified, with a further uniform nonembedding theorem in  $\text{KM} + \text{GC}$ . We give universe-relative and proof-assistant formulations, and propose further research on the higher-order structure.

[merge] This report merges four manuscripts written independently on 2 October 2026 on the same question and delivered together in batch 80: source 11 (the base, whose abstract is printed above), and sources 12, 09 and 08. They prove the same core up to four times. Each shared theorem is printed once; the other sources' versions are recorded in numbered notes, and their genuinely different arguments are kept as marked routes. Source 12 adds an exact dichotomy at birthday cutoffs: for an infinite cardinal  $\kappa$  and  $\mu = 2^{<\kappa}$ , the minimal-length enumeration order  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  is equimorphic with the binary cube  $\mathbb{B}_{\kappa \cdot \kappa}$  (ordinal product) exactly when  $\kappa$  is a singular strong limit, and with  $\mathbb{B}_\mu$  otherwise, with  $\kappa = \beth_\omega$  as an unconditional example. It also adds a second direct comparison of all class well-orders, by their largest common labelled prefix,

and an exact external identification of both global orders in a full-class model at an inaccessible cardinal. Source 09 adds bounded reflection of set-indexed families, an explicit unfilled (Ord, Ord) configuration, and the embeddability in **No** of every uniformly class-coded family. Source 08 adds a separator of exactly prescribed birthday, the failure of finite support, and relation-code lexicography of all class well-orders. Source 11's choiceless proof answers source 12's question on the weak-choice strength; the direct comparisons of sources 11 and 12 answer source 08's question on comparing non-set-like class well-orders; and source 12's dichotomy answers in part a question of the repository's report on the reals. The whole set-sized general-alphabet layer re-proves that report and is printed with pointers to it, never as new.

[merge] (3 October 2026.) Six further manuscripts of batch 81, sources 13–18, continue this report and are merged into it as Parts VI–IX. They compute the density, cellularity, characters, gap spectrum and gap multiplicities of the set-sized strata at birthday cutoffs and the coding lengths of the strata  $\mu \cdot \gamma + n$ ; classify the termination conventions of word orders; classify every proper class cut of the set-coded core and recognize the cuts of global enumerations, which answers source 11's question on represented cuts, with automorphism orbits, class-extension absoluteness and support thresholds; decompose every class well-order canonically into Ord-blocks, with every class well-order as a block-index order and explicit condensation histories; settle source 08's question on full virtual products; bound the comprehension needed for the uniform nonembedding by  $\Sigma_1^1$ ; and classify the full order of every countable  $\omega$ -standard model as a factorial shuffle. Results proved by several of them are printed once, with every proof credited; their re-proofs of this report are notes.

[merge] Twelve further manuscripts of batch 83 (sources 19–30, all of 3 October 2026) continue the report as Parts X–XIV. On set-sized strata they determine the embedded binary-cube spectrum of every fixed enumeration type of **No**<sub>< $\kappa$</sub>  and its coding length except at singular non-strong-limit residual cardinals, the weight and point characters of every fixed-length stratum, and the topology of the minimal slice: Baire space with real-line completion at the countable cutoff, a generalized Baire space at regular sizes, and, at uncountable sizes of countable cofinality, a space that is not Borel in its injection completion and has no complete metric; the maximal and self-normalizing bounded subgroup and the canonical group topology above the prefix topology. Across birthday cutoffs they show that the native alphabet **No**<sub>< $\theta$</sub>  remembers  $\theta$  exactly, glue coherent cutoff profiles to class well-orders and detect set-likeness on a club, and treat noncardinal cutoffs and coherent embeddings. For word orders they factor increasing words at the terminator and reduce the centered increasing order to  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ , and compare relation-table scans. For the core they classify branch configurations under core-and-cylinder automorphisms, show that exhaustiveness is invisible even to the cylinders, give the exact least ordinal support bound, and recover an available class realization from its labelled global enumerations. For unrestricted orders they prove a local coding dichotomy, describe the countable class models and their common complete theory, and show over GBC that canonical terminating condensation histories are equivalent to strong comparability of class well-orders. Many of these results are proved by several of the twelve independently; each is printed once with every source credited.

[merge] One manuscript of batch 89 (source 31, dated 4 October 2026) is printed as Part XV. Over Zermelo set theory with Choice, a selector required to choose only from nonempty countable sets, with Separation extended to it, is not conservative; the proof combines a bounded uniformization theorem with Glazer's published countermodels, used through an interface whose exact match with them has not been reviewed. In the full-class rank models  $(V_\lambda, \mathcal{P}(V_\lambda))$  at every limit height  $\lambda > \omega$ , global choice and birthday-monotone set-like well-orders of the sign carrier always exist, while ordinal enumeration of the sign carrier, birthday-monotone enumeration, universal set coding (equivalently, ordinal abstraction) and full Class Replacement have the distinct exact thresholds: a cardinal height  $\kappa$  with  $2^{<\kappa} = \kappa$ , a strong-limit cardinal height, a beth fixed point  $\kappa = \beth_{\kappa}$ , and a strongly inaccessible height; Class Replacement on one set holds exactly when its size is below the cofinality of the height. This answers in part source 28's question on separating Class Replacement from uniform set choice, and extends source 12's inaccessible full-class model to every limit height.

[merge] Four manuscripts of batch 96 (sources 32–35, dated 4 and 5 October 2026) are merged

as Part XVI. Two of them prove independently that strong comparability of class well-orders and the existence of canonical condensation histories, which source 29 showed equivalent over GBC, are equivalent over GB without set or global choice: the polynomial orders  $P(\Gamma)$  are class well-ordered by a choice-free minimization, and a class linear order is well-ordered as soon as its nonempty set subsets have least elements. The Part develops the arithmetic of class well-orders beyond Ord (sums, products, finite-support powers, division by  $\Omega = (\text{Ord}, <)$ ), a hereditary term order  $\mathbf{E} \cong \text{Ord}^{[\mathbf{E}]}$  that is the least such fixed point and has external type  $\varepsilon_{\kappa+1}$  over an inaccessible  $\kappa$ , and a fixed-point completion of every class well-order initially embedded in its polynomial order, giving a further equivalent of comparability, here proved over GB as well. No uniformly coded family of class well-orders is cofinal under embedding; for each definability level a single order escapes all orders of that level. Over  $V_\kappa$  the definable order types form an interval  $[0, \Theta)$  with  $\kappa < \Theta < \kappa^+$ , of countable cofinality under a named global well-order, closed under ordinal arithmetic with  $\kappa^\Theta = \Theta$ , and a truth predicate represents  $\Theta$  exactly.

[merge] A fifth manuscript on the same request (source 36, batch 97) is printed whole as Part XVII. Besides independent proofs of Part XVI's localization, power, hereditary, diagonal, definability-ceiling and truth-presentation theorems, it computes sums and products of the points of the hereditary order by explicit normal-form algorithms, characterizes when a finite-support power  $A^{[B]}$  is set-like, extends the epsilon-term functor to class well-orders, and shows that over every transitive model of ZFC of height  $\kappa$  the definable order types form an interval whose supremum  $\mathfrak{H}(M)$  is a fixed point of  $\xi \mapsto \varepsilon_\xi$  above  $\zeta_{\kappa+1}$ , and that over  $V_\kappa$  the ceilings are unbounded in  $\kappa^+$  as the named global enumeration varies.

**Status.** This is a mathematical research report with proofs, not a claim of machine verification or bibliographic priority. Existing general set-alphabet results are credited to the repository. The further constructions are proved here and should be evaluated by their arguments. The repository audit was targeted; no Lean build or remote change was made.

[merge] **Status of the merged report.** AI-assisted and unrefereed; not formalized. Sources 12 and 09 call themselves AI-assisted in their title pages; sources 08 and 11 do not use the word (author lines: 08 and 09 “Research manuscript prepared for Vladimir Reshetnikov”, 11 “Research report”, 12 “Research report prepared for Vladimir Reshetnikov”). None of the four claims historical priority, peer review or machine verification. Their finite checks verify finite instances only, never a transfinite or class-theoretic statement. No statement of this report is formalized; the formal status of the inputs it uses is in [section 1.5](#).

[merge] **Batch 81 (3 October 2026).** Sources 13–18 are research manuscripts with written proofs. Sources 13, 15, 17 and 18 call themselves AI-assisted, source 14 unrefereed, and source 16 says that its checks are not external peer review. None claims priority, peer review or machine verification, and none of their statements is formalized ([sections 1.4 and 1.8](#)).

[merge] **Batch 83 (3 October 2026).** Sources 19–30 are research manuscripts with written proofs. Sources 19–26, 28 and 29 call themselves AI-assisted, source 30 reports AI-assisted proof review, and source 27 claims no priority or external peer review. None claims historical priority, peer review or a machine-checked formalization, and none is formalized here ([section 1.9](#)).

[merge] **Batch 89 (3 October 2026).** Source 31 is a research article with written proofs (“Research article prepared for Vladimir Reshetnikov”). It claims no machine verification and no historical priority, uses Glazer’s countermodel theorem as an explicitly cited input, and names expert review of its localized theorem as the next step; it is not formalized here ([section 1.10](#)).

[merge] **Batch 96 (4 October 2026).** Sources 32 and 33 are “Research manuscript[s] prepared for Vladimir Reshetnikov” and call themselves AI-assisted and unrefereed; sources 34

and 35 are “Research report[s] prepared for Vladimir Reshetnikov”, “not a refereed publication” and “unrefereed”, with “independent mathematical checks during preparation”. None claims historical priority, peer review or a machine-checked formalization, and none is formalized here ([section 1.11](#)).

[merge] **Batch 97 (4 October 2026)**. Source 36 is a research manuscript with “conventional written proofs with independent review during preparation”; it has no author line and does not call itself AI-assisted. It claims no publication priority, no resolution of a recognized open problem, no referee and no proof-assistant certification, and it is not formalized here ([section 1.12](#)).

# 1 About this report

## 1.1 Four manuscripts, one report

[merge] (Added 3 October 2026: six further manuscripts of batch 81 are merged as sources 13–18 and described in [section 1.8](#). This subsection describes the four batch-80 sources.) [merge] All four manuscripts arrived in commit 4e270aa46 and were placed in ccc046989 (batch 80, cluster K3). Their batch-80 manuscript numbers are their source numbers here.

| Source       | Manuscript (archive)                                                                                                                                                                                                                                  | Pin and date line                                                                                              | Labels and files                        |

The two pairs of archives sharing a name (08 and 09, 11 and 12) are not editions of one another. Every pair of the four texts has word 8-gram overlap of 0.6–1.1 % (preamble boilerplate), no member file is shared, the pins differ within each pair, and the result sets differ. They are four independent manuscripts on one spine; none supersedes another, and all four are merged (union).

Source 11 is the base. Its global-choice equivalence is proved over GB without set choice, the weakest base theory of the four ([theorem 13.1](#)); it covers set alphabets, set-length words, and set-like and unrestricted class well-orders; and it alone attributes the general set-alphabet theorems to the repository’s report on the reals, `SetTheory/Cardinals/docs/reports/ordinals-and-order-types/lexicographic-well-orderings-of-reals/` (cited below as the reals report, labels lwo:).

## 1.2 How the four texts are printed

[merge] Source 11’s text is printed in full and in its own order. The other sources’ material is inserted where it belongs.

- Their introductions ([section 4](#)) and foundational sections are printed whole, as sections headed “Source  $N$ ”.

- A result that a printed result already proves by the same argument is recorded in a numbered *Note*: the note gives the source’s statement, its number in that source, and what differs (hypotheses, strength, extra remarks). Prose of the source that makes a point not made elsewhere is kept in the note.
- A genuinely different proof is printed in full as a marked route (“Source 12’s route”, “second proof”). A result proved only by one source is printed in full where it belongs, with its source named in the heading or the first sentence.
- Every label of every source survives, with the source’s prefix (**swo:** for 11, **swo:st:** for 12, **swo:ec:** for 09, **swo:sk:** for 08). Numbered statements without a label in their source carry **swo:sub:nnumber**, for example **swo:st:n10.4** for source 12’s Corollary 10.4. [Appendix D](#) maps every numbered statement of the four sources to its place here.
- Text written for the merge is marked **[merge]**. Dated notes of 2 October 2026 record where one source answers another ([section 1.7](#)).

Statements and sections are numbered by their place in this report; source numbers appear in headings, notes and [appendix D](#). Apart from the renamings of [section 1.3](#) and the corrections listed in [section 1.6](#), the sources’ text is verbatim. Statements of the reals report and of other repository reports are cited by label name, as the sources do; those reports are not reproduced. The same rules govern sources 13–18 ([section 1.8](#)); their introductions are in [section 4.5](#).

### 1.3 One notation for four sources

**[merge]** The sources’ symbols collide. The following convention is fixed before any of them is used; every renaming is listed, and the tempting false reading is printed where confusion is likely.

| Here                                       | Meaning, and the sources’ symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|--------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| GB, GBC                                    | GB has a ZF set part, elementary class comprehension and class replacement, and <i>no</i> choice principle, as in the foundations report ( <b>found:sub:gbconvention</b> ) and the collection’s notation guide; GBC = GB + GC. Sources 09 and 12 analyse the necessity of choice “over GB plus set-level AC” (09, <a href="#">proposition 13.7</a> ; 12, <a href="#">theorem 13.2</a> ); that theory is written GB + AC in the merge text. Source 11 works over GB itself. <i>False reading</i> : the letters GB in sources 09 and 12 do not include set choice here. |
| bd( $x$ )                                  | Birthday, the length of the sign sequence (08, 09; the foundations and birthday-cutoff reports). Source 11’s $\ell(x)$ and source 12’s $b(s)$ are renamed bd( $x$ ), bd( $s$ ). In sources 08 and 09 the letter $b$ is the baseline enumeration, never a birthday.                                                                                                                                                                                                                                                                                                    |
| $\mathbf{No}_{<\kappa}$                    | $\{x \in \mathbf{No} : \text{bd}(x) < \kappa\}$ , the birthday cutoff (foundations report $\mathbf{No}_{<\alpha}$ ). Renamed: source 08’s $X_\lambda$ , $X_\kappa$ ; source 09’s $X_\theta$ (its $\kappa_\theta =  \mathbf{No}_{<\theta} $ ); source 11’s $X_\kappa$ ; source 12’s $S_\kappa$ . The reals report writes $S_{<\theta}$ . <i>False reading</i> : source 12’s $S_\kappa$ is $\mathbf{No}_{<\kappa} = S_{<\kappa}$ , not $S_{<\kappa^+}$ .                                                                                                                |
| $\ell_2(L)$                                | Binary coding length $\min\{\gamma : L \hookrightarrow \mathbb{B}_\gamma\}$ , as in the reals report ( <b>lwo:def:binary-length</b> ). Source 12 prints the same symbol $\ell_2$ and calls it the “binary coding rank” (its macro was named <b>\rk</b> ); its prose is kept. rank( $x$ ) is the von Neumann rank of a set (source 11’s <b>\rk</b> ), used only in the proof of <a href="#">theorem 13.1</a> . <i>False reading</i> : the “rank” of source 12 is $\ell_2$ , not rank.                                                                                  |
| $\mathcal{W}(X)$ , $\mathcal{W}_\alpha(X)$ | All exhaustive well-order enumerations of a set $X$ (lengths below $ X ^+$ ), and those of length exactly $\alpha$ , compared at the first unequal entry in the given order of $X$ (reals report’s $\mathcal{W}$ , $\mathcal{W}_\lambda$ ). The minimal slice is $\mathcal{W}_{ X }(X)$ . Source 11’s $\mathcal{P}_\lambda(X)$ is renamed $\mathcal{W}_\lambda(X)$ ; source 12’s script $\mathscr{W}$ is printed $\mathcal{W}$ .                                                                                                                                      |

| Here                                                              | Meaning, and the sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|-------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\mathcal{I}(X), \mathcal{I}, \mathcal{T}$                        | $\mathcal{I}(X)$ : injective words of length below $ X ^+$ over a set $X$ (source 11).<br>$\mathcal{I} = \mathcal{I}(\mathbf{No})$ : the class of all injective set-length surreal words, proper prefixes first (source 11's $\mathcal{I}$ ; source 08's $\mathcal{I}(\mathbf{No})$ ; source 09's $\mathcal{T}$ , renamed). $\mathcal{T}$ : all set-length words, not necessarily injective (source 11's $\mathcal{T}$ ). <i>False reading</i> : source 09's $\mathcal{T}$ was the injective class. The reals report's $\mathcal{I}$ (injections $\kappa \rightarrow \mathbb{R}$ ) is unrelated.                                                                                                                                                                                                                                                                                     |
| $\mathfrak{W}_{sl}(\mathbf{No}), \mathfrak{W}_{all}(\mathbf{No})$ | Set-like global well-orders of $\mathbf{No}$ , equivalently class bijections $\text{Ord} \rightarrow \mathbf{No}$ ; and all class well-orders of $\mathbf{No}$ . Both are predicates on classes (“metanotation”), never classes of classes. Source 12's $\mathcal{E}(\mathbf{No})$ , written $\text{SL}(\mathbf{No})$ in its macros, and its $\mathcal{W}_{cl}(\mathbf{No})$ ; source 09's $\mathcal{E}$ ; source 08's “virtual” $\mathcal{E}$ are renamed. $\mathfrak{J}$ is source 11's collection of class injections $\text{Ord} \rightarrow \mathbf{No}$ .                                                                                                                                                                                                                                                                                                                      |
| $\mathbb{B}_\gamma, \mathbb{B}_{\text{Ord}}$                      | $\mathbb{B}_\gamma = (\{0, 1\}^\gamma, <_{\text{lex}})$ (reals report, 08, 12). $\mathbb{B}_{\text{Ord}}$ : class binary words on $\text{Ord}$ compared at their least disagreement (source 08's $\mathbb{B}_{\text{Ord}}$ ; source 12's $\mathfrak{B}$ , renamed; source 11 writes $\{0, 1\}^{\text{Ord}}$ ).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| $\simeq_e, \hookrightarrow$                                       | Equimorphism (embeddings both ways; not isomorphism) and order embedding. Source 11's $\approx_{\text{emb}}$ is printed $\simeq_e$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| $\mathcal{P}_{bd}(e_0), \mathcal{P}_s(b)$                         | The <i>core</i> : enumerations that agree with a fixed baseline enumeration outside a set of positions. Source 11 codes them by normalized permutations $\sigma : \lambda \rightarrow \lambda$ ( $\mathcal{P}_{bd}(e_0)$ , <a href="#">definition 19.3</a> ); sources 09 and 08 by fixed-point-free bijections $\sigma : S \rightarrow S$ of a set $S$ of ordinals (source 09's $\mathcal{C}_b$ , source 08's $\mathcal{P}_b$ , both written $\mathcal{P}_s(b)$ here; source 08's code carrier $\mathcal{P}$ is $\mathcal{P}_s$ , and its power-set $\mathcal{P}(V_\kappa)$ keeps the letter $\mathcal{P}$ ). The two codings have the same evaluations: restrict the identity extension of a support code to $\lambda = \sup\{\xi + 1 : \xi \in S\}$ , and conversely discard fixed points. With the same baseline, every order statement about one is a statement about the other. |
| $e_0, B, b$                                                       | The fixed baseline class bijection $\text{Ord} \rightarrow \mathbf{No}$ of sources 11, 12, and 09 and 08 respectively.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| $d(F, G), \Delta(E, F), \delta(e, f)$                             | The least ordinal at which two class functions on $\text{Ord}$ differ (sources 11, 09, 08).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| $\eta_{\text{Ord}}, \eta_\kappa$                                  | The set-cut property, and its version for cuts of fewer than $\kappa$ elements, empty sides allowed (11, <a href="#">definition 5.1</a> ; 08, <a href="#">definition 5.8</a> ); source 09 writes “set-cut property”. The subscript is a cardinal bound, not an $\aleph$ -index.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| Termination                                                       | Sign sequences compare with $- < \text{termination} < +$ (numerical order); words compare with proper prefixes first. Exhaustive enumerations of one set are prefix-free, so no convention is needed there.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| (S08. $n$ )                                                       | Source 08's displayed equations (1)–(13) keep their numbers as (S08.1)–(S08.13). (S08.10), an inequality inside a proof recorded in <a href="#">note 19.13</a> , is described there, not displayed.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

### 1.3.1 Addendum of 3 October 2026: notation for sources 13–18

[merge] The six batch-81 sources ([section 1.8](#)) reuse the symbols above with other meanings, and several reuse this report's macro names for other objects. The convention below is fixed before any of their material is printed; it applies to Parts VI–IX and changes nothing in Parts I–V. Every renaming is listed; the tempting false reading is printed where confusion is likely.

| Here                                                   | Meaning, and the batch-81 sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|--------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\kappa, \mu, r, q$                                    | $\kappa$ is an infinite cardinal used as a birthday cutoff, $\mu = 2^{<\kappa} =  \mathbf{No}_{<\kappa} $ , $r = \text{cf } \kappa$ and $q = \text{cf } \mu$ , as in source 17. Renamed: source 18's $\nu, \tau$ (printed $r, q$ ; in source 18's general principle, $\nu$ stays the point character of an abstract order $D$ ); source 14's $\tau = \text{cf } \kappa$ (printed $r$ ); source 15's $\delta = \text{cf } \kappa$ in its saturation section (printed $r$ ). Source 16 writes $\kappa$ for the cardinality of a general alphabet and $\theta$ for the cutoff; in its text these are printed $\mu$ and $\kappa$ . Sources 13–18's $X_\kappa$ and source 16's $X_\theta$ are printed $\mathbf{No}_{<\kappa}$ . <i>False reading:</i> $r$ is a cofinality, never a coding length (next row). |
| $X,  X  = \mu$                                         | A general alphabet: an infinite linearly ordered set, of cardinality $\mu$ (source 18's convention; source 16's $\kappa$ ).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| $\rho_\kappa, \mathbb{B}_\sigma \times_{\text{lex}} m$ | Source 15's $r_\kappa$ ( $\kappa \cdot \kappa$ at a singular strong-limit cutoff, $\mu$ otherwise; by <a href="#">theorem 8.3</a> it is $\ell_2(\mathcal{W}_\mu(\mathbf{No}_{<\kappa}))$ ), renamed to keep $r = \text{cf } \kappa$ ; and source 15's $D_{\sigma,m} = \mathbb{B}_\sigma \times_{\text{lex}} \{0, \dots, m-1\}$ , the binary cube with a finite chain of $m$ points as last coordinate, renamed because source 15's core is $\mathcal{D}$ .                                                                                                                                                                                                                                                                                                                                              |
| d, cell, w                                             | Source 18's letter $\rho$ for a regular cardinal is printed $\theta$ , as in source 17. Density, cellularity (a supremum, not necessarily attained) and weight of an order topology, as in the reals report; sources 15–18 write $d, c, w$ . Cellularity is never written $c$ . Source 15's $d(a, b)$ (a first-difference coordinate) and source 18's $d_* = \mu^{<\mu}$ keep their letters.                                                                                                                                                                                                                                                                                                                                                                                                            |
| ci, characters                                         | ci is coinitality. The left and right characters of a point $x$ are $\text{cf}(L_{<x})$ and $\text{ci}(L_{>x})$ (sources 17, 18; source 15 writes $\text{cf}^-(f)$ , $\text{ci}^+(f)$ ). A point character, the global cofinality of the order, and the character of a gap are three different invariants (source 18's warning).                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| GapChar( $L$ ), Reg                                    | The set of characters ( $\text{cf } A, \text{ci } B$ ) of the gaps $(A, B)$ of $L$ , a gap having nonempty sides with no endpoints (principal cuts and the external ends are excluded). Source 17's $\Sigma(L)$ and source 18's $\text{GapSpec}(L)$ are printed with the reals report's symbol GapChar; the report <b>surreal-fields-across-universes</b> writes GapSpec. Reg is the class of infinite regular cardinals (source 17's $\text{Reg}_\infty$ ; the reals report writes $\text{Reg}(<\kappa)$ for those below $\kappa$ ).                                                                                                                                                                                                                                                                   |
| $\eta_\nu$                                             | Source 17: for regular $\nu$ , every cut $A < B$ with $ A ,  B  < \nu$ is filled; sources 15 and 18: every cut with $ A  +  B  < \nu$ (resp. $ A \cup B  < \nu$ ) is filled, for any infinite cardinal $\nu$ . Empty sides are allowed throughout. For regular $\nu$ the three definitions agree with this report's $\eta_\kappa$ ( <a href="#">section 1.3</a> ), and every threshold statement printed concerns the regular cardinal $r$ .                                                                                                                                                                                                                                                                                                                                                            |
| $P, [p], C_p$ ; straddling                             | $P = \mathcal{W}_\mu(\mathbf{No}_{<\kappa})$ is the minimal slice (sources 17, 18; source 15 writes $L$ ). For an injective prefix $p$ , $[p]$ (source 17) and $C_p$ (sources 16, 18, and source 11 in Part IV) are the same cylinder. A cylinder that meets both sides of a cut <i>straddles</i> it; this is the word of sources 16, 17 and 18 and is used in all batch-81 Parts. Sources 13 and 14 say that a prefix <i>crosses</i> a cut, source 15 that it is <i>persistent</i> ; these words are explained where printed.                                                                                                                                                                                                                                                                          |
| $\mathcal{T}, \mathcal{I}, \mathcal{T}^{\text{inc}}$   | All set-length words, injective set-length words, numerically increasing set-length words. Source 16's $\mathcal{T}, \mathcal{T}^{\text{inj}}, \mathcal{T}^{\text{inc}}$ , whose macro <code>\Words</code> names <i>all</i> words while this report's <code>\Words</code> names the injective ones; source 13's $\mathcal{T}, \mathcal{I}$ agree with this report. Source 18's centered classes $\mathcal{C}, \mathcal{C}_{\text{inj}}, \mathcal{C}_{\text{inc}}$ are printed $\mathcal{T}_c, \mathcal{I}_c, \mathcal{T}_c^{\text{inc}}$ (its $\mathcal{C}$ would clash with $\mathcal{C}_b$ ). Source 16's termination types $T_{\min}, T_\kappa$ are printed $\mathbf{T}_{\min}, \mathbf{T}_\kappa$ . <i>False reading:</i> source 16's $\mathcal{T}$ is not the injective class.                     |

| Here                                                                            | Meaning, and the batch-81 sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|---------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\mathfrak{W}_{\text{sl}}(\mathbf{No}), \mathfrak{W}_{\text{all}}(\mathbf{No})$ | As in <a href="#">section 1.3</a> . Renamed: $\mathfrak{E}$ (sources 13, 14, 16, 17) for set-like global orders (source 15 already writes $\mathfrak{W}_{\text{sl}}$ ); source 14's $\mathfrak{W}$ (macro <code>\Hwell</code> ), source 16's $\mathfrak{H}$ and source 17's $\mathfrak{W}$ (macro <code>\HW0</code> ) for all class well-orders (sources 13 and 15 already write $\mathfrak{W}_{\text{all}}$ ). Source 18's macros <code>\Hsl</code> , <code>\Hall</code> print script $\mathcal{H}_{\text{sl}}$ , $\mathcal{H}_{\text{all}}$ there and $\mathfrak{W}_{\text{sl}}$ , $\mathfrak{W}_{\text{all}}$ here.                                                                                                                                                                                                                                                                                                  |
| $\mathfrak{J}$                                                                  | Class injections $\text{Ord} \rightarrow \mathbf{No}$ , as source 11's $\mathfrak{J}$ (sources 13, 14, 17 write $\mathfrak{J}$ with the macro <code>\J</code> ; source 16 writes $\mathfrak{J}$ with the macro <code>\I</code> ; source 15's $\mathfrak{J}$ ). <i>False reading</i> : source 16's <code>\I</code> is not this report's $\mathcal{I} = \mathcal{I}$ , the class of injective set-length words.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| $\mathcal{P}_{\text{bd}}(b), \mathcal{P}_{\text{s}}(b)$                         | The core, as in <a href="#">section 1.3</a> , in the source's own coding: normalized permutations $\mathcal{P}_{\text{bd}}(b)$ for sources 15 ( $\mathcal{D}$ ) and 16 ( $\mathcal{P}_b$ ); fixed-point-free support codes $\mathcal{P}_{\text{s}}(b)$ for sources 13 ( $\mathcal{D}$ ), 14 ( $\mathcal{P}_b$ ), 17 ( $\mathcal{C}_b$ ) and 18 ( $\mathcal{C}_b$ , macro <code>\Pbd</code> ). <i>False reading</i> : source 18's <code>\Pbd</code> is the support coding, not this report's $\mathcal{P}_{\text{bd}}(e_0)$ ; the two codings have the same evaluations.                                                                                                                                                                                                                                                                                                                                                 |
| $\mathcal{P}_{<\kappa}(b)$                                                      | Source 14's support-cardinality layer: codes whose support has cardinality less than $\kappa$ . <i>False reading</i> : it is not $\mathcal{P}_{\text{bd}}$ , whose subscript means bounded (set-sized) support; source 14 itself warns that a cardinality filtration and an ordinal-height filtration must not share the word "bounded".                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| $\simeq_e, <_{\text{lex}}$                                                      | Equimorphism is $\simeq_e$ for all six sources (source 16's $\simeq_{\text{emb}}$ ; source 18's macro <code>\equim</code> prints $\rightleftharpoons$ there and $\simeq_e$ here). Source 14's macro <code>\lex</code> prints the relation $<_{\text{lex}}$ ; this report's <code>\lex</code> is the subscript $\text{lex}$ , so source 14's relation is printed $<_{\text{lex}}$ . Source 18's bold $\mathbf{B}_\gamma$ is printed $\mathbb{B}_\gamma$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| Cuts of the core                                                                | A normalized class cut $(L, U)$ has a lower side $L$ without greatest element; the cut of an injective branch $F$ is written $L_F$ (source 16's $L_F$ , source 17's $L_f$ ; source 14's $D_F, D_p^\pm, D_{p,H}$ and source 13's $(L, U)$ are explained where printed). In Part VIII, source 13's code cylinder $\mathcal{D}_p$ is printed $\mathcal{P}_{\text{s}}(b)_p$ , and source 17's $\mathcal{C}_p$ and source 18's $\mathcal{C}_b(p)$ are printed $\mathcal{C}_p$ ; in source 14's support section its decreasing sequence $(r_i)$ is printed $(u_i)$ and the regular cardinal of its definition of $\eta$ -orders $\theta$ , since $r = \text{cf } \kappa$ there.                                                                                                                                                                                                                                               |
| $\varepsilon, \text{end}, \dagger$                                              | A formal termination symbol adjoined to the alphabet of a word order; it is never a surreal number. Source 16's $\varepsilon$ sits at a cut $L_\varepsilon < \varepsilon < R_\varepsilon$ of $\mathbf{No}$ , and its $0^-, 0^+$ sit immediately below and above zero; source 14 writes <code>end</code> ; source 18's centered $\dagger$ takes the place of zero, which is then not a letter, and its $\dagger_-, \dagger_+$ sit immediately below and above an available zero. Source 13's central termination pads a word with zeros, zero again not being a letter. Source 18 writes $\ell(p)$ for the length of a word $p$ and $\mathcal{J}$ for the increasing words, printed $\mathcal{T}^{\text{inc}}$ . <i>False reading</i> : the Conway sign order $- < \text{end} < +$ is not prefix-first dictionary order.                                                                                                 |
| $(\text{SNN}.n)$ , labels                                                       | Displayed equations of source $NN$ keep their numbers as $(\text{SNN}.n)$ , as for source 08. Labels: <code>swo:fs</code> : (13, replacing its <code>swf</code> :), <code>swo:tc</code> : (14), <code>swo:cb</code> : (15, keeping its internal <code>cce</code> : and <code>new</code> :, since dropping them would merge two of its labels), <code>swo:ds</code> : (16), <code>swo:gs</code> : (17), <code>swo:sh</code> : (18, keeping its internal <code>wv</code> :); unlabelled numbered statements get <code>swo:sub:nnumber</code> ; labels written for the merge in Part VI begin <code>swo:vi</code> :, in Part VII <code>swo:vii</code> :, in Part VIII <code>swo:viii</code> :, in Part IX <code>swo:ix</code> :. Two labels of source 13 printed in Part VI carry its old prefix as well, <code>swo:fs:swf:sec:fixed</code> and <code>swo:fs:swf:thm:fixed</code> ; like every label they are not renamed. |

| Here                               | Meaning, and the batch-81 sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
|------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Blocks, ranks, $\kappa$ in Part IX | Source 15's $B_W$ , $C_b$ (least representatives, block of $b$ ), source 16's $J_R$ , $\alpha_R$ and source 18's $B_R$ , $\theta_R$ (representatives of the proper blocks, type of the final set block) are kept; $\rho_R(x)$ (sources 16 and 18) is a rank inside a block, not $\rho_\kappa$ . <i>False readings:</i> in source 15's block section $b$ is not the baseline and $C_b$ is not a cylinder; source 14's $J_R$ is an initial branch, not source 16's $J_R$ . In Part IX's sections on larger universes $\kappa$ is strongly inaccessible (source 14's $\Omega$ , sources 17's and 18's $\lambda$ ). Source 18's plain $H_{sl}$ , $H_{all}$ are printed $\mathfrak{W}_{sl}$ , $\mathfrak{W}_{all}$ . |

### 1.3.2 Addendum of 3 October 2026: notation for sources 19–30

[merge] The twelve batch-83 sources (section 1.9) reuse the symbols of sections 1.3 and 1.3.1 with other meanings, give one object up to five names, and reuse this report's macro names (`\Words`, `\BB`, `\JJ`, `\End`, `\I`) for other objects. The convention below is fixed before any of their material is printed; it applies to Parts X–XIV and to the batch-83 sections of the front and back matter, and changes nothing earlier. The conventions of section 1.3.1 continue to hold. Every renaming is listed; the tempting false reading is printed where confusion is likely. Each printed section names the renamings it uses.

| Here                                                          | Meaning, and the batch-83 sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|---------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\kappa$ , $\mu$ , $r$ , $q$                                  | As in section 1.3.1: $\kappa$ is an infinite cardinal used as a birthday cutoff, $\mu = 2^{<\kappa} =  \mathbf{No}_{<\kappa} $ , $r = \text{cf } \kappa$ , $q = \text{cf } \mu$ ; for a general alphabet $ X  = \mu$ . Renamed: source 26 writes $\kappa$ for $ X $ and $\theta$ for the cutoff, printed $\mu$ and $\kappa$ throughout (so its $\mu = 2^{<\theta}$ reads $\mu = 2^{<\kappa}$ , and its $H_\kappa$ reads $H_\mu$ ); source 27 writes $\kappa$ for $ X $ and $\theta$ for a cardinal cutoff in its scan and convex-copy sections, printed $\mu$ and $\kappa$ ; source 23 writes $\kappa =  X $ and $\lambda$ for the cutoff in its spectra section, printed $\mu$ and $\kappa$ ; source 29's fixed set of cardinality $\kappa$ in its baseline section is printed with $\mu$ ; source 24's $r = \text{cf } \mu$ and source 28's $\delta = \text{cf } \mu$ are printed $q$ . Sources 19–30's $X_\kappa$ , $X_\theta$ and source 27's $S_{<\theta}$ are printed $\mathbf{No}_{<\kappa}$ , $\mathbf{No}_{<\theta}$ . <i>False reading:</i> source 26's and source 27's $\kappa$ is not a birthday cutoff. |
| $\theta$ noncardinal; $\mu = 2^\kappa$ there                  | At a <i>noncardinal</i> cutoff (an infinite ordinal $\theta$ that is not a cardinal: source 21's noncardinal section, source 29's birthday-spectrum and noncardinal sections) the sources write $\kappa =  \theta $ and $\mu =  \mathbf{No}_{<\theta}  = 2^\kappa$ ; this is kept, with $\theta$ for the cutoff. <i>False reading:</i> there $\mu = 2^\kappa$ , not $2^{<\kappa}$ , and $\kappa$ is $ \theta $ , not the cutoff. In Part XI $\theta$ is any cutoff ordinal and $\mathbf{No}_{<\alpha} = \{x : \text{bd}(x) < \alpha\}$ for every ordinal $\alpha$ (source 20's $X_\alpha$ , source 29's $X_\theta$ ); elsewhere $\theta$ keeps its meaning in section 1.3.1 (a regular cardinal).                                                                                                                                                                                                                                                                                                                                                                                                                    |
| $\rho_\kappa$ ; $\text{wt}$ , $\varrho_{lo}$ , $\varrho_{up}$ | $\rho_\kappa$ is $\kappa \cdot \kappa$ at a singular strong-limit cutoff and $\mu$ otherwise (section 1.3.1). Source 19's and source 29's $r_\kappa$ are printed $\rho_\kappa$ (source 30 already writes $\rho_\kappa$ ). The residual-layer weights ( $\lambda \cdot \lambda$ for a singular strong-limit $\lambda$ , else $\lambda$ ), source 19's and source 29's $r(\lambda)$ , $u_\kappa(\lambda)$ and source 30's $r(\nu)$ , are printed $\text{wt}(\lambda)$ , $\text{wt}_\kappa^+(\lambda)$ , $\text{wt}(\nu)$ (Parts X and XI). The weighted lower and upper lengths $R$ , $U$ of sources 19 and 29 are printed $\varrho_{lo}$ , $\varrho_{up}$ , since $R$ , $S$ name raw class orders. Their $D_{\rho,m}$ (also source 30's) is printed $\mathbb{B}_\rho \times_{\text{lex}} m$ , as source 15's $D_{\sigma,m}$ was; source 21's $\text{br}$ and source 29's $\ell_2$ are this report's $\ell_2$ . <i>False reading:</i> $\varrho_{lo}$ is an ordinal, never a relation, and $r$ is still $\text{cf } \kappa$ .                                                                                           |

| Here                                                                                                                                                                                   | Meaning, and the batch-83 sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\mathcal{P}_{\text{bd}}(b), \mathcal{P}_{\text{s}}(b)$ (the core)                                                                                                                     | The ordinary class of set codes of bounded-support perturbations of a baseline $b : \text{Ord} \rightarrow \mathbf{No}$ , ordered by evaluation, in the source's own coding (section 1.3): normalized permutations of an ordinal, printed $\mathcal{P}_{\text{bd}}(b)$ , for sources 19 ( $\mathcal{C}$ ), 20, 24, 26 and 28 ( $\mathcal{C}_b$ ), 21 ( $S_b = \mathcal{P}_b$ ) and 29 ( $P_e$ , printed $\mathcal{P}_{\text{bd}}(e)$ , its baseline being $e$ ); fixed-point-free support codes, printed $\mathcal{P}_{\text{s}}(b)$ , for sources 22, 25 and 27 ( $\mathcal{D}_b$ ) and 30 ( $\mathcal{B}_b$ ). The two codings have the same evaluations. <i>False reading</i> : source 25's $\mathcal{C}_b$ , printed $\mathbf{C}_b$ (next row), is not the core.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| $\mathbf{C}_b$                                                                                                                                                                         | Source 25's two-sorted reduct: the core with its order, the injective set-length words as nodes with the prefix order, and the incidence of codes in node cylinders; no label relation. Source 25's script $\mathcal{C}_b$ (macro $\backslash \mathbf{C}$ ), printed $\mathbf{C}_b$ ; its set version at a regular $\kappa$ is $\mathbf{C}_b^\kappa$ , with $\mathcal{P}_{\text{s}}^\kappa(b)$ , $\mathcal{I}^\kappa$ , $\mathfrak{J}^\kappa$ for its $\mathcal{D}_{b,\kappa}$ , $\mathcal{T}_\kappa$ , $\mathfrak{J}_\kappa$ , and source 25's direction sign $\varepsilon(f, g)$ is printed $\text{sgn}(f, g)$ . <i>False reading</i> : sources 20, 24 and 26 write the calligraphic $\mathcal{C}_b$ for the core itself.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| $\mathcal{T}, \mathbf{T}_{\min}, \mathbf{T}_{\min}^+$                                                                                                                                  | $\mathcal{T}$ is the class of all set-length surreal words, with repetitions (section 1.3); source 21's $\mathcal{T}$ (macro $\backslash \text{Words}$ ) is printed $\mathcal{T}$ . Its shorter-first order, the type $\mathbf{T}_{\min}$ of source 16's termination family (theorem 36.2), is written $\mathbf{T}_{\min}$ , and $\mathbf{T}_{\min}^+$ is its nonempty part: source 27's $\mathcal{B} = \text{Words}_\perp(\mathbf{No})$ (macro $\backslash \text{Bword}$ ) and $D = \mathcal{B} \setminus \{\emptyset\}$ , source 29's bold $\mathbf{T}$ and $\mathbf{P}$ (macro $\backslash \text{Pnon}$ ). <i>False reading</i> : source 21's and source 27's macro $\backslash \text{Words}$ is not this report's $\mathcal{I}$ ; source 27's $\mathcal{B}$ is a word order, not a cube $\mathbb{B}$ , not source 28's ideal $\mathcal{B}_\mu$ , not source 24's $\mathfrak{B}$ (macro $\backslash \text{BB}$ , unused).                                                                                                                                                                                                                                                                                                                              |
| $\mathcal{I}$ , the prefix tree                                                                                                                                                        | Injective set-length surreal words (section 1.3), and, with the prefix order $\sqsubseteq$ , the ordered prefix tree. Renamed: the node classes $\mathcal{T}$ of sources 22, 25 and 27 (macros $\backslash \mathbf{T}$ , $\backslash \text{Tree}$ ); source 26's $\mathcal{T}_{\text{inj}}(\mathbf{No})$ ; source 29's script $\mathcal{I}$ is already $\mathcal{I}$ . <i>False reading</i> : $\mathcal{T}$ is $\mathcal{T}$ in this report, never the injective tree.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| $\varepsilon; \mathcal{T}_\varepsilon, \mathcal{I}_\varepsilon, \mathcal{T}_\varepsilon^{\text{inc}}$                                                                                  | A formal marker at a cut $A = L \sqcup R$ of an alphabet, as source 16's $\varepsilon$ (section 1.3.1), and the all, injective and strictly increasing set-length words over $A$ compared with it. Renamed: source 23's $\mathbf{e}$ , $\mathcal{W}_\mathbf{e}$ , $\mathcal{I}_\mathbf{e}$ , $\mathcal{U}_\mathbf{e}$ ; source 27's $\dagger$ at a cut and its $\text{Inc}_C$ ; source 29's $\dagger$ at a cut (macro $\backslash \text{End}$ ) and its $\text{Inc}_\dagger$ . The symbol $\dagger$ stays reserved for source 18's centered terminator in the place of zero, with $\dagger_-$ , $\dagger_+$ ; in the Conway sign order source 29's $\backslash \text{End}$ is printed <b>end</b> ( $- < \text{end} < +$ ). <i>False reading</i> : source 29's $\backslash \text{End}$ is not this report's <b>end</b> = <b>end</b> .                                                                                                                                                                                                                                                                                                                                                                                                                      |
| $\mathcal{T}_{\text{sf}}^{\text{inc}}, \mathcal{T}_{\text{lf}}^{\text{inc}}; \mathcal{T}_c^{\text{inc}}, \mathcal{T}_{\dagger\pm}^{\text{inc}}, \mathcal{T}_{\text{pad}}^{\text{inc}}$ | Increasing words over an alphabet with proper prefixes first or last (source 27's $\text{Inc}_\perp$ , $\text{Inc}_\dagger$ ; source 29's $\text{Inc}_{\text{sf}}$ , $\text{Inc}_{\text{lf}}$ ); over $\mathbf{No}$ the first is $\mathcal{T}^{\text{inc}}$ , and source 29's increasing tree $\mathcal{J}$ is $\mathcal{T}^{\text{inc}}$ with $\sqsubseteq$ . The centered increasing words with zero excluded (source 18's $\mathcal{T}_c^{\text{inc}}$ ), with zero retained and $\dagger_-$ or $\dagger_+$ , and the zero-padding quotient: source 27's $J, J_-, J_+, Q_0$ and source 29's $\mathcal{C}, \mathcal{C}_-, \mathcal{C}_+, \mathcal{C}_{\text{pad}}$ . Source 27's residual maps $J(S, T; a, c)$ are unrelated and keep their letter. <i>False reading</i> : source 29's $\mathcal{C}$ is neither a core nor a cylinder.                                                                                                                                                                                                                                                                                                                                                                                                                  |
| $\mathcal{W}_\mu(X), \mathcal{I}_\mu(X), \mathcal{I}_{<\mu}(X), \mathcal{I}_\mu^{\text{b}}$                                                                                            | For $ X  = \mu$ infinite: the minimal slice $\text{Bij}(\mu, X)$ ; the injections $\text{Inj}(\mu, X)$ , which form the length- $\mu$ layer of this report's $\mathcal{I}(X)$ ; the short prefixes $\bigcup_{\alpha < \mu} \text{Inj}(\alpha, X)$ ; and the forward-bounded injections of $\mu$ (bounded sets have bounded images). Renamed: the $\mathcal{P}_\mu(X), \mathcal{I}_\mu(X)$ of sources 21, 24, 26 and 28 (source 26's $\mathcal{P}_\kappa, \mathcal{I}_\kappa$ ), source 24's $\mathcal{T}_\mu(X)$ , source 26's $\mathcal{B}^+$ and source 28's $\mathcal{I}_\mu^{\text{b}}$ . Source 28's $S_\mu = \text{Sym}(\mu)$ and its subgroup $H_\mu$ (source 24's $H_\mu$ , source 26's $H_\kappa$ ) keep their letters; its one-sided loci $B_\mu^+, B_\mu^-$ are printed $H_\mu^+, H_\mu^-$ , so that $H_\mu = H_\mu^+ \cap H_\mu^-$ . Where these sources write $\mathcal{P}$ for the slice itself it is printed $P$ . <i>False reading</i> : $\mathcal{P}_\mu(X)$ is neither $\mathcal{P}_{\text{bd}}$ nor $\mathcal{P}_{\text{s}}$ , and $\mathcal{I}_\mu(X)$ is only one layer of $\mathcal{I}(X)$ (all injective words of length below $\mu^+$ ); source 11's $\mathcal{P}_\lambda(X)$ was renamed $\mathcal{W}_\lambda(X)$ (section 1.3). |

| Here                                                                                                                                                 | Meaning, and the batch-83 sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |

| $\mathcal{J}_b, \mathcal{J}$ , topologies                                                                                                            | Source 28's bounded ideal $\mathcal{B}_\mu$ (macro <code>\BB</code> ), printed $\mathcal{J}_b$ , and its admissible coordinate ideals $\mathcal{J}$ (macro <code>\JJ</code> ), with topologies $\tau_{\mathcal{J}}, \tau_b, \tau_{<\mu}, \tau_{\leftrightarrow}$ ; source 29's $\tau_{\text{lex}}, \tau_{\text{coord}}$ . <i>False reading:</i> $\mathcal{J}$ and $\mathcal{J}_b$ are not $\mathfrak{J} = \mathfrak{J}$ , and this report's <code>\BB</code> is the cube $\mathbb{B}$ ; source 26's <code>\JJ</code> is $\mathfrak{J}$ , printed $\mathfrak{J}$ , and source 24's $\mathfrak{J}$ (its <code>\JJ</code> ) is $\mathfrak{J}$ too. $\tau(h)$ is still the reserve of a partial injection (theorem 49.7), as in source 27.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| $\mathfrak{W}_{\text{sl}}, \mathfrak{W}_{\text{all}}, \mathfrak{J}; \mathfrak{W}_{\text{all}}^{\mathcal{M}}, \mathfrak{W}_{\text{sl}}^{\mathcal{M}}$ | As in sections 1.3 and 1.3.1. Renamed: $\mathfrak{E}$ (sources 22, 23, 24, 25, 26, 28), $\mathfrak{W}$ (sources 23, 25: <code>\Raw</code> ; 26: <code>\HH</code> ), source 19's script $\mathcal{H}_{\text{sl}}, \mathcal{H}_{\text{all}}$ and source 30's macros <code>\SL, \ALL</code> . The external sets of admitted class well-orders and of set-like ones of a set-sized two-sorted model $\mathcal{M}$ , as in Part IX: source 19's $\mathcal{H}_{\text{all}}^{\mathcal{M}}, \mathcal{H}_{\text{sl}}^{\mathcal{M}}$ , source 20's $H^{\mathcal{M}}$ , source 30's $\mathcal{W}^{\mathfrak{M}}$ (printed $\mathfrak{W}_{\text{all}}^{\mathfrak{M}}$ ); source 21's $L, L^{\mathcal{M}}$ are kept in its text, where they are defined. The external set-like order of a realization $(M, \mathcal{X})$ , the $H_{\mathcal{X}}$ of sources 21 and 27, keeps that name; source 30's $\mathcal{E}(\mathcal{C})$ (the graphs of the admitted set-like enumerations) and $\mathcal{K}_c(\mathcal{C})$ keep theirs. Realizations are written $\mathcal{X} \subseteq \mathcal{Y}$ (sources 21, 22, 27) or $\mathcal{C} \subseteq \mathcal{D}$ (source 30). <i>False reading:</i> source 30's $\mathcal{C}, \mathcal{D}$ are class collections, not cores, and $H_{\mathcal{X}}$ is not a fibre $H_q$ or a history $H_i$ . |
| $I_\infty, \mathcal{F}, \sigma(\mathcal{A})$                                                                                                         | $I_\infty = \omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*$ , the external type of an internally finite interval of nonstandard length in a countable model (source 20's symbol; source 19's $K$ and source 21's $H$ renamed); $\mathcal{F} = \{n! : n \in \omega\}$ (source 20; source 19's $\mathcal{D}$ ); and $\sigma(\mathcal{A})$ , the dense shuffle of a set $\mathcal{A}$ of colours, as in Part IX (all three write $\sigma$ ). <i>False reading:</i> $I_\infty$ has a first and a last element; $\sigma(\mathcal{A})$ is not a core code $\sigma$ or $E_\sigma$ (Part VIII).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| $H_q; H, H_i, D_W(A), p_i, c_i, \text{NF}_H$                                                                                                         | Source 19's $H_q$ is the admitted raw fibre over a core cut $q$ . Condensation histories (sources 20 and 29): the least-representative condensation operator $D_W(A)$ , history slices $H_i$ (source 20's $H_x$ ), floor maps $p_i$ , digits $c_i$ , the finite normal form $\text{NF}_H$ . Source 23 writes $D(H)$ for one condensation of a class well-order $H$ and $E_t$ for its stages (unions at limits). Source 30's orientation predicate $H$ is its own. <i>False reading:</i> source 23's $H$ is a class well-order, not a history; $H_\mu$ is a group.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| $C(R, S), Y(R, S), \equiv_{\text{set}}, K_R; E, T_R, n(R)$                                                                                           | Source 20's local-size section: the common-prefix carrier (its $P(R, S)$ , printed $C(R, S)$ as in Part III), the residual $Y(R, S) = \mathbf{No} \setminus C(R, S)$ , “the residual is a set”, and $K_R$ , the largest final set segment (source 16's $A_R$ ). The internal-finite-residual equivalence $E$ and the maximal finite terminal tail $T_R$ with its length $n(R) = n_R$ (sources 18–21); source 19's $E(x, y), S(x)$ are first-order formulas of the pure order; source 21's $C_R, P_R$ are its own. <i>False reading:</i> source 18's $K_R$ (Part IX) is an initial set-like part of $B_R$ , and source 20's $A_R$ is printed $\text{Min}_R$ (next row).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| $\pi_Y, \pi_{\beta\alpha}, \text{lr}_\alpha(x), \text{Min}_R$                                                                                        | Restriction maps $R \mapsto R \upharpoonright Y$ (source 19's $r_Y$ ) and $\mathcal{W}(\mathbf{No}_{<\beta}) \rightarrow \mathcal{W}(\mathbf{No}_{<\alpha})$ (source 20's $\rho_{\beta\alpha}$ ); source 20's local ranks $r_\alpha(x)$ and its class $A_R$ of strong-limit cutoffs $\kappa$ at which $\text{otp}(R \upharpoonright \mathbf{No}_{<\kappa}) = \kappa$ . Source 20's $X_\alpha$ is $\mathbf{No}_{<\alpha}$ for every ordinal $\alpha$ . <i>False reading:</i> $\text{Min}_R$ is not source 16's $A_R$ , now $K_R$ , and not source 30's $A_\alpha = e[\alpha]$ ; $\rho_\kappa$ keeps its meaning.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| $P_{\omega+n}, E_n, S_n, \text{Tab}_n$                                                                                                               | For a countable dense alphabet $D$ (in particular $\mathbf{No}_{<\omega}$ or $\mathbb{Q}$ ): $P_{\omega+n} = \text{Bij}(\omega + n, D)$ and $E_n$ , the $\omega$ -injections omitting exactly $n$ labels. Source 29's notation is kept; source 30's $P_n$ is printed $P_{\omega+n}$ , its alphabet $X$ is $D$ , its set $D_n$ of nonisolated points is $S_n$ (source 29's $S$ ), and its relation tables $\mathcal{T}_n$ of type $\omega + n$ are printed $\text{Tab}_n$ (here $\mathcal{T} = \mathcal{T}$ ), with its maps $\Phi_n, r_n$ ; source 29's real completion $C$ is printed $\hat{I}$ . <i>False reading:</i> source 30's $P_2$ is $P_{\omega+2}$ , not $\text{Bij}(2, D)$ , and $\text{Tab}_n$ is not $\mathcal{T}$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

| Here                                                                   | Meaning, and the batch-83 sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $s, \vartheta, t_R, N(p), \mathcal{L}_s(X)$                            | A relation-table scan $s : \vartheta \rightarrow X \times X$ , the table bits of $R$ , realized prefix cylinders and the linear-order tables: source 27's $q : \theta \rightarrow X \times X$ , $b_R, C(p), \mathcal{L}_q$ (and source 29's scan $s$ ). Source 27's density and cellularity $d, c$ are printed $d$ , cell, its $\mathbb{B}_\kappa$ is $\mathbb{B}_\mu$ , and its gap characters $\lambda, \rho$ are printed $\lambda_L, \lambda_R$ . <i>False reading:</i> $s$ is not this report's $q = \text{cf } \mu$ , and $t_R$ is not a baseline.                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| $\text{Inv}(W), g; U(A), \prec_{\text{sf}}, \prec_{\text{lf}}$         | Source 30's inversion class $I(W)$ and the rank $\rho$ of a forced relation of a partial table, printed $\text{Inv}(W)$ (this report's $\mathcal{I}$ is the injective words) and $g$ ; its inverse ranks $\text{rk}_R$ are printed $r_R$ , as in Part VII. Source 29's next-label class $U(A)$ above a numerical class carrier (Part VII's $U(q)$ for set words) and its shorter- and longer-first carrier orders $\prec_{\text{sf}}, \prec_{\text{lf}}$ ( $\prec_{\text{lf}}$ is source 15's $<_\chi$ ).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| $P(\Gamma); \text{CTH}, \text{CWO}$                                    | Finite-support functions from a class well-order $\Gamma$ to nonzero ordinals, compared at the greatest disagreement, as Part IX prints source 15's $P(J)$ ; source 23's $P(\Gamma)$ (macro <code>\Po1</code> ) and source 29's $\mathcal{P}(\Gamma)$ are printed $P(\Gamma)$ . <b>CTH:</b> every class well-order $W$ has its canonical terminating history on $W + 1$ ; <b>CWO:</b> strong comparability of class well-orders (source 29). <i>False reading:</i> $P(\Gamma)$ is not a power class; $\mathcal{P}(V_\kappa)$ remains the power set.                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| $\mathbb{B}, \simeq_e, \times_{\text{lex}}, \text{Ord as a character}$ | As before: the cube $\mathbb{B}_\gamma$ (source 19's bold <b>B</b> , source 27's <code>\Binary</code> ), equimorphism $\simeq_e$ (source 27's $\rightleftharpoons$ , source 30's <code>\eqemb</code> ), $\times_{\text{lex}}$ (source 29's $\otimes_{\text{lex}}$ ). In a character pair, <b>Ord</b> means “no set-sized cofinal (coinitial) family”, never a cardinal (source 23's <b>On</b> , source 20's $\Omega$ ).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| Labels                                                                 | Sub-prefixes: <b>swo:rs:</b> (19), <b>swo:lm:</b> (20), <b>swo:fu:</b> (21), <b>swo:rg:</b> (22), <b>swo:tm:</b> (23), <b>swo:pc:</b> (24), <b>swo:ph:</b> (25), <b>swo:nb:</b> (26), <b>swo:sc:</b> (27), <b>swo:ge:</b> (28), <b>swo:bw:</b> (29), <b>swo:rt:</b> (30). Each delivered label $L$ becomes <b>swo:sub:</b> $L$ , internal prefixes included: source 21's and source 29's <b>gl:</b> become <b>swo:fu:gl:</b> and <b>swo:bw:gl:</b> and are unrelated to source 11's <b>swo:gl:</b> ; source 30's <b>fnd:</b> labels and its <b>fnd:prop:pairs</b> , <b>fnd:thm:faithful</b> (names also used by sources 21 and 22) are distinct under <b>swo:rt:</b> . Unlabelled numbered statements get <b>swo:sub:nnumber</b> ; displayed equations keep their numbers as $(\text{SNN}.n)$ . Labels written for the merge begin <b>swo:x:</b> , <b>swo:xi:</b> , <b>swo:xii:</b> , <b>swo:xiii:</b> , <b>swo:xiv:</b> in Parts X–XIV and <b>swo:b83:</b> in the front and back matter. |

### 1.3.3 Addendum of 3 October 2026: notation for source 31

[merge] Source 31 (section 1.10) works in first-order Zermelo set theory and in full-class rank models, and uses symbols that this report uses otherwise. The convention below applies to Part XV, to source 31's questions (section 113.26) and to its abstract (Appendix C); it changes nothing earlier, and the conventions of sections 1.3.1 and 1.3.2 continue to hold. Every renaming is listed; the tempting false reading is printed where confusion is likely.

| Here          | Meaning, and source 31's symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|---------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $Z, ZC, ZC_F$ | Zermelo set theory in Glazer's convention, as source 31 fixes it: Extensionality, Empty Set, Pairing, Union, Power Set, Infinity and the Separation schema, with no Replacement, Collection, Foundation or Choice; $ZC = Z + \text{Choice}$ , and $ZC_F$ adds Foundation. Source 31's macro <code>\Z</code> is printed with <code>\Zer</code> (same symbol). <i>False reading:</i> $Z$ is a theory, not the integers; $ZC$ has neither classes nor Replacement, unlike <b>GB</b> (section 1.3). |

| Here                                                            | Meaning, and source 31's symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|-----------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $c, \text{Sep}(c), \text{GC}_{\leq \omega}, \text{GC}_{\leq D}$ | A total unary operation symbol $c$ ; $\text{Sep}(c)$ is Separation for every formula that mentions $c$ ; $\text{GC}_{\leq \omega}$ requires $c(X) \in X$ only for nonempty $X \rightarrow \omega$ , and $\text{GC}_{\leq D}$ only for nonempty $D$ -small $X$ . <i>False reading:</i> $\text{GC}_{\leq \omega}$ is a restricted selector over $\text{ZC}$ , not this report's global choice $\text{GC}$ over $\text{GB}$ ; in the column "GC" of the table in <a href="#">section XV.11</a> , $\text{GC}$ is full global choice.                                                                                                                                                                                                                                                                                                                     |
| $X \rightarrow D$                                               | There is an injection of $X$ into $D$ , given by a set graph (by a class, where the text says "class injection"); source 31's $\hookrightarrow$ (macro <code>\inj</code> ), renamed. <i>False reading:</i> $\hookrightarrow$ remains an order embedding throughout this report; $\rightarrow$ is no order embedding.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| $D, \text{Small}_D, \mathcal{C}_D, \prec_D$                     | A fixed well-ordered set $(D, <_D)$ ; $\text{Small}_D(X)$ iff $X \rightarrow D$ ; the code set $\mathcal{C}_D = \mathcal{P}(D) \times \mathcal{P}(D \times D)$ and a fixed well-order $\prec_D$ of it. <i>False reading:</i> $D$ is not Part X's countable dense alphabet, and $\mathcal{C}_D$ is not a core (sources 20, 24 and 26 wrote $\mathcal{C}_b$ for the core, printed $\mathcal{P}_{\text{bd}}(b)$ ).                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| $\text{Thr}_X, W_X, i_X, e_X$                                   | The set of threads on $X$ (source 31's $\mathcal{T}_X$ , renamed because $\mathcal{T} = \mathcal{T}$ is the class of all set-length words here); the selector-compatible well-order of <a href="#">lemma XV.3.1</a> ; the uniform injections into $D$ and the countable enumerations of <a href="#">theorem XV.3.3</a> and <a href="#">corollary XV.3.5</a> .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| $H_a, Q, \Theta, T, \mathbb{T}$                                 | In <a href="#">sections XV.4</a> and <a href="#">XV.5</a> : the incidence trace $H_a \subseteq I \times D$ , the partial surjection $Q$ , Glazer's obstruction sentence $\Theta$ and its target set $T$ , and the base theory $\mathbb{T}$ ( $\text{ZC}$ or $\text{ZC}_F$ ). <i>False reading:</i> $H_a$ is not a fibre $H_q$ , a history slice $H_i$ or the group $H_\mu$ ; the sans-serif theory $\mathbb{T}$ is not the order type $\mathbf{T}_{\min}$ .                                                                                                                                                                                                                                                                                                                                                                                          |
| $\mathcal{M}_\lambda, \lambda, \kappa$                          | $\mathcal{M}_\lambda = (V_\lambda, \mathcal{P}(V_\lambda))$ for a limit ordinal $\lambda > \omega$ , with every external subset of $V_\lambda$ as a class (source 31's macro <code>\M</code> , printed with <code>\RM</code> , same symbol); at a strongly inaccessible $\kappa$ it is source 12's $\mathcal{M}$ of <a href="#">section 21</a> . The height $\lambda$ is also the birthday cutoff of $S_\lambda$ , and $\kappa =  \lambda $ , as in the noncardinal convention of <a href="#">section 1.3.2</a> with $\lambda$ for $\theta$ . <i>False reading:</i> $\kappa$ is the cutoff only when $\lambda$ is a cardinal; $\mathcal{M}_\lambda$ is not one of the arbitrary set-sized GBC models $\mathcal{M}$ of Parts IX and XIV, and it satisfies Class Replacement only at strongly inaccessible heights ( <a href="#">theorem XV.9.3</a> ). |
| $S_\lambda, \text{bd}$                                          | The sign carrier $S_\lambda = \bigcup_{\alpha < \lambda} {}^\alpha 2$ and $\text{bd}(s) = \text{dom}(s)$ . Reading 0, 1 as $-, +$ , $S_\kappa = \mathbf{No}_{< \kappa}$ as a set of sign sequences, and $ S_\kappa  = 2^{< \kappa} = \mu$ ( <a href="#">lemma XV.7.1</a> ). Kept, not renamed $\mathbf{No}_{< \lambda}$ , because source 31 asserts no field operations on $S_\lambda$ at arbitrary cutoffs (Part XI's $\mathbf{No}_{< \theta}$ is the same set, used as an ordered alphabet). <i>False reading:</i> $S_\lambda$ is neither source 28's $S_\mu = \text{Sym}(\mu)$ nor Part X's set $S_n$ . Source 12's $S_\kappa$ , printed $\mathbf{No}_{< \kappa}$ in Parts I–V, is the same set as source 31's $S_\kappa$ .                                                                                                                       |
| $\text{CR}(a), \text{CR}(\text{Ord}), \text{CR}, \text{OA}$     | Class Replacement for the admitted class functions on the internal set $a$ , on every internal ordinal, and on every internal set; ordinal abstraction (every internal set well-order is isomorphic to an internal von Neumann ordinal by an internal set graph).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| Numbers, labels                                                 | The sections of Part XV are numbered XV.1–XV.15, and source 31's statement $k.m$ is printed as XV. $k.m$ ; its equations (1)–(10) are tagged (S31.1)–(S31.10); its research questions 1–12 are printed in <a href="#">section 113.26</a> . Labels: <code>swo:gcz:</code> before each delivered label; unlabelled numbered statements <code>swo:gcz:nnumber</code> ( <code>swo:gcz:n3.4</code> ); its questions <code>swo:gcz:n1–swo:gcz:n12</code> , numbered consecutively as source 28's <code>swo:ge:nk</code> ; labels written for the merge <code>swo:gcz:part</code> , <code>swo:gcz:sub:...</code> , <code>swo:gcz:sec:status</code> , <code>swo:gcz:sec:qstatus</code> and <code>swo:gcz:app:...</code> . Source 31 defines a macro <code>\rk</code> that it never uses; its <code>\restr</code> and <code>\code</code> are this report's.   |

### 1.3.4 Addendum of 4 October 2026: notation for sources 32–35

[merge] Sources 32–35 (section 1.11) work with class well-orders as presentations, in GB, GBC and full or definable class models over  $V_\kappa$ , and use several symbols that this report and each other use otherwise. The convention below applies to Part XVI, to their questions (section 113.28) and to their abstracts (Appendix C); it changes nothing earlier, and the conventions of sections 1.3.1 to 1.3.3 continue to hold. Every renaming is listed; the tempting false reading is printed where confusion is likely.

| Here                                                                        | Meaning, and the sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|-----------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\Omega$                                                                    | The presentation $(\text{Ord}, <)$ of the class of ordinals, used as a factor, base or exponent (sources 32 and 35 write $\backslash\text{Om}$ , source 33 $\backslash\text{On}$ ). <i>False reading:</i> $\Omega$ is not a set ordinal of the same universe and not a surreal number; it is not source 14's inaccessible $\Omega$ (printed $\kappa$ in Part IX) nor source 20's $\Omega$ in a character pair (printed $\text{Ord}$ ). In the external models of Section XVI.8 it has external type $\kappa$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| $A^{[B]}, A^{[B]}, P(\Gamma)$                                               | The finite-support power: finite partial functions from $B$ to $A$ minus its least point, compared at the greatest disagreement; $P(\Gamma) = \Omega^{[\Gamma]}$ is the polynomial order of Parts IX and XIV (source 15's $P(J)$ , source 23's $P(\Gamma)$ , source 29's $P(\Gamma)$ ). Source 34 writes $\backslash\text{Pow}\{A\}\{B\}$ (printed with $\backslash\text{fsp}$ , because $\backslash\text{Pow}$ is this report's power set) and $P(\Gamma)$ as $\backslash\text{PWO}$ ; source 35 writes $A^{[B]}$ and $P(\Gamma)$ , printed $P(\Gamma)$ ; sources 32 and 33 write $A^B$ and $P_\Gamma$ , printed $A^{[B]}$ and $P(\Gamma)$ wherever the operands are class orders. For set ordinals $A^{[B]}$ is ordinary ordinal exponentiation, and $\Omega^n$ for finite $n$ abbreviates $\Omega^{[n]} = \Omega \cdots \Omega$ . <i>False reading:</i> $A^{[B]}$ is not the class of all functions $B \rightarrow A$ and not cardinal exponentiation; in a hereditary term display $\Omega^t a$ the superscript is a term, not a power. A superscript $M$ , as in $\text{Ord}^M$ , is relativization to a model. |
| $\mathcal{E}, \mathcal{E}(A), \mathcal{E}[\kappa], \mathcal{E}^{\leq n}$    | The class of hereditary finite base- $\Omega$ terms (source 34's $\backslash\text{Eps} = \mathcal{E}$ , source 35's $\mathcal{E}$ ), its version over a base class well-order $A$ (source 34's $H(A)$ , source 32's $\mathcal{H}(A)$ ), the terms with coefficients below $\kappa$ , and the terms of height at most $n$ (source 34's $E_n$ ). <i>False reading:</i> $\mathcal{E}$ is not source 09's $\mathcal{E}_\kappa$ of Part V or the $\mathcal{E}$ of Section 1.3, and $\mathcal{E}(A)$ is not a history; $\mathcal{E}[\kappa]$ is not an initial segment of $\mathcal{E}$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| $\mathbb{T}, T_n$                                                           | Source 33's tower $T_0 = \Omega$ , $T_{n+1} = \Omega^{[T_n]}$ and its direct limit, which source 33 writes $E$ . <i>False reading:</i> $\mathbb{T}$ is an order isomorphic to $\mathcal{E}$ (section XVI.6.8), not a truth predicate.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| $\hookrightarrow, \nrightarrow, \preceq_{\text{init}}, \prec_{\text{init}}$ | An order embedding exists; none exists; an embedding with initial image exists; one with proper initial image exists. Sources 33 and 34 write $\preceq_{\text{emb}}$ , source 32 $\preceq_e$ and $\preceq_i$ , sources 33–35 $\preceq_{\text{init}}$ ; all are printed as here. <i>False reading:</i> $\hookrightarrow$ needs no initial image and does not give a comparison of lengths without CWO.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| $H, H_i, D_W, p_i, c_i, \text{NF}_H, \text{CWO}, \text{CTH}, \text{ETR}$    | As in Part XIV (section 108): histories, their slices, the condensation operator, floors, digits, normal forms and the three principles. $E_i, E_t, E_c, E_b, F_b$ are the stage equivalences of a history or a tower (sources 35, 32, 33). <i>False reading:</i> source 32's $D_W$ meant the domain of $W$ and is printed $\text{dom } W$ ; its and source 33's $D, D_n$ are diagonal orders, not $D_W$ ; source 34's $\Delta$ is its diagonal sum.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| $G, T, T_A, A$                                                              | A named set-like global well-order; a full satisfaction class (source 34's $T$ for $(V, \in, A, G)$ , source 33's $T$ for $(V_\kappa, \in, G)$ , source 32's $T_A$ for $(V_\kappa, \in, G, A)$ ); a named class predicate. <i>False reading:</i> $G$ is not source 23's exponent class $G$ of Part XIV, and $T$ is not $\mathbf{T}_{\text{min}}$ . Source 35 also writes $T$ for the class of terms of its lemma XVI.4.8 and for the reflection tree in Section XVI.8, printed as delivered; in neither place is it a truth predicate.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |

| Here                                                                                           | Meaning, and the sources' symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\Theta_L, \delta_A, \delta_G, \delta_G^0, \delta_0, \delta_{\text{ord}}, \delta_{\text{set}}$ | External suprema of definable order types: source 34's $\Theta_L$ for a finite language $L$ with set parameters (and $\Theta_{A,G}$ ), source 32's $\delta_A$ for $\{\in, G, A\}$ , source 33's $\delta_G$ and parameter-free $\delta_G^0$ for $\{\in, G\}$ , source 35's $\delta_0, \delta_{\text{ord}}, \delta_{\text{set}}$ for $\{\in\}$ with no, ordinal or set parameters; over $V_\kappa$ these are one invariant (the [merge] paragraph at the end of source 34's text in Section XVI.8). Source 34's remainder $\delta$ in $\Omega \cdot Q + \delta$ is Part IX's $\theta_R$ . <i>False reading:</i> $\Theta_L$ is not Glazer's obstruction sentence $\Theta$ of Part XV nor the inaccessible $\Theta$ of <a href="#">section 71</a> ; none of these suprema exists inside the model. |
| $\mathcal{S}_{\text{par}}^L, \mathcal{S}_0^L, S_A, S_0, S_{\text{ord}}, S_{\text{set}}$        | External sets of definable order types (sources 34, 32, 35). <i>False reading:</i> not the sign carrier $S_\lambda$ of Part XV or $\text{Sym}(\mu)$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| FPE, $C(A, j), \iota, \Phi$                                                                    | Source 35's fixed-point extension principle and completion. <i>False reading:</i> $\Phi$ is also source 33's digit map (Section XVI.5); the two are different maps.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| WO, Sat, Valid                                                                                 | Formula-level well-order and satisfaction predicates (sources 32–35, written $\backslash\text{WO}, \backslash\text{Sat}$ ). <i>False reading:</i> WO is not this report's $\mathcal{W} = \mathcal{W}$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| Numbers, labels                                                                                | The sections of Part XVI are numbered XVI.1–XVI.12; source 34's equation $(k)$ is tagged (S34. $k$ ), source 35's (S35. $k$ ), source 32's (S32. $k$ ), source 33's ( $s.k$ ) (S33. $s.k$ ). Labels: <b>swo:bo:</b> (34), <b>swo:fc:</b> (35), <b>swo:dc:</b> (32) and <b>swo:dh:</b> (33) before each delivered label; unlabelled numbered statements <b>nnumber</b> with that prefix ( <b>swo:fc:n2.1</b> ); source 34's agenda items <b>swo:bo:R1–R12</b> ; labels written for the merge <b>swo:part:beyondord</b> and <b>swo:xvi:...</b>                                                                                                                                                                                                                                                   |

### 1.3.5 Addendum of 4 October 2026: notation for source 36

[merge] Source 36 ([section 1.12](#)) uses the objects of Part XVI under other names, and some of its letters mean other things here. The convention below applies to Part XVII, to its questions ([section 113.30](#)) and to its abstract ([Appendix C](#)); the conventions of [section 1.3.4](#) and the earlier addenda continue to hold. Every renaming is listed; the tempting false reading is printed where confusion is likely.

| Here                                                          | Meaning, and source 36's symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
|---------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\Omega, \Omega_u$                                            | $\Omega$ is the presentation $(\text{Ord}, \in)$ , as in Part XVI (source 36's bold $\Omega$ , macro $\backslash\text{Om}$ ). In Section XVII.8 the light-face $\Omega_u$ is the order type of $\text{Ordinal}_u$ , an ordinal of the next universe level, printed as delivered. <i>False reading:</i> $\Omega_u$ is not the presentation $\Omega$ .                                                                                                                                                                                                                                                                          |
| $A^{[B]}, \Omega^t \alpha$                                    | The finite-support power (source 36's $A^B$ ), printed $A^{[B]}$ wherever the operands are class orders, as in Part XVI; $\Omega^n$ for finite $n$ abbreviates $\Omega^{[n]}$ , and for set ordinals $(a^b, \kappa^\xi, \omega^\alpha)$ the power is ordinary ordinal exponentiation. In a term display $\Omega^{t_0} \alpha_0 + \dots$ or a point display $\Omega^{b_0} \alpha_0 + \dots$ the superscript is a term or an exponent point, not a power, as source 36 explains. <i>False reading:</i> $0^{[0]} = 1$ and $0^{[B]} = 0$ are conventions, not instances of <a href="#">definition XVII.3.1</a> .                  |
| $\mathbf{E}, \mathbf{E}^{\leq n+1}, w_n, \bar{\alpha}, \ t\ $ | The hereditary term order, source 36's sans-serif $\mathbf{T}_\Omega$ (macro $\backslash\text{treeord}$ ), which is source 34's $\mathbf{E}$ ; its height stages, source 36's $T_n$ (height at most $n+1$ ), printed $\mathbf{E}^{\leq n+1}$ as in source 34; the tower codes $w_0 = [(\bar{1}, 1)]$ , $w_{n+1} = [(w_n, 1)]$ , which are source 34's terms $\tau_{n+1}$ ; the constant $\bar{\alpha} = [(0, \alpha)]$ ; and $\ t\  = \mathbf{E}_{<t}$ . <i>False reading:</i> $\mathbf{E}^{\leq n+1}$ is a subclass of $\mathbf{E}$ , isomorphic to but not equal to source 33's separate order $T_n$ ; $w_n$ is not a word. |

| Here                                                                                                            | Meaning, and source 36's symbols                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|-----------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $f \boxplus g, f \boxtimes g, F_\beta$                                                                          | Normal-form addition and multiplication of points of $\mathbf{E}$ ( <a href="#">theorems XVII.5.1 and XVII.5.2</a> ); the addition rule also applies to points of $\Omega^{[B]}$ . The terms $F_\beta$ are the coefficient multiples ( <a href="#">S36.5.1</a> ). <i>False reading</i> : not the natural (Hessenberg) sum and product; $\ f \boxplus g\  \cong \ f\  + \ g\ $ is ordinal addition of presentations.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| $\text{Ep}(B), e_b, \llbracket t \rrbracket$                                                                    | The epsilon-term functor (source 36's sans-serif $\mathbf{E}$ , macro <code>\epsop</code> ), its constants and its set-case evaluation. Renamed because $\mathbf{E} = \mathbf{E}$ is the hereditary order here. <i>False reading</i> : $\text{Ep}$ is not $\mathbf{E}$ , not source 09's $\mathcal{E}_\kappa$ or the $\mathcal{E}$ of Section 1.3, and not a stage equivalence $E_i$ ; $\text{Ep}(\Omega) \cong \Omega$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| $\varepsilon_\xi, \zeta_\xi$                                                                                    | The enumerations of the fixed points of $\alpha \mapsto \omega^\alpha$ (with $\varepsilon_0$ the first) and of $\xi \mapsto \varepsilon_\xi$ .                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| $\mathfrak{H}(M), \mathfrak{H}_0(M), \mathfrak{H}_p(M), \mathfrak{H}_G, \mathfrak{H}_{G,T}, \mathcal{H}_\kappa$ | Definability horizons, source 36's $H(M), H_0(M), H_p(M), H_G, H_{G,T}$ : external suprema of definable order types with set parameters, without them, with one fixed tuple $p$ , and in the languages $\{\in, G\}$ and $\{\in, G, T\}$ ; $\mathcal{H}_\kappa$ is the set of the $\mathfrak{H}_G$ (as delivered). Renamed because $H, H_i$ are histories here. They are the invariants of Part XVI: $\mathfrak{H}(M) = \Theta_{\{\in\}}$ and $\mathfrak{H}_G = \Theta_{\{\in, G\}}$ in source 34's notation, $\mathfrak{H}_G = \delta_G$ (source 33) and $= \delta_A$ for trivial $A$ (source 32); over $V_\kappa$ , $\mathfrak{H}(V_\kappa)$ is source 35's $\delta_{\text{set}}$ . <i>False reading</i> : not source 16's $\mathfrak{H}$ (printed $\mathfrak{W}_{\text{all}}$ ); $H_{\kappa+}$ in <a href="#">proposition XVII.8.1</a> is the class of sets hereditarily of size at most $\kappa$ ; $\mathcal{H}_\kappa$ is not source 32's $\mathcal{H}(A)$ , printed $\mathbf{E}(A)$ . |
| $\text{Spec}(M), \text{Spec}_G, \text{Spec}_G^0, \text{Spec}_{\text{full}}$                                     | External sets of definable (or all) class order types, source 34's $\mathcal{S}_{\text{par}}^L$ and $\mathcal{S}_0^L$ , source 32's $S_A$ , source 35's $S_{\text{set}}$ . <i>False reading</i> : external sets of ordinals, not classes of the model.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| $D_n, \mathcal{D}, \delta_n, h_n, A_{n,u}, E_G, W, \tau_n, T$                                                   | Diagonal orders (as source 33's $D_n$ ) and their external types; the complexity heights $h_n$ ; the validated candidates $A_{n,u}$ ; the truth-promotion order $E_G$ ; the zeta order $W$ of <a href="#">theorem XVII.6.7</a> ; the ordinals $\tau_n$ in the proof of <a href="#">theorem XVII.6.6</a> ; the full satisfaction predicate $T$ for $(V_\kappa, \in, G)$ , as source 33's $T$ . <i>False reading</i> : $h_n$ is not source 20's $h_\kappa$ ; $E_G$ is not a stage equivalence; $W$ is not a generic class well-order; $\tau_n$ there are ordinals, not source 34's terms; $D_n$ is not the operator $D_W$ ; $T$ is a truth predicate, not a term class (source 36's $T_\Omega$ and $T_n$ are printed $\mathbf{E}$ and $\mathbf{E}^{\leq n+1}$ ).                                                                                                                                                                                                                             |
| $G, G_A, \pi$                                                                                                   | A named bijection $\kappa \rightarrow V_\kappa$ (source 32's $G$ ; it induces source 33's set-like global well-order); the swap-coded bijection of <a href="#">lemma XVII.7.10</a> ; the canonical pairing of ordinals. <i>False reading</i> : $G_A$ codes a subset $A \subseteq \kappa$ ; it is not source 32's pair $(G, A)$ of predicates.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| $\preccurlyeq_{\text{init}}, \prec_{\text{init}}, L_{<x}$                                                       | Source 36's $\preccurlyeq_{\text{init}}, \prec_{\text{init}}$ and <code>\cut</code> . Source 36 also defines $\preccurlyeq_{\text{emb}}$ and an operator $\text{WO}$ that it never uses.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| Numbers, labels                                                                                                 | The sections of Part XVII are numbered XVII.1–XVII.11; source 36's equation $(k.m)$ is tagged (S36. $k.m$ ) and its $(*)$ (S36. $*$ ); the credit notes of the merge are XVII. $k.A$ , XVII. $k.B$ , ... Labels: <b>swo:hn:</b> before each delivered label (source 36's prefixes <b>intro:</b> , <b>ar:</b> , <b>ns:</b> , <b>hz:</b> , <b>form:</b> , <b>agenda:</b> , <b>audit:</b> ); its unlabelled Definition 6.1 <b>swo:hn:n6.1</b> ; its research questions <b>swo:hn:q1–swo:hn:q10</b> ; labels written for the merge <b>swo:part:horizons</b> and <b>swo:xvii:....</b>                                                                                                                                                                                                                                                                                                                                                                                                           |

## 1.4 What the report claims, and what it does not

[merge] The report claims the written proofs printed below, each in the foundation its statement names (ZF, ZFC, GB, GB + AC, GBC, KM + GC, or ZFC with a strongly inaccessible cardinal). The results new against the repository are: the singular transition at birthday cutoffs ([theorem 8.3](#)); the choiceless global-choice equivalence ([theorem 13.1](#)); the direct comparison of all class well-orders

(theorem 14.2, theorem 14.7), its canonical initial part and convex fibres, and its adjacency criterion (theorems 15.1 and 16.2 and proposition 15.3); the core of bounded-support perturbations and its interpolation theorem (theorem 19.10 and corollary 19.15); binary-class equimorphism and the diagonal non-coding theorems (theorems 19.32, 19.37 and 19.38); omitted ranges (theorems 19.42 and 19.43 and corollary 19.46); bounded reflection (theorem 19.30); the failure of finite support (proposition 19.31); relation-code lexicography (proposition 17.1); explicit word coding and the word-cut classification (theorems 9.1 and 11.1); and the universe models and non-embedding theorems (theorems 20.1, 20.2, 21.1 and 22.1). None of these is claimed to be historically first.

It does *not* claim the following; every limitation stated by any source is kept.

- *No novelty for re-proofs.* The set-sized general-alphabet layer (prefix-freeness, cardinality  $2^{|X|}$ , universality, no  $|X|^+$ -chain, ordinal and cube spectra, coding length  $|X|^+$ , extrema, adjacency,  $n!$  blocks, strict cubes) re-proves the reals report for every infinite linear alphabet and is printed with pointers to it (section 6.1). Universality and homogeneity of **No** are classical (Ehrlich [15]; Hamkins [20]); all four sources say so. The coding of sets behind the choice equivalence is, in source 09's words, a standard well-founded-coding argument; the connection is discussed by Hamkins [18, 19].
- *Source 11* (its Status paragraph, its delivery README's "Scope and verification" and its audit): no machine verification, no Lean build, no new Lean file; no bibliographic priority for constructions proved in the report; research questions are proposed directions, not a certified list of published open problems; the repository audit was targeted and repository-wide correctness was not assessed; the finite checks do not verify transfinite proofs, cardinal arithmetic or class comprehension. Its README states: "The mathematical proofs underwent a separate proof review." That is the delivery's own statement; no such review is recorded in the repository, and this report does not rely on it.
- *Source 12* (title page, its Section 1.2, and 12-singular-RESEARCH\_STATUS.md, "What is not claimed"): AI-assisted, unrefereed; historical priority not claimed; no previously catalogued open problem is claimed settled, nor that its exact formulations are new; no new Lean or Rocq verification; the Python checks are not substitutes for the proofs; the bounded theorem is not a construction of a full class model at a singular cardinal; the full collection of class well-orders is not treated as a set or ordinary class at the same foundational level; no universal semantic decoder for formula codes is assumed; its nine research questions are proposed continuations; its source search was not sufficient to establish originality.
- *Source 09* (title page, its Appendix A, and 09-core-RESEARCH\_STATUS.md, "Important boundaries"): AI-assisted, not peer-reviewed or Lean-verified, no historical priority; classical ingredients and repository results are distinguished from its constructions; no class whose members are proper classes is formed; the global-enumeration representation covers set-like class well-orders only, and no complete classification of the relation-code comparison is claimed; the core realizes uniform set-sized cuts, not all proper-class cuts (an explicit counterexample is supplied); for fixed alphabets the absence of  $\kappa^+$  and its reverse is not claimed to be a sufficient embeddability criterion; automorphisms and higher-level cuts are not classified; its research directions are proposals; literature and repository searches were targeted, not exhaustive.
- *Source 08* (its Status box and delivery README): explicit derivations, not a claim of historical priority; not independently refereed and not checked in Lean; no new Lean formalization; repository declarations are separated from proposed extensions; repository sources were read but not rebuilt; the finite tests do not establish any transfinite or class-theoretic theorem; every use of "class" is relative to the stated foundational model.

- *Proposed Lean modules are proposals.* The module names in the Lean plans of [sections 20 and 24 to 26](#) do not exist in the repository; the existing declarations they cite do ([section 1.5](#)).
- *Review status.* The repository’s Hilbert’s-tenth research tree holds a written-proof review of the four archives (`Computability/HilbertTenthProblem/Papers/research-wip/naive-stream-queue/review_batch80_surreal.md`, commit `c338541e3`). It found their principal arguments sound under the stated foundations, with one scoped correction to source 08, which is applied here ([section 5.6](#)), and it reran the four finite checks. A second note there authenticates the placement (`review_surreal_placement_ccc046989.md`, commit `3aa123856`). That review is pinned to the delivered archives and does not cover the text written for this merge; it is not an entry of the surreal collection’s review record, where this report’s review is pending. ([merge] Added 3 October 2026: the same tree has since reviewed the merged text as well. Its synthesis review (`review_surreal_synthesis_0be9b9134.md`, commit `280583d2f`) read every passage written for the merge and found no mathematical defect under the stated hypotheses, but two overstatements, both corrected here in place: the choice recursion of [theorem 13.1](#) had been called a “coherent” sequence of well-orders in [remark 13.4](#) and [remark 113.15](#), and the README had understated the largest delivered file. Its preservation audit (`review_surreal_transfer_0be9b9134.md`, commit `afb706742`) accounts for all 166 formal statements of the four sources (124 printed with normalized-exact bodies, 41 as duplicate-result notes, one question inside an answered remark). Neither is an entry of the collection’s review record either.)

[merge] *Addendum of 3 October 2026: sources 13–18.* The batch-81 addition claims the written proofs printed in Parts VI–IX, each in the foundation its statement names. Its results that are new against the repository are those called new in [sections 33, 39, 50 and 60](#); its re-proofs of this report, of the reals report and of the report `surreal-fields-across-universes` are notes. None is claimed to be historically first, and results proved by several batch-81 sources are credited to all of them. Every limitation stated by the six sources is kept:

- *Source 13 (13-products-RESEARCH\_STATUS.md):* AI-assisted and unrefereed; no peer review or priority claimed; a targeted audit of this report at `0ecd158fd`, no Lean build, no new Lean proof. Its six “critical scope conditions”: cut reconstruction concerns normalized cuts and all set-ordinal levels, exhaustion being a separate coverage condition; the classification is relative to a supplied coded core and prefix system, which the pure order does not canonically recover; the product nonembedding is proved for arbitrary external maps in the full inaccessible universe and for fixed-formula uniform maps in `KM + GC`, and is not advertised as a theorem of bare `GBC` about a third sort; externally countable models admit external embeddings that need not be internally uniform; central termination reserves zero as a marker; ordinary classes of set codes, class relations and a higher collection of all class relations are never identified. Its finite checks do not verify ordinal limits, class comprehension, global choice or transfinite recursion.
- *Source 14 (14-trichotomy-RESEARCH\_STATUS.md):* `GBC` with a fixed baseline; the inaccessible model is an illustration, not a hypothesis; historical priority not established; no Lean theorem compiled. Its scope cautions: the trichotomy uses named prefix cylinders; the orbit theorem is a coarser classification; equimorphism is not isomorphism; a principal normalized cut has its point on the upper side; cardinal support bounds are not ordinal location bounds; the class-extension theorem fixes the sets and the baseline; raw trace fibres forget tails, and singleton fibres can be non-set-like; a coherent injective branch can omit labels; a virtual quotient is not a collection of class equivalence classes. Its status file says that the inspected

Lean simplicity theorem “is NOT an independent arbitrary-small-cut existence theorem”; that is true of `SignSequenceSimplicity.lean`, while the existence theorem is `small_cut_fillers` in `SignSequenceCut.lean` (section 1.5).

- *Source 15* (its delivery README, not shipped): AI-assisted and unrefereed; its extensions “received independent mathematical review within the task”, with no claim of priority or formal certification; the fixed-type classification covers  $\mu \cdot \gamma + n$  with finite  $n$  only.
- *Source 16* (`16-strata-SOURCE_STATUS.txt`): a targeted audit at 491ed8411; “The proofs underwent independent mathematical checks during preparation”, the delivery’s own statement, which “is not external peer review, a proof of historical novelty, or verification by a proof assistant”; no Lean build; its  $\Sigma_1^1$  theorem is a sufficient bound, with no reversal.
- *Source 17* (`17-gaps-research_status.md`): AI-assisted, no referee review, no compiled Lean; proposed module names only; a targeted audit; no priority. Its unresolved scope: no isomorphism classification of the minimal slice; nonminimal types and noncardinal cutoffs not classified; the automorphism group, arbitrary baseline changes, higher residual blocks and their recursion strength open; the condensed unrestricted order not identified with the set-like order or with **No**; the class-extension theorem not a reconstruction of the class realization. Its reserve formula minimizes the number of extra moved positions, not an ordinal support bound or a birthday.
- *Source 18* (its delivery README, not shipped): “conventional proofs and independent AI-assisted proof review”; no literature priority, peer review or machine-checked formalization; no Lean build or imported-axiom audit; its status table is printed whole (section 115.8).

The repository’s Hilbert’s-tenth research tree, which reviewed the batch-80 sources, holds no review of sources 13–18 at the time of this write.

[merge] *Addendum of 3 October 2026: sources 19–30.* The batch-83 addition claims the written proofs printed in Parts X–XIV, each in the foundation its statement names. Its results that are new against the repository are those called new in sections 72, 79, 85, 105 and 112; its re-proofs of this report, of sources 13–18 and of the reals report are notes or marked routes, and a result proved by several batch-83 sources is credited to all of them (section 1.9). None is claimed to be historically first. Every limitation stated by the twelve sources is kept in the sections that print them; the principal ones:

- *Source 19* (`19-residual-source_status.txt`): its proofs were checked “independently during preparation”, which “is not external peer review”; no Lean build. The least coding length of a fixed type is exact only when its two weighted bounds agree; at singular non-strong-limit residual cardinals at most  $\kappa$  it stays open (research question 113.94). Its common complete theory of all set-sized GBC models (theorem 109.9) is the strongest unreviewed claim of the addition.
- *Source 20* (its title page and delivery README, not shipped): AI-assisted; its results are claims “with internal mathematical review, not machine-checked theorems or claims of priority in the literature”; of its condensation-history theorems: “No necessity or reverse-mathematical equivalence is asserted”.
- *Source 21* (`21-obstructions-SOURCE_AUDIT.txt`, `21-obstructions-LEAN_INTERFACE_AUDIT.txt`): unrefereed and unformalized; “No exhaustive novelty search or historical priority claim is made”; its countable-model results “must not be silently transferred to arbitrary uncountable class realizations”.
- *Source 22* (`22-unranked-RESEARCH_STATUS.md`, `22-unranked-SOURCE_AUDIT.md`): AI-

assisted and unrefereed; no priority; its density and cellularity column re-proves source 16 (only weights and characters are new, [note 63.5](#)); its checks do not test cardinal arithmetic, cofinalities or class comprehension.

- *Source 23* (23-termination-RESEARCH\_STATUS.md, 23-termination-SOURCE\_AUDIT.md): no Lean proof generated; GBC + ETR is a sufficient framework, “not claimed necessary”; its termination criterion is a second route to source 16’s theorem.
- *Source 24* (24-completions-SOURCE\_AUDIT.md): “No claim of historical priority, peer review, or Lean kernel certification is made”; its homeomorphisms are not order isomorphisms.
- *Source 25* (25-symmetries-RESEARCH\_STATUS.md, 25-symmetries-SOURCE\_AUDIT.md): AI-assisted; not claimed refereed or historically first; its invisibility theorem concerns unlabelled cylinders and does not make exhaustiveness undefinable from label equality.
- *Source 26* (26-nonborel-RESEARCH\_STATUS.md): “a relative contribution statement, not a bibliographic-priority claim”; unrefereed; no Lean build; it treats minimal lengths and ordinary Borel sets.
- *Source 27* (27-scans-SOURCE\_AUDIT.txt): no claim of historical priority or external peer review; its least support bound optimizes ordinal height only, not birthdays.
- *Source 28* (28-envelope-SOURCE\_AUDIT.md): unrefereed; no priority, no Lean kernel verification; its character bound concerns the coarsest group refinement, and its headline metrizable question is answered by source 26 ([note 70.13](#)).
- *Source 29* (29-birthdays-PROOF\_STATUS.txt, 29-birthdays-SOURCE\_AUDIT.txt): AI-assisted, internal review only, “not external refereeing or proof-assistant certification”; it does *not* establish  $\text{CWO} \Rightarrow \text{ETR}$ .
- *Source 30* (30-tables-proof\_review.txt, 30-tables-source\_audit.txt): conventional proofs with AI-assisted proof review, which is not “a substitute for external peer review”; its classification under GCH is conditional.

No review of sources 19–30 or of Parts X–XIV exists in the repository at the time of this write.

[merge] *Addendum of 3 October 2026: source 31.* The batch-89 addition claims the written proofs printed in Part XV, in the settings its statements name: first-order  $\text{ZC}$  or  $\text{ZC}_F$  with a selector and expanded Separation ([sections XV.2 to XV.5](#)), and an external ZFC metatheory for the full-class rank models ([sections XV.6 to XV.11](#)). Its results that are new against the repository are listed in [section XV.15](#); none is claimed to be historically first. Every limitation it states is kept where it is printed; the principal ones (its Scope paragraph, [Appendix C](#); [sections XV.12 and XV.14](#); its delivery README, not shipped):

- Conventional mathematical proofs; no Lean or Rocq verification and no machine-checked formalization; its formalization architecture ([section XV.12](#)) is a proposal.
- The nonconservativity theorem ([theorem XV.5.1](#)) uses Glazer’s countermodel theorem [70, Propositions 3.8 and 4.11] as an explicitly cited input; the countermodels are not reconstructed. Source 31 states that input as an abstract interface ([section XV.5.1](#)); whether Glazer’s obstruction has exactly that shape has not been checked in this repository, and source 31 says that expert review of the localized statement “would be the next scholarly step”. The theorem and its corollaries are printed as claimed, with that dependency.
- The rank-model classification is proved in an external ZFC metatheory and concerns full classes; the “fourth row” (universal set coding, equivalently ordinal abstraction) is an equivalence within this family of full-class rank models, not over every weak class theory; no closure of  $S_\lambda$

under the surreal field operations is asserted at arbitrary cutoffs; nothing is asserted about first-order Replacement at singular heights.

- No claim that the repository’s supported-prefix extension, small-net rigidity or inverse-reconstruction schemes are each equivalent to a row of its table; no solution of the surreal transfer problem; no classification for definable-class realizations; no proof of the finite-input conservativity boundary.
- Targeted literature and repository searches only: “this is not a proof of priority”. Restricted global-choice principles have prior literature (Enayat’s global finite choice [71]); the bounded proof of the well-ordering theorem is classical in method; ordinal abstraction and the example  $V_{\omega_1}$  (Hamkins, Rin), set-like class orders without Replacement (Carneiro), the global-choice equivalences over GB (Hamkins), well-ordered Replacement (Freire and Hamkins) and beth fixed points (MathOverflow) are credited.

No review of source 31 or of Part XV exists in the repository at the time of this write; the Hilbert’s-tenth research tree has routed its archive without a correctness finding (section 1.10).

[merge] *Addendum of 4 October 2026: sources 32–35.* The batch-96 addition claims the written proofs printed in Part XVI, in the settings its statements name: GB with ZF sets for sources 34 and 35’s choice-free results, GBC where a statement says so, GBC with an assumed full satisfaction class for the truth jumps, and an external ZFC metatheory with a strongly inaccessible  $\kappa$  (or a transitive  $\beta$ -model) for the spectra. Its results that are new against the repository are listed in section XVI.12; none is claimed to be historically first. Every limitation the sources state is kept where it is printed; the principal ones:

- Neither source 34 nor source 35 proves CWO or CTH in GB; both leave open whether CWO implies ETR (“a dated literature-status statement, not a proof that no resolution exists”, source 34). The reduction to the surreal carrier keeps global choice. Source 34’s lemma XVI.2.2 is specific to linear orders and does not identify the absence of descending sequences with well-foundedness without choice.
- Source 32’s termination theorem is conditional on the existence of the hierarchy, and ETR is “sufficient, not proved necessary”; source 33’s digit theorem consumes a supplied tower. (Both are re-proofs of source 20’s theorem, remark XVI.1.1.)
- The spectra are external and assume an inaccessible  $\kappa$  with  $V_\kappa$ , or a transitive  $\beta$ -model; they do not transfer to arbitrary countable, non- $\beta$  or nonstandard models. Countable cofinality of a ceiling does not make it countable or internally represented; the inequalities among source 35’s three suprema are not claimed strict.
- The truth jumps assume a full satisfaction class; the orders  $J_\gamma$  are “not canonical absolute class ordinals”; source 32’s theorem does not compute  $\delta_{T_A}$ .
- The bounded-complexity diagonals are schemata in a standard  $n$ , not one definable sequence; source 35 claims no separation of two consecutive levels.
- Hereditary ordinal notation and class epsilon notation are not claimed as inventions (Weiermann, Freund, Rathjen through Jeon are credited); the fixed-point completion is new against the sources each author examined.
- The finite checks of sources 32, 33 and 35 check coding conventions only (“NOT machine proofs”); no Lean or Rocq development exists, and the module plans are proposals.
- Targeted repository and literature searches only; source 33 did not read the 860-page report line by line, source 32 read three files.

The Hilbert’s-tenth research tree’s bounded intake of the four archives checked source 34’s choice-free power theorem and set-subset criterion and found no defect, without auditing the rest of the GB equivalence or the other proofs; no review covers Part XVI as written ([section XVI.12](#)). (Dated note, 4 October 2026: an independent check of the four statements written for Part XVI, [theorem XVI.6.21](#) and [remarks XVI.5.24](#), [XVI.5.29](#) and [XVI.5.31](#), is recorded in [section XVI.12](#); it found them valid after editorial corrections.) A later bounded publication review and the empty-domain follow-up are also recorded there; Review remark H5 qualifies the earlier passes and records the remaining cases repaired in this text. [\[merge\]](#) *Addendum of 4 October 2026: source 36*. The batch-97 addition claims the written proofs printed in Part XVII, in the settings its sections name: GB with ZF sets and no choice for the arithmetic, notation and transfer results; an external ZFC metatheory with an arbitrary transitive set model of ZFC for the calibrations and spectra; and an inaccessible  $\kappa$  with a named enumeration  $G$  of  $V_\kappa$  (and a full truth predicate for the promotion) for the horizon theorems. What is new against Parts I–XVI is listed in [section XVII.11](#); nothing is claimed to be historically first, and source 36’s horizon theorems, bounded-complexity diagonal and truth promotion are theorems of sources 32–34 (credit notes in Part XVII). Every limitation source 36 states is kept where it is printed; the principal ones:

- “Publication priority and a breakthrough resolution of a recognized open problem are not asserted”; long class orders, their arithmetic and the epsilon notation functor “have established antecedents”; the converse from comparability to ETR is not established.
- The arithmetic is relative to ordinal coefficients; no normalization of general powers inside E is proved; the transfer theorem does not apply to an arbitrary normal ordinal function.
- The spectra count externally well-founded orders; an arbitrary transitive model need not recognize external ill-foundedness; the horizon theorem at  $V_\kappa$  uses the inaccessibility of  $\kappa$  and a named  $G$ , and “parameter-free” excludes only set parameters;  $\text{cf}(\mathfrak{H}(M)) = \omega$  is not claimed for unrestricted parameters over an arbitrary  $M$ ; the diagonal formulas are an external schema, not one evaluator; the size of the truth jump is not computed; the admissible bound’s equality cases are not claimed as new.
- Conventional written proofs only; no referee, no Lean or Rocq; the five proposed modules are design targets; the demonstrator checks natural coefficients only and “does not prove any class-theoretic theorem”.
- A targeted repository audit (README, this report’s README and `29-birthdays-PROOF_STATUS.txt`, the ListCoding README); this report’s article was not read end to end, and the audit is “not an exhaustive duplicate search”.

The Hilbert’s-tenth research tree’s bounded intake of the archive (commit `39bb02ece`) found no defect in the proofs it read. A later bounded publication review of `a21a42d8c` checks selected arithmetic and effective-interface proofs and corrects three editorial scope claims; its coverage and remaining exclusions are in [section XVII.11](#).

## 1.5 Formal status

[\[merge\]](#) No statement of this report is formalized, and no `swo:` label has a Lean mapping in the collection’s formalization ledger (`Algebra/SurrealNumbers/docs/FORMALIZATION.md`). Placement in the surreal collection, beside the Lean foundations of `Algebra/SurrealNumbers/Surreal/Foundations/`, confers no formal status.

Four inputs that the sources use *are* proved in Lean, in the universe-relative form recorded in that ledger, where a “set” of surreals is a family indexed by a `Small.{u}` type and the sign carrier

lives in `Type (u+1)`:

- properness and bounded birthdays (found:prop:proper; [proposition 5.4](#), first three clauses): `SignSequence`, `birthdays_bounded`, `small_bounded`, `not_small` in `SignSequence.lean`;
- filling of small cuts (found:sub:cutdata): `small_cut_fillers` in `SignSequenceCut.lean` and `exists_separator_of_small_sets` in `SignSequenceCutOperation.lean`;
- a separator of exactly a prescribed birthday above all option birthdays, [theorem 5.6](#): `exists_cut_separator_of_birthday_lt` in `SignSequenceCut.lean`, by the same route as source 08’s proof (the complete lexicographic lattice of Boolean words of one length, which is [lemma 5.5](#), there taken from Mathlib);
- the inconsistency of unrestricted cuts (found:prop:allcuts): `noUnrestrictedCuts` in `SizeObstructions.lean`.

The other declarations the sources cite exist at the current revision: `ordinalOrderEmbedding`, `small_strict_upper_bounds`, `simpler_wellFounded`, `existsUnique_simplest_separator`, `cut_realizes`, `cut_isPrefix`, `birthday_cut_le`, `birthday_cut_le_iSup`, `cut_congr`, `SmallCutData`, `HasSmallCutFillers`, `not_small_of_small_cut_fillers`, `lt_iff`, and the others in their tables. None of them states a result of this report.

[merge] (3 October 2026.) The same holds for sources 13–18: none ships Lean code, no statement of theirs is formalized, the declarations they cite exist at the current revision (including `le_iff_options_lt` and `lt_iff_exists_option` in `SignSequenceComparison.lean`, cited by source 18), and the modules they propose do not exist ([note 59.1](#)).

[merge] (3 October 2026, batch 83.) The same holds for sources 19–30: none ships Lean code or compiled a Lean file, no statement of theirs is formalized, and the module names in their formalization plans ([section 111](#)) are proposals: no module of those names exists. The declarations those plans name as existing were checked against `Algebra/SurrealNumbers/Surreal/Foundations/` when the plans were printed; none of them states a result of this report. Source 21’s audit of the declarations it uses is shipped as `21-obstructions-LEAN_INTERFACE_AUDIT.txt`.

[merge] (3 October 2026, batch 89.) Source 31 ships no Lean or Rocq code and cites no Lean declaration; no statement of Part XV is formalized. Its formalization architecture ([section XV.12](#)) proposes the domain-size criterion [lemma XV.9.2](#) as a first machine-checked milestone, and its [research question 113.243](#) a verified bounded uniformization theorem; no such development exists.

[merge] (4 October 2026, batch 96.) Sources 32–35 ship no Lean or Rocq code; no statement of Part XVI is formalized. Source 32 cites `SetTheory/ZF/Lean/ZF/Zf.lean` (its declarations `Sep_form`, `Repl_form`, `ZFax`, `ZFprov`) as a foundation for a future extension, and Mathlib’s `Ordinal.univ` and `Ordinal.type_lt_ordinal`; source 33 proposes a directory `SetTheory/ClassWellOrders/`, which does not exist. Their first proposed milestones are the choice-free power theorem and the capped normal-form reconstruction ([section 113.28](#)). [merge] (4 October 2026, batch 97.) Source 36 ships no Lean or Rocq code; no statement of Part XVII is formalized. It proposes five modules (`ClassOrderPresentation`, `FiniteSupportPower`, `OmegaNormalForm`, `EpsilonTerms`, `DefinabilityHorizon`), none of which exists, and cites `Logic/PeanoArithmetic/ListCoding/REA DME.md` and Mathlib’s `Mathlib.SetTheory.Ordinal.CantorNormalForm` as engineering patterns, not as theorems about classes. Its natural-coefficient demonstrator (`code/36-horizons-notation_demo.py`) is a finite test, not a formalization.

## 1.6 Where the merge had to choose

[merge]

- *Base and order.* Source 11, for the reasons in [section 1.1](#); its section order is kept, and member material follows the base result it duplicates or extends.
- *Strongest statement printed as the statement.* The choice equivalence is source 11's (over GB; sources 12 and 09 assume set choice, and source 09 treats set-like orders only). The diagonal theorem is printed twice: source 11's ([theorem 19.37](#), rows of set codes) and source 12's ([theorem 19.38](#), every uniform family of class well-orders, with a set-like witness); sources 09's and 08's are notes (source 08's indexes by Ord only). The birthday-cutoff statement is source 12's dichotomy; source 08's regular case is a note.
- *Different routes kept in full:* source 09's stabilization proof of the ordinal spectrum; source 12's route to the set-sized spectra through binary coding length; the second and third proofs that a set can be avoided ([lemmas 5.3](#) and [5.10](#)); source 12's and 09's proofs of the choice equivalence over GB + AC; source 12's largest common labelled prefix; source 12's residual decomposition and adjacency criterion; source 12's concatenation proof of the binary-class embedding; source 12's prefix extension through the complement of the prefix; source 09's support coding of the core; source 09's explicit unfilled configuration; source 09's general universality and homogeneity theorems; source 12's birthday-bounded universality.
- *Kept whole:* each member's introduction, foundational section, universe and model sections, Lean plan, research questions, conclusion, ledger and reproducibility record.
- *Corrections to source text.* The renamings of [section 1.3](#); one mistyped reference in source 11 (a proposition cited as "Theorem", in [section 12](#)); source 08's predecessor citation ([section 4.3](#) and the note after it); source 12's question on the weak-choice strength, printed as an answered remark ([remark 113.15](#)); source 08's question 11 annotated as answered; one sentence of source 08 on well-foundedness replaced by the correction of the Hilbert's-tenth review ([section 5.6](#) and the note before it). Statements that name delivery files (build scripts, `finite_checks.py`, `surreal_well_orders.tex`) are kept and annotated with the shipped names ([appendix B](#)).

## 1.7 Where one source answers another

[merge] Dated notes, 2 October 2026.

- Source 12's question on the weak-choice strength* ([remark 113.15](#), and its [remark 13.3](#)): answered by source 11. Over GB without set choice, a class well-order of **No** exists exactly when global choice holds ([theorem 13.1](#)); see [remark 13.4](#). The same theorem shows that the set-choice hypothesis of source 09's [proposition 13.7](#) is unnecessary. Source 09's direction on the exact axiomatic strength of *other* universality and homogeneity assertions ([section 113.3](#)) is unaffected.
- Source 08's question 11, comparison of non-set-like class well-orders* ([section 113.4](#)): answered by sources 11 and 12. [Theorems 14.2](#) and [14.7](#) compare all class well-orders of a labelled class directly, with elementary comprehension, without ETR and without comparing abstract class order types; this also supplies the single comparison that source 08's [section 17](#) says does not follow by aligning domains (see the note after it). Source 09's relation-code direction concerns a different comparison and stays open.
- Source 08's question 3, singular birthdays and code lengths:* answered in part by source 12's [theorem 8.3](#): at a singular cutoff the least binary coding length of the fixed-length enumeration order is  $\kappa \cdot \kappa$  when  $\kappa$  is a strong limit and  $2^{<\kappa}$  otherwise. Which cuts fail at singular cutoffs stays open.

- (d) *Source 08’s question 2, invariants at regular cutoffs*: partly answered by source 11’s [proposition 12.1](#) (the minimal slice is  $\eta_\kappa$ , with every global and local cofinality and coinitality  $\kappa$ ); density, cellularity and the cut cofinalities beyond these stay open.
- (e) *The reals report’s question “Other ground orders”* (its Section “Further research questions”, `lwo:sec:research`, which names “set-sized suborders of surreal numbers”): answered in part by [theorem 8.3](#) for  $X = \mathbf{No}_{<\kappa}$  and the minimal stratum ( $n = 0$ ):  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_\mu$ , except at singular strong-limit  $\kappa$ , where it is  $\simeq_e \mathbb{B}_{\kappa \cdot \kappa}$  and not  $\simeq_e \mathbb{B}_\kappa$ . It stays open for  $n > 0$ , for longer strata, and for other alphabets (source 12’s [research question 113.11](#), source 08’s question 4).
- (f) *Hamkins’s question whether universality of the surreal line is a weak global choice principle [21]*: not settled here, as source 12 says after its [remark 113.15](#).

[merge] Dated note, 3 October 2026 (batch 81). Items (c) and (d) are completed and item (e) is extended by Part VI: the cut spectrum at singular cutoffs, the density, cellularity and cut cofinalities at regular cutoffs, and the longer strata  $\mu \cdot \gamma + n$  of  $\mathbf{No}_{<\kappa}$  ([section 33](#)).

[merge] Dated note, 3 October 2026 (batch 83). Sources 19–30 answer, fully or in part, source 12’s [research questions 113.11](#), [113.12](#), [113.18](#) and [113.19](#), source 11’s [research question 113.3](#), source 08’s question 9 and source 09’s fifth direction, open items of Parts VII and VIII, and questions of sources 13–18 and of each other; the dated status notes are in [section 113.25](#).

[merge] Dated note, 3 October 2026 (batch 89). Source 31 answers source 28’s [research question 113.209](#) in part and extends source 12’s full-class model [theorem 21.1](#) from inaccessible heights to every limit height ([sections XV.15](#) and [113.27](#)). Hamkins’s question in item (f) is not settled by it.

[merge] Dated note, 4 October 2026 (batch 96). Sources 34 and 35 answer over GB the strength of complete condensation histories, which [note 108.4](#), item (b) of [section 112](#) and source 20’s [research question 113.111](#) left open without global choice; together with sources 32 and 33 they answer source 31’s [research question 113.239](#) in part ([sections XVI.12](#) and [113.29](#)). Hamkins and Woodin’s Question 7 is not settled.

[merge] Dated note, 4 October 2026 (batch 97). Source 36 answers source 33’s [research question 113.286](#) and the addition and multiplication part of source 34’s [research question 113.275](#), and advances source 32’s [research question 113.284](#), source 33’s [research question 113.285](#) and source 34’s [research questions 113.272](#) and [113.283](#) ([sections XVII.11](#) and [113.31](#)). Hamkins and Woodin’s Question 7 is not settled.

## 1.8 The batch-81 addition: six further manuscripts

[merge] (3 October 2026.) Six manuscripts of batch 81, all dated 3 October 2026 and all continuing this report, are merged into it as one addition, sources 13–18. Sources 13–17 arrived in commit `9a4ce14e9` and were placed in `f0cd7032d` (batch 81L); source 18 arrived in `bd599ac06` and was placed in `c4720e1b2` (batch 81L2). Their local numbers continue this report’s sequence; the batch-81 manuscript number is in the second column.

| Src. | B81 | Manuscript (archive), pages                                                                                                  | Pin       | Labels, files                                       |

| 16   | 04  | <i>Lexicographic Orders of Surreal Well-Orders: Cuts, Canonical Blocks, and the Limits of Set-Sized Coding</i> ; 33 pp. (surreal_well_orders_further.zip)                                                                 | 491ed8411 | swo:ds;;<br>16-strata-*     |
| 17   | 05  | <i>Lexicographic Well-Orders of the Surreal Numbers, II: exact cut spectra, branch recognition, optimal support reserves, and automorphism-extension obstructions</i> ; 29 pp. (surreal_well_orders_further_study(1).zip) | 0ecd158fd | swo:gs;;<br>17-gaps-*       |
| 18   | 06  | <i>Lexicographic Well-Orders of the Surreal Numbers: Cuts, canonical class blocks, and changes of interpretation</i> ; 53 pp. (surreal_lexicographic_orders_further_study.zip)                                            | 83befe707 | swo:sh;;<br>18-shuffle-*    |

The six are independent texts, not editions of one another. Every pair shares 0.6–1.4% of word 8-grams (preamble, this report’s title and address, bibliography), no member file is shared, and the theorem sets differ. Sources 14 and 17 share only the inner directory name `surreal_well_orders_II` and a “II” in the title; source 18’s archive name extends source 15’s, but its pin, structure and results differ. None supersedes another; all six are merged (union). Sources 13–17 read this report at commit `0be9b9134`, before the corrections of `0f52c0dca`; source 18 read it at `83befe707`, after them, and before sources 13–17 arrived, so it never saw them.

They overlap heavily with each other and with this report. The represented-cut theorem that answers source 11’s [research question 113.1](#) is proved in all six by one argument; all six re-prove the core layer of Part IV (fresh separators, completion, interpolation, the core isomorphic to **No**, the diagonal theorem, direct comparison); and the set-sized layer re-proves the reals report. What is new is a second wave of results on questions of this report: the topology, cut spectra and coding lengths of the set-sized strata at birthday cutoffs; the termination classification of word orders; the trichotomy, characters, automorphism orbits, absoluteness and support thresholds for cuts of the set-coded core; the canonical block decomposition of class well-orders with explicit condensation histories; product (non)absorption; a  $\Sigma_1^1$  comprehension bound; and the countable models.

The addition is printed by theme, not by source, because the sources overlap: Part VI ([part VI](#)) prints the set-sized strata; Part VII ([part VII](#)) prints the six sources’ maps of interpretations, the word orders, the termination conventions and the other comparison orders; Part VIII ([part VIII](#)) prints the class cuts of the core: their classification and recognition, automorphisms, class extensions and support; Part IX ([part IX](#)) prints the unrestricted class well-orders: the canonical block decomposition and condensation histories, finite components and trace fibres, products, a  $\Sigma_1^1$  comprehension bound, larger universes and countable models, and the sources’ formalization plans. The sources’ introductions are printed in [section 4.5](#), their questions in [section 113.5](#), and their conclusions, ledgers, reproducibility records, title pages and statement crosswalks after those of the batch-80 sources. The rules of [section 1.2](#) apply unchanged: each shared result is printed once,

with every source that proves it named; the other versions are numbered notes, genuinely different proofs are marked routes, and every label of every source survives with the prefixes of [section 1.3.1](#). Re-proofs of results of this report or of other repository reports are printed as notes with pointers, never with a novelty claim.

*Status.* Sources 13, 15 and 17 call themselves AI-assisted and unrefereed, source 14 unrefereed ([merge] corrected 3 October 2026: source 14 does not call itself AI-assisted); source 18 calls itself “an AI-assisted research manuscript with mathematical proof review”, and its validation “consists of conventional proofs and independent AI-assisted proof review”; source 16 says its checks are “not external peer review”. None claims historical priority, peer review or a machine-checked formalization, and none is formalized here. The status files of sources 13, 14, 16 and 17 are shipped in this directory under their prefixed names.

*Where the last write of the addition had to choose* (3 October 2026). The six introductions are printed in [section 4](#), with the batch-80 introductions; the foundations sections, the universe sections and the Lean plans of sources 13–18 are printed at the end of Part IX rather than in Part V, so that no existing section is renumbered. Corrections made to source text: “In GBC” added to source 15’s [proposition 51.10](#); source 13’s “new point” about split products annotated as already contained in source 11’s proofs ([note 55.6](#)); source 15’s sentence that adding classes can destroy internal well-foundedness withdrawn for GBC realizations ([note 57.5](#)); source 17’s question table and source 14’s “Four main results” annotated ([section 4.5](#)); citations of this report replaced by cross-references, with the sources’ numbers “at the pin”. Source equations are tagged ( $SNN.n$ ).

## 1.9 The batch-83 addition: twelve further manuscripts

[merge] (3 October 2026.) Twelve manuscripts of batch 83, all dated 3 October 2026 and all continuing this report, are merged into it as one addition, sources 19–30. They arrived in five commits: b63f0c852 (sources 19–24), 5ad44b1ed (source 25), 0d7b2441d (source 26), 79049d58c (sources 27 and 28) and 51b0a69d7 (sources 29 and 30), and were placed together in 2e06337d5 (batch 83L). Their local numbers continue this report’s sequence; the batch-83 manuscript number is in the second column. Batch-83 manuscripts 07–10 are Research Reports placed elsewhere.

| Src. | B83 | Manuscript; archive and inner directory; pages                                                                                                                                                                  | Pin; arrival            | Labels; files                                                            | Parts               |

All twelve also contribute to the head of Part X (their scope sections, [section 61](#)), the close of Part XIV (their foundations, formalization plans, ledgers and verification records, [section 111](#)), the research questions ([section 113.12](#)) and the appendix of abstracts. The pins are the revisions of this report that each source read: `d5bd4a67b` and `109aaca15` have Parts I–V only; `7ff7736ec` has Parts I–VIII, with Part IX announced but not written. Several sources also read unplaced manuscripts, now sources of this report: source 19 read sources 15, 16 and 18; source 20 read source 18; sources 22 and 23 read sources 13 and 17; source 24 read sources 13, 14 and 17; source 25 read sources 13, 17, 22 and 23; source 26 read source 24; source 28 read sources 13 and 24; source 29 read sources 19, 20 and 21 (its manifest records their hashes). Sources 21, 27 and 30 cite none of them.

The twelve are independent texts, not editions of one another or of earlier sources. Every pair shares at most 3.3 % of word 8-grams (source 28 with source 24; source 22 with source 25 2.4 %; all other pairs, and each source against this report and sources 13–18, at most 2.2 %); no member file is shared, byte-identical to another delivered file or present in the repository before `2e06337d5`. Three name coincidences are not editions: source 27’s archive and main file have the names of source 15’s (`surreal_lexicographic_orders.zip`; different title, pin and theorems, 0.6 % overlap); source 30’s archive has the name of source 12’s, and its inner directory and main file those of sources 11 and 08 (`surreal_well_orders.zip`; at most 0.5 % overlap); source 23’s inner directory is source 13’s (`surreal_lexicographic_further/`). None supersedes another; all twelve are merged (union).

They overlap heavily, with each other and with this report. The countable-cutoff theorem (the minimal slice of a countable dense alphabet is homeomorphic to Baire space and has the real line as Dedekind completion, with continuum many omitted points in every interval) is proved by sources 19, 20, 21, 24, 29 and 30, and its complete metrizability again by source 26; the represented-cut theorem of Part VIII again by sources 20, 21 and 22; the automorphism-extension criterion of Part VIII by sources 20, 21 and 25; the termination criterion of Part VII by source 23; the canonical blocks and condensation histories of Part IX by sources 23 and 29 (the blocks also by sources 19 and 21); the residual-code classification by sources 19 and 30; the countable-strata topology by sources 29 and 30; the faithful reconstruction of a class realization by sources 22, 27 and 30; the centered-word product by sources 27 and 29. Each is printed once, with every source that proves it named; the other versions are numbered notes, genuinely different proofs are marked routes. What is new is a third wave of results on questions of this report and of sources 13–18: the binary-cube spectrum and coding length of every fixed type (source 19); weights and characters of every fixed-length stratum (source 22); the exact birthday spectrum of  $\mathbf{No}_{<\theta}$  and the noncardinal cutoffs (sources 29 and 21); the topology of the minimal slice at every size and the non-Borel boundary (sources 24, 26 and 28); coherent limits and club detection across cutoffs (source 20); the increasing-word factorization and scan-dependent tables (sources 27, 29 and 30); configuration homogeneity, invisible exhaustiveness and label rigidity of the core (source 25); the least ordinal support bound (source 27); reconstruction of class realizations (sources 22, 27 and 30); the local coding dichotomy, countable class models and their common theory (sources 19, 20 and 21); and the equivalence of canonical condensation histories with class comparability (source 29).

*How Parts X–XIV are organized.* The addition is printed by theme, not by source, after Part IX. Part X prints the set-sized strata, their topology and the permutation groups of the minimal slice (sources 19, 21, 22, 24, 26, 28, 30). Part XI goes across birthday cutoffs: restrictions, coherent limits, noncardinal cutoffs and coherent embeddings (sources 19, 20, 21, 29). Part XII prints words, termination markers and comparison codes (sources 23, 27, 29, 30). Part XIII prints the core and its cylinders: automorphisms, decorated completions, support and class realizations (sources 25, 22, 20, 21, 19, 27, 29, 30). Part XIV prints unrestricted class well-orders: local size, condensation histories and external models (sources 20, 19, 21, 23, 27, 29, 30), and closes with the twelve

sources' foundations, formalization plans, ledgers and verification records ([section 111](#)). The rules of [section 1.2](#) and of [section 1.8](#) apply unchanged; re-proofs of results of this report, of sources 13–18 or of other repository reports are printed as notes with pointers, never with a novelty claim. Where a source says that this report lacks something it now has (most read it before Parts VI–IX existed), the sentence is kept as pinned provenance with a dated [merge] correction. Source 28's headline question, complete metrizable of the full singular permutation space, is answered negatively in ZFC by source 26, which source 28 did not see; it is printed with that status. The questions of this report and of sources 13–18 that the addition answers fully or in part are recorded in [section 113.25](#).

*Status.* Sources 19–26, 28 and 29 call themselves AI-assisted on their title pages; sources 23–26 and 28 add “unrefereed”, sources 19 and 29 “not a refereed publication” (“paper”), and sources 20, 21 and 29 that their proofs had internal review only. Source 27 makes “no claim of historical priority or external peer review”; source 30 reports “independent AI-assisted proof review” and no machine-checked formalization. None claims historical priority or a machine-checked formalization, none built the repository or compiled a new Lean file, and none is formalized here; their finite checks verify finite mechanisms only. Their status files, audits, finite checks and records are shipped in this directory under their prefixed names ([section 111](#)).

*Where the batch-83 merge had to choose.*

- *One theme, one Part.* Each mathematical section of the twelve sources is printed once, in the Part of its theme; a result already printed (in Parts I–IX or by another batch-83 source) becomes a numbered note that quotes the statement and keeps the source's label, followed by the source's proof where it differs. The maps of interpretations of sources 23, 27, 29 and 30 are printed in Part XII, beside the word orders and relation tables they introduce, and not in [section 61](#); source 29's section on global well-orders and represented cuts is printed in Part XIII ([section 86.5](#)).
- *The core.* The two codings of Part I are kept apart by source: normalized permutations of an ordinal are printed  $\mathcal{P}_{\text{bd}}(b)$  (sources 19, 20, 21, 24, 26, 28 and 29), fixed-point-free support codes  $\mathcal{P}_s(b)$  (sources 22, 25, 27 and 30). Source 20's  $\mathcal{C}_b$  is defined by normalized permutations  $\pi : \lambda \rightarrow \lambda$  with  $\lambda = \sup\{\xi + 1 : \pi(\xi) \neq \xi\}$ , so it is printed  $\mathcal{P}_{\text{bd}}(b)$  in every Part (a draft of Part XI had  $\mathcal{P}_s(b)$ ; the evaluations are the same).
- *Residual weights.* Source 19's and source 29's weights  $r(\lambda)$ ,  $u_\kappa(\lambda)$  and weighted lengths  $R$ ,  $U$  are printed  $\text{wt}(\lambda)$ ,  $\text{wt}_\kappa^+(\lambda)$ ,  $\varrho_{\text{lo}}$ ,  $\varrho_{\text{up}}$  in Parts X and XI alike, and source 30's  $r(\nu)$  is  $\text{wt}(\nu)$  ([section 1.3.2](#)).
- *Placement of the shared front and back matter.* The twelve sources' opening sections head Part X ([section 61](#)); their foundations, formalization plans, ledgers and verification records close Part XIV ([section 111](#)); their questions follow those of sources 13–18 ([section 113.12](#)); their title pages and abstracts close [appendix C](#); their numbered statements are mapped in [appendix D](#). No existing Part, section or label was renumbered or renamed; the sections of the questions part and the appendices move by the number of new sections.
- *Provenance correction.* The placement commit 2e06337d5 records source 25's archive `Surreal_1_Well_Orders_Prefix_Symmetries.zip` as arriving in 0d7b2441d; it arrived in 5ad44b1ed, as the table above says. The staged bytes are unaffected.

## 1.10 The batch-89 addition: source 31

[merge] (3 October 2026.) One manuscript of batch 89, its manuscript 01, continues this report and is printed as Part XV ([part XV](#)), source 31. It arrived in commit 7c0f2d9f9 and was placed in 23adb85f9. It shipped only its manuscript, its PDF and a delivery README, so the placement

staged no file here; 31 is its number in this report’s local sequence (the highest prefix in this directory is 30–). Batch-89 manuscripts 02–05 are placed in other reports.

| Src. | B89 | Manuscript; archive and inner directory;<br>pages                                                                                                                                                                                 | Pin; arrival            | Labels; files  | Parts |
|------|-----|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------|----------------|-------|
| 31   | 01  | <i>Countable Global Choice and Surreal Coding over Zermelo Set Theory: A localized nonconservativity theorem and exact rank-model spectra</i> ;<br>global_choice_surreal_coding.zip,<br>same inner directory; 1,547 lines, 21 pp. | 2b7b388ba;<br>7c0f2d9f9 | swo:gcz:: none | XV    |

The pin 2b7b388ba (“Catalogue batches 81 to 86”) holds this article as blob 05807d292, the text written by the batch-83 write 07ee2b30c, with Parts I–XIV, unchanged until this write; source 31 names that blob, so the numbers it cites (for example Theorem 13.1, swo:cf:choice) are the current ones. Its title page reads “Research article prepared for Vladimir Reshetnikov” and is dated 4 October 2026, the UTC date of its arrival (3 October 2026, 21:36 PDT). It is not an edition of any earlier source: it shares no file with them, its subject (Zermelo set theory with a selector; full-class rank models at every limit height) is new to this report, 0.6% of its word 8-grams occur in this report (bibliography and standard phrasing), and it shares at most 0.33% with any other batch-89 manuscript. Two of those bear on it: manuscript 03, printed as Part VI of **birthday-cutoffs-and-hereditary-sets**, shows that  $V_{\omega+\omega}$  fails Replacement for definable families, the definable special case of [lemma XV.9.2](#) at a height of cofinality  $\omega$  (its Proposition 30.1, hset:zr:prop:rankmodel, which also refutes there its bounding scheme NIB inside  $(-1, 0)$ ; its Remark 24.7, hset:zr:rem:swo, records the inclusion; labels added 4 October 2026, after that write was committed); and manuscript 05, the report **naming-elementary-embeddings** of the research-report collection, studies Replacement and Collection schemes in a language expanded by named maps, a theme related to the expanded Separation of [proposition XV.5.5](#), with different theorems.

*How Part XV is printed.* Source 31 is the only source of its material, so nothing is merged across sources: Part XV prints its Sections 1–12 whole and in order as Sections XV.1–XV.12, then its Appendices A and B (axiom ledger and source audit) as Sections XV.13 and XV.14, and a status section XV.15. Its research questions are printed in the questions part ([section 113.26](#)), its title page, abstract and scope statement in [Appendix C](#), its delivery record in [appendix A.12](#), and its numbered statements are mapped in [appendix D](#). Where it re-proves or extends a result of Parts I–XIV, a [merge] paragraph after the statement says so; there are two re-proofs (the count of [lemma XV.7.1](#) at a cardinal cutoff, and the inaccessible case of [theorem XV.9.3](#)).

*Status.* A research article with written proofs; it claims no machine verification and no historical priority, uses Glazer’s countermodel theorem as an explicitly cited input, and names expert review of its localized theorem as the next step ([section XV.14](#)). It is not formalized here. The Hilbert’s-tenth research tree routed its archive with the other topology and surreal arrivals of that day (Computability/HilbertTenthProblem/Papers/research-wip/native-stream-queue/review\_topology\_surreal\_arrivals\_20261003.md, commit 6aadaa4f2): it hashed the archive, read bounded line ranges and ran nothing, and found that source 31 yields no Diophantine construction; that note records scope, not a proof review, and has no correctness finding.

*Where the batch-89 write had to choose.*

- *Numbering.* The sections of Part XV are numbered XV.1–XV.15 instead of continuing from 112, so that the questions part keeps its Sections 113–115 and every statement, question and

appendix keeps the number it had before this write (the batch-81 and batch-83 writes moved the closing sections; this one does not). Source 31’s statement  $k.m$  is  $XV.k.m$ , and the [merge] paragraphs inside its sections add no numbered statement.

- *Placement.* Source 31’s questions follow those of sources 19–30 (section 113.26), with the dated notes of section 113.27; its abstract closes appendix C; its ledger and source audit close Part XV, as the batch-83 ledgers close Part XIV.
- *Citations of this report.* Source 31’s references to `swo:cf:choice` and `swo:ge:n10` keep its words and gain cross-references; “the inspected ProveIt report” is annotated; its bibliography entry for this report is [69].
- *Renamings* (section 1.3.3): threads  $\text{Thr}_X$  for source 31’s  $\mathcal{T}_X$ ; injections  $X \mapsto D$  for its  $X \hookrightarrow D$ . No other symbol changes.
- *Bibliography.* Its entry for Hamkins’s 2014 post on transfinite recursion is this report’s [63], not [26] (2017), which source 31’s key names; its entry for Hamkins’s post on global choice is [19]; its other entries carry the prefix `gcz`.
- *The Glazer interface* is printed as source 31 states it, with a [merge] paragraph (section XV.5.1) saying that it is unreviewed. No source text was corrected and no statement strengthened.

### 1.11 The batch-96 addition: sources 32–35

[merge] (4 October 2026.) Four manuscripts of batch 96, its manuscripts 08, 09, 10 and 11, continue this report and are merged as Part XVI (part XVI). They arrived together in commit `e3839ad2c` and were placed in `111c38012`. In this report’s local sequence they are sources 32–35 (the highest prefix in this directory was 30–; 31 is source 31, which staged nothing), with file prefixes `32-ceilings-`, `33-heights-`, `34-choicefree-` and `35-completion-` and label prefixes `swo:dc:`, `swo:dh:`, `swo:bo:` and `swo:fc:`. The other batch-96 manuscripts are placed in other reports.

| Src. | B96 | Manuscript; archive and inner directory; size                                                                                                                                                                          | Pin; arrival                                                                  | Labels; files            | Parts         |

*Pins.* Source 34 read this report at `e1d2f3048` and source 35 at `f158f27b4` (both 4 October 2026, 16:34 and 16:37 PDT). Source 32 records a “root tree” `8f7d4a5c8`, which is a commit (16:32 PDT, tree `08039c482`), and two blobs, source 23’s status file and `SetTheory/ZF/Lean/ZF/Zf.lean`. Source 33 records no commit, only the blobs of `Algebra/SurrealNumbers/docs/README.md` (introduced in `c14a866bc`) and of this report’s README (introduced in `e50dde15b`). At every one of these revisions, and until this write, `article.tex` is blob `72eee5cc8`, the text with Parts I–XV, and the README is blob `d2e24b58`; so all four read the same report, and the numbers they cite (Theorems 52.3, 53.4, 108.16 and 108.19 among them) are the current ones. Sources 32, 33 and 34 are dated 4 October 2026; source 35 is dated 5 October 2026, after its pin and its arrival (4 October 2026, 17:22 PDT), and source 33’s files carry 5 October timestamps; the dates are printed as delivered. Title pages: sources 32 and 33 “Research manuscript prepared for Vladimir Reshetnikov”, sources 34 and 35 “Research report prepared for Vladimir Reshetnikov”.

*Not editions.* The four are independent answers to one request: no file is shared, and shared word 8-grams are at most 1.64% (sources 34 and 35) and at most 1.62% of any source against this report (preambles, bibliography, quoted phrasing of this report). Their main theorems overlap heavily, as Part XVI’s Notes record.

*How Part XVI is printed.* Source 34 is the base: on the shared theorems it has the weakest hypotheses (GB for the history equivalence, as source 35; GB for the hereditary order and its universal property, where sources 32, 33 and 35 use GBC; any transitive  $\beta$ -model for the definable ceiling, where sources 32 and 33 use  $V_\kappa$ ), and its set-subset criterion lowers the other sources’ GBC steps. Its Sections 1–10 are Sections XVI.1–XVI.10, each followed by the corresponding sections of sources 35, 32 and 33 as subsections; the four sources’ appendices and ledgers form Section XVI.11, and XVI.12 is the status section. The research questions of all four are merged by theme in [section 113.28](#), with dated notes in [section 113.29](#); their title pages and abstracts are in [Appendix C](#), their delivery records in [appendix A.13](#), and their numbered statements are mapped in [appendix D](#).

*Status.* Sources 32 and 33 call themselves AI-assisted and unrefereed; sources 34 and 35 report “independent mathematical checks during preparation” and are not refereed. All four give written proofs, claim no historical priority and no machine-checked formalization, and are not formalized here. The Hilbert’s-tenth research tree reviewed the archives in a bounded intake (commit `fcc4098ec`), with a placement audit (`b16786caf`) and a related computability note (`c6082d075`); what they checked and what they did not is recorded in [section XVI.12](#).

*Literature cited only by source 35* (status at this write). Checked online on 4 October 2026: Frittaion and Genovesi’s *Axiom Beta Implies Elementary Transfinite Recursion* is arXiv:2603.13913, version 3 of 14 July 2026, with the stated result for its weak theory **C**; Jeon and Walsh’s *Generalized ordinal analysis and reflection principles in set theory* was first published online in the Journal of Symbolic Logic on 28 April 2026 (arXiv:2312.12859, version of 20 December 2023); Jeon’s note states as its Proposition 1.5 the class order  $E_0 = \varepsilon_{\text{Ord}+1}$  with a reference to Rathjen’s Definition 4.1 and Lemma 4.4; version 2 (10 March 2021) of the class-forcing paper records that Gitman and Hamkins pointed out a flaw in the published proof of their Theorem 9 (clopen determinacy implies ETR), the implication remaining correct, as source 35 says; and Gitman and Hamkins prove the GB + DC form of the well-foundedness test in the discussion before their Definition 6 (in their Section 4, as source 34 cites it). Not checked: Glazer’s MathOverflow question 270535 and its answers by Hamkins and Taranovsky (the site refused automated access), the cited results of Williams’s dissertation, and Rathjen’s chapter itself, which source 35 also did not see.

*Bibliographic notes of the sources.* Entries of this report are reused where the sources cite the same work: [22] (source 34 adds “Contemporary Mathematics 690, 2017, pp. 121–143”), [27] (“the full text checked was arXiv version 1”, source 34; “Theorems 4–6, Observation 8, Theorem 9 and Question 7”), [24] (version 2, source 35), [35], [30], [26] and [28]. New entries carry the prefix **xvi**.

Where the batch-96 write had to choose.

- *Base and arrangement*: source 34, for the reasons above; the other sources' sections follow the base section they continue, whole where possible (source 35's Sections 3 and 9, source 32's Section 3 and source 33's Section 3 are split between two base sections).
- *Duplicates*: a statement proved again by the same argument is a Note; three source equations referred to elsewhere are printed inside their Notes, (S33.7.1), (S33.7.2) and (S35.15). Proofs that differ are printed as routes: source 35's power theorem, leastness and successor obstruction, source 32's power theorem and termination, source 33's definability height.
- *Numbering*: Sections XVI.1–XVI.12, so that no earlier number changes; the questions are one subsection, 113.28, with dated notes in 113.29 (the placement had projected one subsection per source, 113.28–113.31 and 113.32; the four lists are merged by theme instead).
- *Renamings* (section 1.3.4):  $A^{[B]}$  for source 34's  $\backslash\text{Pow}$ ;  $A^{[B]}$  and  $P(\Gamma)$  for sources 32 and 33's  $A^B$  and  $P_\Gamma$ ;  $E$ ,  $E(A)$ ,  $E^{\leq n}$  for  $\mathcal{E}$ ,  $H(A)$ ,  $\mathcal{H}(A)$  and source 34's  $E_n$ ;  $\mathbb{T}$  for source 33's direct limit  $E$ ;  $\text{dom } W$  for source 32's  $D_W$ ;  $\hookrightarrow$ ,  $\nrightarrow$ ,  $\preceq_{\text{init}}$  for the sources' embedding symbols; source 34's agenda items as numbered questions R1–R12.
- *Stale and answered claims*, kept on record with their proofs: source 32's termination priority (remark XVI.1.1); source 33's Remark 5.5 and question 12.7 (remark XVI.5.29); source 32's question 12.1 and source 33's question 12.6 (section 113.28).
- *Added by this write*: the identification of towers with histories (remark XVI.5.24), the consequence of source 33's converse (remark XVI.5.31), and the choice-free completion theorem (theorem XVI.6.21), which answers source 35's question 10.6 from source 34's criterion; none is a source's statement, and none is reviewed. (Dated note, 4 October 2026: all four have since been checked independently and found valid after editorial corrections, which are made and recorded in dated notes at each; section XVI.12.)
- *A correction to the placement record*: the placement dossier read Mathlib's `Ordinal.univ` and `Ordinal.type_lt_ordinal` as deprecated; only `Ordinal.univ_id` is, as source 32 says (Section XVI.10).
- No source text was corrected and no statement strengthened; the delivered texts are printed with the renamings and label prefixes above, with headings replaced by merge headings that carry the source's label.

## 1.12 The batch-97 addition: source 36

[merge] (4 October 2026.) One manuscript of batch 97, its manuscript 01, continues this report and is printed as Part XVII (part XVII), source 36. It arrived in commit d7cf7d554 (4 October 2026, 18:06 PDT), fifteen minutes after the placement 111c38012 of sources 32–35, and was placed in 6571ee1af (batch 97A). In this report's local sequence it is source 36 (the highest prefix in this directory was 35–), with file prefix 36-horizons- and label prefix swo:hn:. Batch-97 manuscripts 02–07 are placed in other reports.

| Src. | B97 | Manuscript; archive and inner directory; size                                                                                                                                                                                                                      | Pin; arrival            | Labels; files | Parts |
|------|-----|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------|---------------|-------|
| 36   | 01  | <i>Beyond Ord: Definable Class Well-Orders, Finite-Support Arithmetic, and Definability Horizons. A constructive notation calculus with exact model-relative bounds;</i><br>Beyond_Ord_Research_Package.zip,<br>inner directory Beyond_Ord; 2,950 lines,<br>40 pp. | e1d2f3048;<br>d7cf7d554 | swo:hn:: 5    | XVII  |

*Pin.* Source 36 read this report at e1d2f3048 (4 October 2026, 16:34:43 PDT, as its audit says in UTC), the pin of source 34, where `article.tex` is blob 72eee5cc8 (3,289,057 bytes, Parts I–XV) and the README blob d2e24b586; its audit adds that a code-search index first offered the older commit 555ee36fb. It read this report’s README, 29-birthdays-PROOF\_STATUS.txt, the repository README and Logic/PeanoArithmetic/ListCoding/README.md, not the article itself; it did not see Part XVI. Its title page has no author line (“An investigation prompted by the ProveIt repository”, October 2026; PDF author “Research manuscript on definable class well-orders”); its audit is dated 4–5 October 2026.

*Not an edition.* Source 36 shares no file with sources 32–35 (the Hilbert’s-tenth review compared every member byte for byte), and its shared word 8-grams are 0.41 %, 0.36 %, 0.72 % and 0.78 % against sources 32, 33, 34 and 35 and 0.90 % against this report with Part XVI (preambles, bibliography, standard phrasing). It is an independent fifth answer to the request of sources 32–35, and its main theorems overlap theirs heavily, as the credit notes of Part XVII record.

*How Part XVII is printed.* Part XVI was written and committed (62b16914e) before source 36 could join its merge, and inserting source 36’s material into it would renumber its Sections XVI.11–XVI.12 or put results after its status section. Source 36 is therefore printed whole as its own Part, as source 31 is in Part XV: its Sections 1–8 as Sections XVII.1–XVII.8, its Section 9 as Section XVII.9 with its questions in [section 113.30](#), its Appendix A as Section XVII.10, and a status section XVII.11. Its title page and abstract are in [Appendix C](#), its delivery record in [appendix A.14](#), and its numbered statements are mapped in [appendix D](#).

*Status.* Conventional written proofs with “independent review during preparation” (its words); no referee, no proof assistant, no priority claim. Not formalized here. The Hilbert’s-tenth research tree reviewed the archive in a bounded intake before placement (`Computability/HilbertTenthProblem/Papers/research-wip/native-stream-queue/review_beyond_ord_package_d7cf7d554.md`, commit 39bb02ece); its scope is recorded in [section XVII.11](#).

*Literature cited only by source 36*, not checked by this write: Reshetnikov’s Mathematics Stack Exchange question 4072813 [95], the MathOverflow discussions 116590 and 379630 [100, 101], Freire and Williams’s Theorem 2.1.1 [96], Marcone and Montalbán’s Definition 2.3 [97], Traytel’s Isabelle theory [98] and the Mathlib documentation of Cantor normal forms [99]. Entries of this report are reused where source 36 cites the same work: [84] (version 4), [22] (source 36 adds Contemporary Mathematics 690, 2017, 121–143), [35] (its Question 2.35 and Lemma 3.17), [27] (Theorems 4–6 and Question 7), [24] and [19] (“especially the rank-first construction”). New entries carry the prefix xvii.

*Where the batch-97 write had to choose.*

- *A Part of its own*, printed whole, for the reason above; the placement 6571ee1af made the same decision.

- *Numbering*: Sections XVII.1–XVII.11 and statements XVII. $k.m$  equal to source 36’s  $k.m$ ; the credit notes are lettered (XVII. $k.A$ , ...), so that no source number moves; the questions are one subsection, 113.30, with dated notes in 113.31.
- *Credit, not correction*: the fifteen credit notes name the statements of Parts I–XVI that source 36 proves again; its novelty sentences (Section XVII.1.5, its title page, the status table of Section XVII.10) are printed as delivered with dated credit notes; its least-fixed-point theorem is printed as delivered, and the stronger form its proof gives is stated in [note XVII.4.B](#) with credit to source 34. No source text was changed and no source statement strengthened.
- *Renamings* ([section 1.3.5](#)):  $A^{[B]}$  for class-order powers  $A^B$ ;  $\mathbf{E}$  and  $\mathbf{E}^{\leq n+1}$  for  $\mathbf{T}_\Omega$  and  $T_n$ ;  $\mathbf{E}_\rho$  for the epsilon-term functor  $\mathbf{E}$ ;  $\mathfrak{H}$  for the horizons  $H$ ;  $\preccurlyeq_{\text{init}}$ ,  $\prec_{\text{init}}$ ,  $L_{<x}$  for its embedding and cut macros. The starred equation is cited by its tag in one sentence.
- *Unproved claims*: none of source 36’s theorems was found false, and none is unproved. Two sentences of its question commentary state expectations without proof (“Further finitary notation operators may force additional closure conditions”; “An audited coding might yield a small constant shift”); they are printed as delivered, marked as conjectures in [section 113.30](#).
- *Corrections to Part XVI*: this write also corrects four passages written on 4 October 2026 for Part XVI, after an independent check of them ([theorem XVI.6.21](#) and [remarks XVI.5.24](#), [XVI.5.29](#) and [XVI.5.31](#)); each carries a dated note.

## 2 The objects being studied

There are two orders in this problem. Each object under consideration is itself a well-order of some collection of surreal numbers. We then compare these objects lexicographically using the *numerical* order on their surreal labels. This second order need not be a well-order. Indeed, the orders below contain abundant descending sequences.

Write  $L \hookrightarrow M$  for an order embedding and  $L \simeq_e M$  for embeddings in both directions. Equimorphism does not imply isomorphism.

| Object                                   | Elements                                                                                                             | Logical size and interpretation                                  |
|------------------------------------------|----------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------|
| $\mathcal{W}(X)$                         | Ordinal-indexed bijections onto a fixed set $X \subseteq \mathbf{No}$                                                | A set; ordinary ZFC order theory                                 |
| $\mathcal{I}(\mathbf{No})$               | Injective set-length ordinal words in $\mathbf{No}$                                                                  | A class of sets; well-orders of arbitrary set-sized subsets      |
| $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  | Set-like class well-orders of all $\mathbf{No}$ , equivalently class bijections $\text{Ord} \rightarrow \mathbf{No}$ | A higher-order totality; use class variables or uniform families |
| $\mathfrak{W}_{\text{all}}(\mathbf{No})$ | All class well-orders of all $\mathbf{No}$ , including non-set-like ones                                             | A higher-order totality; direct labeled comparison is needed     |

The fraktur notation is deliberate. It does not declare a class with proper classes as members. Statements about  $\mathfrak{W}_{\text{sl}}$  and  $\mathfrak{W}_{\text{all}}$  are formulas with class variables, or statements relative to a specified larger universe. An embedding of an ordinary class order into one of these totalities is a uniform family: one class relation encodes the object assigned to each set-valued index.

**Principal answers.** For a fixed infinite alphabet  $X$ , the exact ordinal ceiling is  $(|X|)^+$ . Passing to all set-length surreal words removes that ceiling: there is an explicit embedding of the entire class into  $\mathbf{No}$ , and the singleton words embed  $\mathbf{No}$  in the other direction. The two orders are nevertheless not isomorphic, because limit-length words have set-sized left cofinality.

Under global choice, the set-like global fragment contains a uniformly indexed copy of every class linear order. This includes every set ordinal,  $\text{Ord}$ , reverse  $\text{Ord}$ ,  $\text{Ord} + \text{Ord}$ , and the whole numerical surreal order. Yet the entire fragment cannot be exhausted by one uniform class of set-codes. Class universality of a subfamily is compatible with a larger totality of class objects.

The unrestricted global order is different again. It has adjacent pairs and convex residual fibers. Every raw well-order begins with a canonical  $\text{Ord}$ -sequence; if that sequence omits labels, those labels form a later well-ordered tail. This decomposition permits a precise study of *all* well-orders without treating them all as set-like. It also supplies a nonembedding obstruction: the unrestricted order has too many disjoint two-point fibers to embed into the set-like order in the full containing-universe model. A related uniform definability obstruction is provable in  $\text{KM} + \text{GC}$ .

### 3 Relationship to ProveIt and the literature

We inspected the repository at the immutable revision

`ae7c1e6aae3dc58c9c638b35646865ad6c10387d`.

The closest precursor is the report on lexicographic well-orderings of the reals [1], in the subdirectory `lexicographic-well-orderings-of-reals/` of the repository's ordinal-order reports. Its general alphabet theorems already establish the cardinality, universality, and ordinal cutoff for every infinite linearly ordered set  $X$ . Their application to birthday fragments is a transfer of existing results, not a new generic alphabet theorem.

That report also proves, with  $\mathfrak{c} = 2^{\aleph_0}$ ,

$$\mathbf{No}_{<\theta} \hookrightarrow \mathcal{W}(\mathbb{R}) \quad (\theta < \mathfrak{c}^+), \quad \mathbf{No}_{<\mathfrak{c}^+} \not\hookrightarrow \mathcal{W}(\mathbb{R}).$$

The negative assertion follows from the all-plus chain of length  $\mathfrak{c}^+$ . It warns against taking an incoherent union of stagewise embeddings.

The repository's foundational report [3] supplies the relevant size discipline: individual surreals are set-coded, bounded fragments are sets, arbitrary class cuts need not be fillable, and quantifying over class functions does not create a class of those functions. Its local set-valued recursion arguments are directly useful. A nearby vector-space report uses the same distinction to avoid an unnecessary ETR hypothesis [5].

The sign-sequence presentation is standard [12, 14]. Absolute universality and homogeneity of the surreal order are part of the established theory discussed by Ehrlich [15]. We supply the short recursion arguments needed here.

**The Kanovei–Shelah connection.** There is a methodological connection, but the objects are different. Kanovei and Shelah's actual index consists of maps

$$a : \mathfrak{c} \longrightarrow \mathcal{P}(\mathbb{N})$$

whose ranges are ultrafilters. They compare these maps lexicographically using the binary order on  $\mathcal{P}(\mathbb{N})$  [16, Section 1]. The maps need not be injective and do not enumerate the entire real line. Their construction illustrates how a definable linear order on many codes can replace a definably selected well-order. The present problem shares that idea while introducing a different level of class-size complexity.

**Contribution and attribution.** The central developments here are explicit surreal-word compression, direct comparison of unrestricted class well-orders, their canonical initial-Ord decomposition, the bounded-support interpolation theorem, and the relation between omitted ranges and non-set-like tails. No claim about real-specific countability, separability, or gap spectra is transferred to surreal alphabets without proof.

## 4 The other sources' introductions

[merge] Each of the other manuscripts opens with its own statement of the problem, of its relation to ProveIt, and of the Kanovei–Shelah connection. These introductions are printed whole, one subsection each, followed by notes where the merge corrects or qualifies them. Their summaries of results are not repeated claims: every result they announce is printed, once, in the body.

### 4.1 Source 12: scope, predecessors, and the results at a glance

The phrase “well-orders of surreal numbers” hides several distinct objects. The usual numerical order of **No** is not a well-order. One may instead put an unrelated well-order on the entire surreal carrier, or consider numerical well-orders on subclasses, or work with an ordinary set of bounded-birthday surreals. This article treats all three viewpoints, but the principal object is the lexicographic comparison of *exhaustive well-orders of a fixed carrier*.

The supplied ProveIt repository contains a substantial predecessor, *Lexicographic Orders of the Well-Orderings of the Reals*, merging three reports and distinguishing the full enumeration order from its minimal-length slice [1]. The inspected README explicitly marks that report as unrefereed and not formalized. Its real-number spectra, binary coding, finite-tail geometry, and warnings about isomorphism versus equimorphism motivate the present work. The repository also contains a Lean development of simplest elements of convex sets of sign sequences [10]. These are useful foundations, not a formal verification of the new theorems below.

We pinned the audit to repository commit

63bb8b1d99359e7188abf0a33fb152e121858150.

The audit was targeted, not an exhaustive review of the repository. All essential arguments used here are written out, so no unreviewed research claim from the repository is required as a black box.

#### 4.1.1 Three different orders

For an infinite set-sized linear order  $X$  of cardinality  $\mu$ , define

$$\mathcal{W}_\alpha(X) = \{e : \alpha \longrightarrow X : e \text{ is bijective}\}, \quad \mathcal{W}(X) = \bigcup_{\mu \leq \alpha < \mu^+} \mathcal{W}_\alpha(X).$$

They are ordered by their first unequal entry, using the given order of  $X$ , not the well-order being represented.

For the proper class **No**, let  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  denote, as a *predicate on classes*, the class bijections  $E : \text{Ord} \rightarrow \mathbf{No}$ . These represent exactly the set-like global well-orders. Let  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  denote the predicate of being an arbitrary class well-order relation on **No**. Neither displayed notation asserts the existence of a class having these class-sized objects as members.

The comparison on  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  uses a least ordinal of disagreement. The comparison on  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  uses a largest common *labelled* initial segment. The latter can be a proper class, and this is essential rather than a cosmetic extension.

### 4.1.2 What is proved, and what is not being claimed

The principal developments are the elementary common-prefix theorem ([theorem 14.7](#)), the global-choice equivalence ([theorem 13.2](#)), the non-enumerability theorem ([theorem 19.38](#)), and the singular transition ([theorem 8.3](#)). The full and minimal bounded spectra are proved in [sections 6.2](#) and [8](#). The difference between the dense set-like order and finite-tail geometry in the full order is proved in [sections 16.1](#) and [19.2](#).

These are mathematical claims with supplied proofs. We do not claim that they settle a previously catalogued open problem, that their exact formulations are historically new, or that they have been independently refereed. The proposed research questions at the end are precisely that: questions suggested by the results, not an assertion of a complete literature census.

### 4.1.3 The Kanovei–Shelah connection

Kanovei and Shelah order maps  $a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters, using a fixed lexicographic order on  $\mathcal{P}(\mathbb{N})$  [[16](#), §1]. Their maps need not be bijections, and their index is not the literal collection of all well-orders of  $\mathbb{R}$ , still less all class well-orders of **No**. The useful common idea is to compare representations at their first difference instead of choosing one canonical representative. Their index construction remains set-sized. Moving to all global surreal well-orders creates an additional size level that their construction does not remove.

[merge] *On source 12's introduction.* Source 12 read the reals report's README and the Lean file `SignSequenceSimplicity.lean`, not the reals report's article; it therefore re-proved the set-sized patterns it needed. They are printed here as a marked route with pointers to the reals report ([sections 6.1](#) and [6.2](#)). The reals report's article has not changed since source 12's pin. Source 12's principal developments are printed as [theorem 14.7](#) (a second route to [theorem 14.2](#)), [theorem 13.2](#) (a second route to [theorem 13.1](#), over  $\text{GB} + \text{AC}$ ), [theorem 19.38](#) (printed beside [theorem 19.37](#)) and [theorem 8.3](#) (new).

## 4.2 Source 09: the question and the principal conclusions

A surreal number is a set-sized object, but the totality **No** of surreal numbers is a proper class. Consequently, taking “all well-orders” changes logical level when one passes from  $\mathbb{R}$  to **No**. The main task is not merely to replace the real alphabet by a larger alphabet. It is to specify which objects are being ordered and which collections of those objects are available in the foundational theory.

Throughout, the word *embedding* means an order-preserving and order-reflecting injection. It need not preserve cuts, suprema, the order topology, birthdays, simplicity, or field operations. An order is *equimorphic* with another when each embeds into the other; this is weaker than isomorphism.

### 4.2.1 Three different carriers

For a set  $X \subseteq \mathbf{No}$ , let  $\mathcal{W}(X)$  consist of all bijections  $e : \alpha \rightarrow X$ , with  $\alpha$  an ordinal. These are exactly the exhaustive enumerations associated with well-orders on the fixed labeled set  $X$ . For different  $e, f$ , comparison takes place at the first unequal value. Because both are exhaustive, neither can be a proper initial segment of the other.

Let  $\mathcal{I}$  instead contain every set-length injective word  $p : \alpha \rightarrow \mathbf{No}$ , allowing its range to vary. Here proper-prefix pairs do occur, so an end-of-word convention is necessary. We use the convention that a proper prefix comes first. This is ordinary dictionary order, *not* the convention used to compare surreal sign sequences.

Finally, let  $\mathfrak{W}_{\text{sl}}$  be informal notation for the global class bijections  $E : \text{Ord} \rightarrow \mathbf{No}$ . Each represents a set-like global well-order. In GBC,  $\mathfrak{W}_{\text{sl}}$  is notation for a condition on class variables, not a class whose members are these class functions. A precise, ordinary class substitute is the set-coded core  $\mathcal{P}_s(b)$  of eventual perturbations of a fixed  $b : \text{Ord} \rightarrow \mathbf{No}$ .

**Main global conclusion.** In GBC, for every fixed global enumeration  $b$ ,

$$(\mathcal{P}_s(b), <_{\text{lex}}) \cong (\mathbf{No}, <).$$

The core is order-dense among all global enumerations and even supplies interpolants for every uniformly set-indexed separated cut involving arbitrary global enumerations. Nevertheless, there is no uniform class-indexed enumeration of *all* global enumerations, and certain proper-class-sized separated families have no interpolant at all.

#### 4.2.2 How this extends the repository’s real-line investigation

The inspected ProveIt snapshot contains a substantial merged report on lexicographic well-orderings of the reals [1]. That report studies ordinal spectra, binary coding, finite tails, local characters, and gaps. Its set-sized perspective is useful here, but its continuum bounds cannot simply be applied to the entire surreal class. We reprove the set-sized arguments needed below for an arbitrary linearly ordered set, without importing unverified transfinite claims from that report.

The genuinely global development is organized around four concrete constructions: bounded-support extension of an injective prefix; set-indexed lexicographic interpolation; an eventually-equal surreal core; and diagonalization at independent pairs of positions. These constructions are the main contribution of this manuscript. Whether particular formulations have appeared previously would require a more exhaustive literature search; they are not presented as established historical firsts.

Kanovei and Shelah’s nonstandard-model construction provides motivation for lexicographically ordering redundant codes. Their actual index is not the collection of all real well-orders: it consists of maps from the continuum cardinal to  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters, ordered at their first disagreement [16, §1]. This distinction remains essential in any proposed surreal analogue.

[merge] *On source 09’s introduction.* Source 09 read the reals report’s README and the Lean files `SignSequence.lean` and `SignSequenceCutOperation.lean`. Its set-sized arguments, which it “reproves ... without importing unverified transfinite claims”, are printed as notes and one marked route (section 6.3). The four constructions it calls its main contribution were found independently by the other sources on the same day: bounded-support prefix completion also by sources 11 and 08 (lemma 19.4 and note 19.8); set-indexed interpolation by sources 11, 12 and 08 (theorem 19.10 and notes 19.11 and 19.13); the eventually-equal core by sources 11 and 08 (corollary 19.15 and note 19.17); and the pair-switch diagonalization by sources 11, 12 and 08 (theorems 19.37 and 19.38 and note 19.41). No priority among the sources is implied by the order of printing. The box’s last sentence is theorem 19.42 and theorem 19.43.

#### 4.3 Source 08: the question, disambiguated

The phrase “well-orders of surreal numbers” has two independent ambiguities. First, is the carrier a set of surreal numbers or the whole proper class? Second, is a well-order required to be the restriction of the numerical order, or is it a new ordering of the labelled carrier? A third choice enters when the well-orders themselves are compared: which data are read lexicographically?

This paper uses the following principal convention. An arbitrary well-order on a labelled carrier is represented by its exhaustive increasing enumeration *in that well-order*. Two enumerations are then compared at their first unequal entry, using the *numerical* order of their surreal values. The enumerations themselves need not be numerically increasing. This distinction is indispensable.

For example, the two lists  $(0, 1, -1)$  and  $(0, -1, 1)$  represent two well-orders of the same three-element set. The second list is smaller in our lexicographic order, since  $-1 < 1$ . Both underlying relations have ordinal type 3. Passing to ordinal isomorphism types would identify them and destroy the object being studied.

#### 4.3.1 Five different carriers

| Object                      | Elements or parameters                                     | Foundational size                                       |
|-----------------------------|------------------------------------------------------------|---------------------------------------------------------|
| $\mathcal{W}(X)$            | Exhaustive enumerations of one fixed set $X$               | A set in ZFC                                            |
| $\mathcal{I}(\mathbf{No})$  | Injective ordinal-length, set-sized words in $\mathbf{No}$ | A class of sets                                         |
| $\mathfrak{M}_{sl}$         | Class bijections $\text{Ord} \rightarrow \mathbf{No}$      | A virtual collection of classes                         |
| $\mathcal{P}_s(b)$          | Set codes for set-supported changes of a fixed $b$         | A class of sets                                         |
| Arbitrary class well-orders | Class relations, possibly not set-like                     | A virtual collection; another comparison rule is needed |

A *virtual collection* is notation for a condition on class variables, not a new object whose members are proper classes. Thus “ $e \in \mathfrak{M}_{sl}$ ” abbreviates “ $e$  is a class bijection from  $\text{Ord}$  onto  $\mathbf{No}$ .” All statements involving several such parameters can be translated into the two-sorted language of class set theory. Whenever a family of classes is used, it is represented by one uniform class relation. This convention is made precise in [section 19.1](#).

#### 4.3.2 Main conclusions

The central distinction is between a very large ambient order and its class-sized dense skeleton. Fix a global enumeration  $b : \text{Ord} \rightarrow \mathbf{No}$ . Write  $\mathcal{P}_s(b)$  for canonical set codes for permutations  $\sigma$  of  $\text{Ord}$  that equal the identity outside a set, ordered by the numerical lexicographic comparison of  $b \circ \sigma$ . We prove

$$(\mathcal{P}_s(b), <_b) \cong (\mathbf{No}, <). \quad (\text{S08.1})$$

Moreover, if uniformly given set-sized families  $L, R$  of arbitrary global enumerations satisfy  $L <_{\text{lex}} R$ , then some  $b \circ \sigma$  strictly separates them. The separator is in the same fixed skeleton regardless of the supports, or lack of supports, of the input enumerations.

This yields a useful answer to the embedding question. Every *set* linear order, every ordinal, and indeed every *class linear order whose elements are sets* embeds into  $\mathcal{P}_s(b)$ . In particular,  $\text{Ord}$ ,  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ , their reversals,  $\mathbf{No}$ , and each set-indexed lexicographic power of  $\mathbf{No}$  embed. This does not say that the full virtual order  $\mathfrak{M}_{sl}$  is itself a class order or is isomorphic to  $\mathbf{No}$ .

At a fixed set-sized carrier  $X$ , the answer is different. If  $|X| = \kappa$  is infinite, then

$$|\mathcal{W}(X)| = 2^\kappa, \quad \beta \hookrightarrow \mathcal{W}(X) \iff \beta < \kappa^+. \quad (\text{S08.2})$$

Thus making the carrier larger changes the allowed ordinal spectrum; there is no legitimate substitution of a “cardinal  $|\mathbf{No}|$ ” into [\(S08.2\)](#).

### 4.3.3 Relationship to existing work

The set-sized part extends the exhaustive-enumeration viewpoint of the prior working manuscript on the continuum [2]. Its results are reproved here in a form that does not assume separability of the alphabet. The standard surreal background is the sign-sequence and cut-filling viewpoint associated with Conway, Gonshor, and Alling [11, 12, 13]; Ehrlich’s work places the surreal continuum in a broader universality framework [15].

The immediate formalization base is the inspected ProveIt sign-sequence construction and its small-cut theorem [7, 8]. We do not need the repository’s field arithmetic or stronger research claims. The resemblance to the Kanovei–Shelah definable hyperreal construction is real but limited: their actual index consists of fixed-length maps whose ranges are ultrafilters, not literally all well-orders of the reals [16]. We return to this distinction in [section 4.4](#).

[merge] *On source 08’s predecessor.* The “prior working manuscript on the continuum” that source 08 cites [2] is batch-76 manuscript 02, *Lexicographic Orders of Well-Orderings of the Continuum*, which is now the base source 02 of the repository’s reals report (placed in 2a04b60f2, written in 718bfa3b5 and 603f6ed31). Source 08 did not read that report. Its set-sized results re-prove the reals report’s general-alphabet theorems, which hold for every infinite linear alphabet, separable or not; they are recorded with pointers in [sections 6.1](#) and [6.4](#). The display (S08.1) is [note 19.17](#), and (S08.2) is [notes 6.21](#) and [6.23](#).

## 4.4 Source 08: the Kanovei–Shelah connection, carefully stated

Kanovei and Shelah’s definable nonstandard model uses an index  $A$  of maps

$$a : \mathfrak{c} \longrightarrow \mathcal{P}(\mathbb{N})$$

whose ranges are ultrafilters. They compare these maps lexicographically using the binary characteristic-function order on subsets of  $\mathbb{N}$ . Repetitions are allowed; the index is not a well-order [16]. It is therefore not literally the order of all bijective well-order enumerations of  $\mathbb{R}$ .

The relevant common idea is that ordinal-indexed codes can be linearly compared at their first unequal value even when no definable choice of one representative from each coded object is supplied. Our paired codes, terminal codes, and virtual relations explore that order-theoretic idea in the surreal setting. They do not provide a class ultrapower or a transfer theorem.

An extension to a class-sized ultrapower would need separate decisions about admissible predicates, function families, equivalence-class coding, truth or satisfaction, and the exact size of saturation. Neither a dense index order nor a surreal-sized skeleton settles these questions. In particular, the set-cut interpolation theorem is an order-theoretic theorem, not a claim of saturation for every language or every class-sized family of types.

[merge] The Kanovei–Shelah distinction is made in the same terms by all four sources (source 11 in [section 3](#), source 12 in [section 4.1](#), source 09 in [section 4.2](#), source 08 above) and by the reals report itself, which analyses the actual index (`lwo:eq:KS`, `lwo:sec:KS-topology`, `lwo:rk:sec:KS`). The uniform constructions it suggests are research questions here ([research question 113.10](#); source 09’s and source 08’s last directions).

## 4.5 The introductions of sources 13–18

[merge] (3 October 2026.) The opening sections of the six batch-81 sources are printed whole in the following subsections, in source order, followed by the Kanovei–Shelah remarks of sources 14 and 17; the other four batch-81 sources discuss the Kanovei–Shelah index in their maps of interpretations

(Part VII, [section 34](#)). Every result they announce is printed once in Parts VI–IX. Their equations are tagged (SNN.*n*) as elsewhere. Corrections and qualifications:

- *Stale descriptions of this report.* All six describe this report at their pins, as merged from four manuscripts; sources 13 and 15 (and source 14 in its audit section) give its length as 115 pages. It now merges ten manuscripts in nine Parts. Their citations of this report are printed as cross-references, with section and theorem numbers “at the pin” where the source gives them.
- *One theorem announced six times.* Each source presents the represented-cut criterion among its main results; it is one theorem, proved independently in all six ([note 46.1](#)). Source 16’s “all ordinal-class blocks at once” and source 18’s ([S18.3](#)) are likewise one theorem with source 15’s ([note 52.1](#)), and source 18’s density display ([S18.2](#)) is source 16’s theorem ([theorem 27.2](#)). Source 18, which could not know sources 13–17, calls these results “advances” over the repository in its table; relative to the merged report they are independent proofs of results of the sibling sources, and only the items listed as new in [sections 33, 39, 50 and 60](#) carry that word here.
- *Source 14’s “Four main results”* lists five; the heading is kept.
- *Source 17’s question table* maps its reserve theorem to source 11’s [research question 113.6](#), which asks for birthday bounds of word embeddings; the reserve theorem bears on source 09’s direction 6 and source 08’s question 13 instead ([note 49.11](#)). The table also omits source 08’s questions 2, 3, 6 and 12, on which its results bear ([sections 33 and 50](#)).
- *Parameters.* Source 16’s overview writes  $\kappa$  for the size of an alphabet and source 18’s writes  $\nu, \tau, \rho$ ; they are printed  $\mu$  and  $r, q, \theta$  as in [section 1.3.1](#). Source 18’s display defining  $X_\kappa = \mathbf{No}_{<\kappa}$  is omitted with its symbol.

#### 4.6 Source 13: scope, provenance, and the main advances

The phrase “the lexicographic ordering of all well-orders of surreal numbers” does not determine a single object. There are three independent choices: what is being well-ordered, how that well-order is represented, and in what universe the collection of representations is allowed to exist. A fourth choice appears when representations can have different lengths: the position of a termination symbol.

The ProveIt repository already contains a substantial report on these issues, assembled from four independent manuscripts. Its maintained `article.pdf` is described as 115 pages, and the report explicitly distinguishes written proofs from machine-checked results (this report and its README at the pin; [\[merge\]](#) the page count and the number of sources have grown with the batch-81 addition, and the report is still not formalized). We use the snapshot `0ecd158fd163bc4aca0ee40ccf6479ca6cf5f2a8`. The earlier report supplies the fixed-alphabet theory, the surreal-sized dense core, the direct comparison of raw class well-orders, and several nonembedding and coding arguments. These are credited below and, where needed for the new proofs, re-established in a compact form.

The present investigation addresses four of that report’s proposed continuations rather than relabeling its existing results as discoveries. The term “new” below means an extension developed in this manuscript relative to the inspected material; it is not a bibliographic priority claim.

**Main conclusions.** A normalized cut comes from an injective Ord-word exactly when it crosses a unique prefix cylinder at every set-ordinal length. It comes from a global enumeration exactly when these prefixes eventually include every label. Nonbranch cuts stop either at a successor step, where they separate whole next-letter cylinders, or at a limit step, where they lie on the boundary of one cylinder.

For the virtual order  $\mathfrak{W}_{\text{sl}}$  of all class bijections  $\text{Ord} \rightarrow \mathbf{No}$ ,

$$\mathfrak{W}_{\text{sl}} \cong \mathbf{No} \times_{\text{lex}} \mathfrak{W}_{\text{sl}},$$

but  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} 2 \not\rightarrow \mathfrak{W}_{\text{sl}}$  in the full inaccessible model and in the specified uniform  $\text{KM} + \text{GC}$  sense. This is not a contradiction:  $\mathbf{No}$  is an ordinary class of sets, whereas the full  $\mathfrak{W}_{\text{sl}}$  is a domain of class objects.

An order automorphism can send a prefix cylinder to a non-cylinder. Consequently the numerical linear order on enumerations does not, by itself, canonically specify the prefix tree. Central termination, on the other hand, repairs the small one-sided characters of ordinary dictionary words and produces an order isomorphic to  $\mathbf{No}$ .

#### 4.6.1 What is proved, and what remains conditional

The cut-reconstruction, product-absorption, recoding, and central-word results are proved in GBC. The product obstruction is proved in two separate interpretations: ambient ZFC with a strongly inaccessible universe, and a fixed-formula uniformity schema in  $\text{KM} + \text{GC}$ . The latter proof identifies its impredicative comprehension step. We do not claim that the same argument works over bare GBC.

This separation also prevents a false “absolute” assertion about the full global order. In an externally countable model, the available global enumerations form an externally countable dense order without endpoints, hence a copy of the rationals. Arbitrary external maps and internally uniform constructions therefore answer different embedding questions.

#### 4.6.2 Reading paths

Section 34.1–32.2 survey the interpretations and size constraints. Section 42.2–46.4 establish the dense-core and cut machinery. Section 55–36.4 contain the other main extensions. Sections 57.3 and 59.1 specify foundational and proof-assistant interfaces. The final research agenda distinguishes questions resolved here from stronger problems still to be investigated.

### 4.7 Source 14: the continuation and its main conclusions

The phrase “the lexicographic ordering of all well-orders of surreal numbers” does not specify one mathematical object. It leaves open what is being well-ordered, how it is represented, how termination is compared, and which logical universe supplies the word “all.” These choices are not cosmetic: they change cardinality, adjacency, completeness, and even the logical sort of the objects under study.

The present article continues the merged ProveIt report (this report and its README), inspected at commit 0ecd158fd163bc4aca0ee40ccf6479ca6cf5f2a8. That report combines four earlier manuscripts and already proves a large body of results. In particular, its Section 19 ([merge] Part IV here) supplies the dense set-supported skeleton, and its research agenda explicitly asks which cuts of that core represent exhaustive branches. Repeating the skeleton isomorphism or the set-sized ordinal spectrum would not answer that question.

Our main ambient theory is  $\text{GBC} = \text{GB} + \text{GC}$ , with Power Set and ordinary set Foundation. The letters  $\mathfrak{W}_{\text{sl}}$ ,  $\mathfrak{J}$ , and  $\mathfrak{W}_{\text{all}}$  denote predicates on classes, not classes whose members are proper classes. Fix a class bijection

$$b : \text{Ord} \longrightarrow \mathbf{No}.$$

The ordinary class  $\mathcal{P}_s(b)$  consists of set codes for permutations of  $\mathbf{Ord}$  with set support, evaluated against  $b$ . The virtual order  $\mathfrak{W}_{sl}$  consists of all admitted class bijections  $\mathbf{Ord} \rightarrow \mathbf{No}$ .

**Four main results.** ([merge] Five are listed below.)

**Cut classification and recognition.** Every proper normalized class cut of  $\mathcal{P}_s(b)$  is uniquely a cylinder edge, a numerical gap after a set prefix, or an  $\mathbf{Ord}$ -long injective branch. Such a cut is the trace of an element of  $\mathfrak{W}_{sl}$  exactly when its crossing prefixes occur at every ordinal length and together contain every surreal (Theorem 43.3 and 45.1).

**No newly filled old cuts.** For two GBC class realizations with the same sets and the same  $b$ , an old skeleton cut is realized by a global enumeration in the larger realization if and only if it already was in the smaller one (Theorem 48.1).

**Exact support threshold.** For every infinite set cardinal  $\kappa$ ,

$$\mathcal{P}_{<\kappa}(b) \text{ is } \eta_{cf \kappa} \text{ and is not } \eta_{(cf \kappa)^+}.$$

A witnessing omitted configuration has a minimum possible support cost of exactly  $\kappa$  in the full core (Theorem 49.3).

**What unrestricted tails hide.** Two labelled class well-orders have the same trace on  $\mathcal{P}_s(b)$  exactly when they have the same canonical initial  $\mathbf{Ord}$ -enumeration. Above a fixed injective branch  $F$ , the fiber is precisely the family of well-orders of  $\mathbf{No} \setminus \text{ran } F$  (Theorem 54.6).

**Bare-order cut orbits.** Character pairs completely determine the automorphism orbits of normalized cuts, yet exhaustive representability is not preserved by those automorphisms (Theorem 47.2).

The results are complementary. The first determines the missing boundary points; the second studies dependence on the admitted classes; the third measures the amount of permutation support needed for interpolation; and the fourth distinguishes the full relation order from its set-like part. No one of these conclusions identifies the full collection of class well-orders with an ordinary surreal-sized class.

#### 4.8 Source 15: scope, notation, and the audit boundary

The useful starting point is to specify what the entries of the proposed order actually are. A well-order relation on a fixed set, an enumeration of that set, an isomorphism type, a relation table, and a naturally increasing subclass of  $\mathbf{No}$  are different kinds of data. Some determine one another, but their natural-looking lexicographic comparisons need not agree.

The ProveIt report *Lexicographic Orders of Well-Orderings of the Surreal Numbers* combines four earlier manuscripts into a 115-page document ([merge] at that revision). We inspected its source, guide, the related real-alphabet report, and the sign-sequence foundation at revision 0ecd158fd163bc4aca0ee40ccf6479ca6cf5f2a8. The surreal report's source blob is f20837b76f8d981cb1dce3da79f633e280edad41; the same source was present at the earlier search-index revision 491ed8411cccf7bd57916eb7666bbba762e92f96. This article uses the newer revision as its audit boundary (this report; [1, 7]).

The prior report already establishes general set-sized cardinal and ordinal spectra, direct comparison of labelled class well-orders without abstract class ordinals, the global-choice equivalence, a dense bounded-support core isomorphic to  $\mathbf{No}$ , an omitted-range construction, and the singular minimal-slice dichotomy. We preserve those results as background. The main continuation consists of the block decomposition in Section 52.1, the cut classification in Section 46.2, and the longer

fixed-type calculation in [Section 31](#). The interpretation obstructions in [Section 38](#) explain why these results cannot simply be transferred to every other coding.

**Foundational convention.** GB means Gödel–Bernays set theory with Power Set and with no choice axiom built into the notation.  $\text{GBC} = \text{GB} + \text{GC}$ , where global choice provides a class choice function on nonempty sets. Set-sized results are in ZFC unless stated otherwise. A class well-order is a class strict linear order in which every nonempty available subclass has a least element. This explicit convention avoids silently confusing internal class well-foundedness with well-foundedness in an external metatheory. The standard equivalent formulations under global choice are discussed in [Section 57.4](#).

**Order notation.** An embedding preserves and reflects strict order.  $L \simeq_e M$  means that there are embeddings in both directions; it does not mean that  $L$  and  $M$  are isomorphic. The product  $L \times_{\text{lex}} M$  compares the  $L$  coordinate first. Ordinary ordinal multiplication keeps its usual convention:  $\alpha \cdot \beta$  is  $\beta$  consecutive copies of  $\alpha$ . We write  $\mathbb{B}_\theta = (2^\theta, <_{\text{lex}})$ , where  $0 < 1$ . The binary coding length  $\ell_2(L)$  is the least ordinal  $\theta$  for which  $L \hookrightarrow \mathbb{B}_\theta$ , when it exists. Birthday is written  $\text{bd}(x)$ .

**An essential size distinction.** Symbols such as  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  and  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  name predicates on class variables, with a comparison formula. They are not assertions that an ordinary GB class has other proper classes as its elements. A statement about a uniform family means one class relation whose rows are indexed by sets, possibly by a proper class of set indices. A larger universe may instead make the whole collection into an external set. The two readings are related but must be kept explicit.

#### 4.9 Source 16: main conclusions and relationship to the earlier report

There is a coherent and quite rich theory here, but it is essential to say which objects are being compared. A well-order on surreal labels need not agree with their numerical order. An ordinal-indexed enumeration of the whole surreal class is necessarily a class function. An arbitrary class well-order need not possess such an enumeration. Finally, even when each well-order is a legitimate class, a collection having those classes as its elements is not an ordinary class of the same two-sorted theory.

The ProveIt manuscript (this report, read at revision 491ed8411) already establishes the basic distinctions, exact ordinal embedding bounds for set alphabets, the surreal-sized bounded-support core, direct comparison of non-set-like orders, and a full-universe nonembedding result. Its merged source contains four earlier manuscripts and explicitly leaves several sharper questions. The present article develops those questions rather than treating the earlier conclusions as new. The principal additions are as follows.

1. **Topology at every enumeration length.** For an infinite linearly ordered set  $X$  of cardinality  $\mu$  and an ordinal  $\alpha$  with  $|\alpha| = \mu$ ,

$$\text{d}(\mathcal{W}_\alpha(X)) = \text{cell}(\mathcal{W}_\alpha(X)) = \begin{cases} \mu^{<\mu}, & \alpha \in \{\mu, \mu + 1, \mu + 2\}, \\ 2^\mu, & \text{otherwise.} \end{cases}$$

For the full order, both invariants equal  $2^\mu$ . Every infinite stratum, and the full order, has a countable witness to failure of conditional Dedekind completeness.

2. **Regular-stage gap spectrum.** If  $X$  is an  $\eta_\mu$  order of size  $\mu$ , for regular infinite  $\mu$ , the unfilled two-sided cuts of  $\mathcal{W}_\mu(X)$  have exactly the characters  $(\mu, \lambda)$  and  $(\lambda, \mu)$ , where  $\lambda$  ranges over infinite regular cardinals at most  $\mu$ .
3. **Represented cuts.** A lower cut of the bounded-support core represents an injective Ord-branch exactly when it is straddled by a prefix cylinder of every set ordinal length. The branch is exhaustive exactly when those prefixes collectively contain every label. A failed test has a first successor or limit obstruction; arbitrary non-set-like well-orders do not remove either obstruction.
4. **All ordinal-class blocks at once.** Every class well-order  $R$  admits the canonical decomposition

$$(X, R) \cong \left( \sum_{j \in J_R} \text{Ord} \right) + \alpha_R,$$

where the summands are precisely the equivalence classes for set-sized closed intervals, and  $\alpha_R$  is the optional final set block. The block index can itself be any class well-order. The construction is elementary in GB, and directly defines the entire family of residual tails.

5. **Word conventions and formal strength.** For the shorter-prefix-first convention, arbitrary, injective, and numerically increasing set-length words are isomorphic in GBC by maps preserving lengths and prefixes. Other placements of a termination symbol can instead make the whole unrestricted or injective word order isomorphic to **No**. For elementary relationally specified transformations, a uniform nonembedding theorem needs only  $\Sigma_1^1$  class comprehension over GBC, rather than all of KM.

These are extensions relative to the inspected report, not announcements that previously catalogued problems in the literature have been solved. The proofs below are intended to be independently readable. When a longer existing theorem is only summarized, its provenance and exact scope are stated. We separate mathematical proof, finite diagnostic checks, and formal proof throughout.

## 4.10 Source 17: relation to the repository and statement of the advance

### 4.10.1 Pinned source and scope

The main input is the merged ProveIt report *Lexicographic Orders of Well-Orderings of the Surreal Numbers* (this report), at repository revision

0ecd158fd163bc4aca0ee40ccf6479ca6cf5f2a8.

The relevant path is

Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/article.tex.

Its blob identifier is f20837b76f8d981cb1dce3da79f633e280edad41. The accompanying README describes a union of four independent manuscripts, not four successive editions. It also records the unrefereed and unformalized status of that report. We use the merged text rather than silently selecting one of the earlier conventions.

The source already proves the basic set-alphabet embedding results, the direct comparison of unrestricted labelled class well-orders, bounded-support interpolation, the existence of a surreal-sized dense core, a diagonal no-coding theorem, and a singular-cardinal transition in binary coding length. We do not present these as new. In particular, binary equimorphism is not an order-isomorphism classification, and it does not by itself determine local characters or the cut spectrum.

#### 4.10.2 Questions addressed

The following correspondence uses the source’s stable LaTeX labels, so it does not depend on pagination.

| Source question or topic                           | Result here                                                                                         | Limitation                                                          |
|----------------------------------------------------|-----------------------------------------------------------------------------------------------------|---------------------------------------------------------------------|

These are extensions of specific research questions posed in the repository, not assertions that the questions have an established history as major open problems. Every result used from the source is either restated with a proof or clearly identified as background.

#### 4.11 Source 18: main results and the scope of the continuation

The current **ProveIt** report on surreal well-orders (this report, read at revision `83befe707`) merges four earlier manuscripts. It already distinguishes set and class interpretations, proves the set-sized ordinal spectrum, analyzes binary coding at singular birthdays, compares arbitrary class well-orders directly, characterizes adjacency, and constructs a dense bounded-support core in the set-like global order. Repeating these conclusions would not answer the request for further study. We use them as a starting point, prove the elementary tools needed below, and address the outstanding questions on cuts, block decompositions, termination conventions, and model dependence.

Here is the principal bounded result. Throughout the article,  $\kappa$  is an infinite initial cardinal and

$$\mu = |\mathbf{No}_{<\kappa}| = 2^{<\kappa}, \quad r = \text{cf } \kappa, \quad q = \text{cf } \mu.$$

Let  $P = \mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  consist of all bijections  $\mu \rightarrow \mathbf{No}_{<\kappa}$ , ordered by their first unequal values. We prove

$$|P| = 2^\mu, \quad d(P) = \text{cell}(P) = \mu^{<\mu}, \quad \text{cf}(P) = \text{ci}(P) = r,$$

and every point has left and right character  $q$ . The order fills all cuts specified by fewer than  $r$  points. Its proper Dedekind gaps have exactly the character pairs

$$\{(r, r), (q, q)\} \cup \{(\theta, r), (r, \theta) : \theta < \mu \text{ is an infinite regular cardinal}\}. \quad (\text{S18.1})$$

This is a gap spectrum, not an isomorphism classification. Orders with the same spectrum can still have different global arrangements of cuts. There are exactly  $2^\mu$  proper gaps of character  $(q, q)$ , and exactly  $\mu^{<\mu}$  of every other character in the displayed spectrum. Thus the Dedekind completion has cardinality  $2^\mu$ .

For every infinite ordered alphabet  $X$  of size  $\mu$ , a separate fixed-type result gives

$$d(\mathcal{W}_\alpha(X)) = \text{cell}(\mathcal{W}_\alpha(X)) = \begin{cases} \mu^{<\mu}, & \alpha = \mu, \mu + 1, \mu + 2, \\ 2^\mu, & \mu + 3 \leq \alpha < \mu^+. \end{cases} \quad (\text{S18.2})$$

The third terminal position is the first that supplies an interior point of a finite permutation fiber. This is an order-topological transition, and its numerical values need not differ when  $\mu^{<\mu} = 2^\mu$ .

On the class side, let  $R$  be any supplied well-order of a proper class. Declare two labels equivalent when the closed interval between them is a set. Every block has an actual least label, which represents it without making a class an element. In GB this gives

$$R \cong (B_R \times \text{Ord})_{\text{lex}} + \theta_R, \quad (\text{S18.3})$$

with all proper blocks of type  $\text{Ord}$  and at most one final set block of type  $\theta_R$ . The block index  $B_R$  can be any class well-order; it can even be isomorphic to  $R$ . Thus simultaneous decomposition is elementary, while repeated quotienting need not lower isomorphism type.

A class cut of the bounded-support core comes from a raw global well-order precisely when, at every ordinal length, one prefix cylinder meets both sides. These prefixes uniquely reconstruct an injective  $\text{Ord}$ -word by elementary comprehension. The cut has a set-like representative exactly when that word is onto. A cut that would require the first two entries to be the same surreal is represented by no raw well-order. Allowing arbitrary class well-orders therefore does not fill all class cuts, even though it fills the omitted-range branch cuts.

A further theorem concerns an external, countable model of the class theory. If the model is  $\omega$ -standard, the full admitted order  $\mathfrak{W}_{\text{all}}$  is a dense shuffle of finite chains of sizes

$$1, 2, 6, 24, 120, \dots$$

Its finite-condensation quotient is the rational order with every factorial size appearing densely as a color. The admitted set-like order  $\mathfrak{W}_{\text{sl}}$  is externally isomorphic to  $\mathbb{Q}$ , but it is not definable in the pure full order, even with finitely many parameters. These are external statements; they do not supply an internally coded embedding of all global orders into a class of sets.

The final new group of results concerns set-length words. Ordinary dictionary comparison puts a proper prefix first. Under GBC, arbitrary, injective, and strictly numerically increasing words with this convention are isomorphic as prefix trees and as linear orders. Centered termination over  $\mathbf{No} \setminus \{0\}$  instead makes arbitrary and injective words isomorphic to  $\mathbf{No}$ . Increasing words retain a precisely identified limit-prefix obstruction. Keeping the actual digit 0 immediately above a distinct terminator creates adjacent pairs. Hence “lexicographic” must include a termination rule.

#### 4.11.1 What is established here

| Word conventions    | Prefix-first words and their limit obstructions    | Tree isomorphisms; centered conventions and exact increasing-word obstruction                         |

“Advance” means an extension of the inspected repository text. We make no assertion that these formulations have never appeared elsewhere, and do not describe the repository’s proposed directions as a certified list of open problems in the published literature. The proofs below are independent of the repository’s claimed Lean theorems except where a formalization reuse point is explicitly discussed.

#### 4.12 Source 14: the precise Kanovei–Shelah connection

Kanovei and Shelah’s definable nonstandard-model construction uses a lexicographically ordered family of maps from the continuum cardinal to  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters; the maps may repeat values [16]. That index set is not literally the set of all well-orders of  $\mathbb{R}$ . Its relevance is methodological: a linear order on an entire family of presentations can organize a construction without selecting one privileged presentation. Importing that method into a surreal setting must still state the indexing sort, support restriction, and evaluation relation. The diagonal theorem prevents replacing all global enumerations by one exhaustive ordinary class of set presentations.

#### 4.13 Source 17: the Kanovei–Shelah connection, with its size boundary

The definable nonstandard-real construction is a useful motivation for ordering many presentations rather than selecting one preferred presentation. Its actual index should be stated accurately. In Section 1 of Kanovei–Shelah [16], the index consists of maps from the continuum cardinal into  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters; the maps need not be injective. The authors order this *set* of maps by first difference, using the binary lexicographic order of subsets of  $\mathbb{N}$ , and then use finite-support functions. It is therefore not literally the order of all well-order relations on  $\mathbb{R}$ .

The methodological analogy remains valuable: a specified linear order of codes can organize a construction without a definable choice of one special code. In the present setting,  $\mathcal{W}_\mu(X)$  is a legitimate set index, and a uniform subfamily of global enumerations can be indexed by an ordinary class of set codes. Neither observation makes the full higher-order predicate  $\mathfrak{W}_{\text{sl}}$  into a set index. Any proposed surreal analogue must state where its functions, supports, evaluation maps, and

ultrafilters live. The diagonal obstruction of [Theorem 42.16](#) rules out one tempting shortcut, while leaving many bounded or explicitly uniform constructions available.

[merge] The Kanovei–Shelah distinction is thus made by all ten sources, in the same terms ([section 4.4](#) and the note after it).

## 5 Surreal order facts and foundational conventions

### 5.1 Signs, birthdays, and set cuts

A surreal number is represented by a sign sequence

$$s : \alpha \longrightarrow \{-, +\}$$

of set-ordinal length  $\alpha$ , its birthday  $\text{bd}(s)$ . Numerical comparison at the first disagreement uses

$$- < \text{termination} < +.$$

This differs from dictionary order with every proper prefix smaller than every extension. A sign sequence can be on either side of an extension, depending on its next sign.

For an ordinal  $\theta$ , let

$$\mathbf{No}_{<\theta} = \bigcup_{\alpha < \theta} \{-, +\}^\alpha.$$

It is a set. The full  $\mathbf{No}$  is proper-class-sized, because all-plus sequences embed all ordinals. Every set of surreals has bounded birthdays by Replacement.

**Definition 5.1.** A class linear order  $L$  has the *set-cut property*, called  $\eta_{\text{Ord}}$  here, if for all sets  $A, B \subseteq L$  with  $A < B$  there is  $x$  with  $A < x < B$ . Empty sides are allowed. For a cardinal  $\kappa$ , the set-sized notation  $\eta_\kappa$  requires the same property when  $|A \cup B| < \kappa$ .

The surreal cut construction supplies this property for  $\mathbf{No}$  [[14](#), Section 2]. A separator can be chosen canonically as the unique simplest separator. This statement concerns *sets* of options; applying it to the whole class against the empty right side would be inconsistent.

**Lemma 5.2** (Deleting a set). *If  $S \subseteq \mathbf{No}$  is a set, then  $\mathbf{No} \setminus S$  has the set-cut property. Every nonempty open interval of  $\mathbf{No}$  is a proper class.*

*Proof.* Let  $A < B$  be sets in  $\mathbf{No} \setminus S$ . First choose  $x$  with  $A < x < B$ , and put

$$S_- = \{s \in S : s \leq x\}, \quad S_+ = \{s \in S : x < s\}.$$

Then  $A \cup S_- < B \cup S_+$ . A separator of this new set cut avoids both parts of  $S$ . The argument allows empty sides. If an interval  $(a, b)$  were a set  $S$ , applying the result to  $\{a\} < \{b\}$  in  $\mathbf{No} \setminus S$  would be impossible.  $\square$

Choosing both separators by simplicity makes the deletion argument uniform in the set parameters without global choice.

[merge] *Third route to the first clause of [lemma 5.2](#) (source 12, Lemma 6.2).* Source 12 avoids a forbidden set by using that open intervals of  $\mathbf{No}$  are proper classes.

**Lemma 5.3** (Avoiding a forbidden set). *If  $A < B$  are sets of surreals and  $D$  is a set, then some separator  $z$  of  $A, B$  lies outside  $D$ .*

*Proof.* Choose  $u$  between  $A$  and  $B$ , and then  $v$  between  $\{u\}$  and  $B$ . Every point of  $(u, v)$  separates  $A, B$ , and that interval is a proper class. It cannot be contained in  $D$ . With a fixed global well-order, choose the first acceptable point, making the operation uniform.  $\square$

[merge] Source 08 opens with its own toolkit, printed next. Its [proposition 5.4](#) restates `found:prop:proper` (Lean-proved in universe-relative form; [section 1.5](#)) and adds that neither the numerical order nor “birthday first” well-orders **No**, which source 12 also proves ([section 13.1](#)). Its [theorem 5.6](#) sharpens the birthday bound of the cut theorem to a separator of *exactly* any prescribed birthday above the option birthdays; this is proved in Lean as `exists_cut_separator_of_birthday_lt`, by the same complete-lattice argument ([lemma 5.5](#)). Its [corollary 5.7](#) contains the first clause of [lemma 5.2](#) with a prescribed birthday, and its [definition 5.8](#) is [definition 5.1](#).

## 5.2 Source 08: surreal order and size, the minimal toolkit

We take a surreal number to be a sign sequence

$$s : \alpha \longrightarrow \{-, +\}, \quad \alpha \in \text{Ord}.$$

Its birthday is  $\text{bd}(s) = \alpha$ . To compare two sequences, extend them by a termination symbol 0 and compare at the first disagreement using  $- < 0 < +$ . This is the numerical order. The simplicity relation is proper initial-segment extension, and is not the numerical order.

**Proposition 5.4.** *Every birthday-bounded collection of surreals is a set, every set of surreals has bounded birthdays, and **No** is a proper class. Neither the numerical order nor “birthday first, then numerical order” is a well-order of **No**.*

*Proof.* For a fixed ordinal  $\lambda$ , the sign sequences of length below  $\lambda$  form the set  $\bigcup_{\alpha < \lambda} \{-, +\}^\alpha$ . Replacement bounds the birthdays of any given set. Conversely, the all-plus sequences give a distinct surreal for every ordinal, so a set containing all surreals would bound all ordinals. The negative integers already descend numerically. For the second claim, let  $s_n$  have birthday  $\omega$ , with  $n$  initial minus signs followed by plus signs forever. At coordinate  $n$  one has  $s_{n+1}(n) = - < + = s_n(n)$ , so  $s_0 > s_1 > s_2 > \dots$  within a single birthday level.  $\square$

### 5.2.1 A birthday-controlled separator theorem

We record a proof of the exact order-theoretic fact used later. It also explains the repository’s bounded-word implementation [8].

**Lemma 5.5.** *For every set ordinal  $\beta$ , the binary lexicographic order  $\mathbb{B}_\beta = (\{0, 1\}^\beta, <_{\text{lex}})$  is a complete lattice.*

*Proof.* The least and greatest elements are the constant 0 and 1 words. Given a set  $A$  of words, form  $w$  recursively. At coordinate  $\xi$ , put  $w(\xi) = 1$  exactly when some  $a \in A$  agrees with the already constructed prefix  $w \upharpoonright \xi$  and has  $a(\xi) = 1$ ; otherwise put 0. If some  $a \in A$  exceeded  $w$ , its first disagreement would contradict the rule for a 0 coordinate. If  $v < w$ , then at their first disagreement  $\xi$  we have  $v(\xi) = 0$ ,  $w(\xi) = 1$ , and a witness  $a \in A$  agreeing with  $w$  through that 1 coordinate. Thus  $v < a$  and  $v$  is not an upper bound. This proves that  $w = \sup A$ , including  $A = \emptyset$ . Infima follow by reversing all bits.  $\square$

**Theorem 5.6** (Birthday-controlled cut filling). *Let  $A, B$  be sets of surreals with  $A < B$ , meaning  $a < b$  for all  $a \in A$ ,  $b \in B$ . If  $\beta$  is an ordinal strictly greater than every birthday in  $A \cup B$ , then a surreal  $z$  of birthday exactly  $\beta$  satisfies  $A < z < B$ . Either side may be empty.*

*Proof.* For a shorter word  $x$ , let  $u_\beta(x)$  be the word of length  $\beta$  obtained by appending a plus to  $x$  and then filling all remaining coordinates with minuses. It is the least full-length word strictly above  $x$ . Dually, let  $v_\beta(x)$  be  $x$  followed by a minus and then pluses; it is the greatest full-length word strictly below  $x$ . These assertions follow by inspecting the first differing sign: an extension above  $x$  must choose plus when  $x$  terminates, and the least possible continuation then uses only minuses.

If  $x < y$  and both have length below  $\beta$ , then  $u_\beta(x) \leq v_\beta(y)$ . Indeed  $u_\beta(x) \leq y$  by the same first-disagreement check; equality is impossible because their birthdays differ. Applying the dual greatest-word property gives the claim. By lemma 5.5, full-length sign words have a supremum, and

$$z = \sup\{u_\beta(a) : a \in A\}$$

satisfies  $a < u_\beta(a) \leq z$  for every  $a \in A$  and  $z \leq v_\beta(b) < b$  for every  $b \in B$ . All words in this complete lattice have birthday exactly  $\beta$ . If  $A$  is empty, its supremum is the all-minus word. The vacuous case  $\beta = 0$  causes no problem.  $\square$

**Corollary 5.7** (Fresh separators). *If  $A < B$  are sets and  $S$  is a set of forbidden surreals, a separator  $z \notin S$  exists. It can be required to have any specified birthday strictly exceeding all birthdays in  $A \cup B \cup S$ .*

**Definition 5.8.** A class linear order is an  $\eta_{\text{Ord}}$ -order if every pair of sets  $A < B$  has a strict separator, including empty sides. For an infinite cardinal  $\kappa$ , an  $\eta_\kappa$ -order satisfies the same condition when  $|A \cup B| < \kappa$ .

The notation  $\eta_\kappa$  here uses a cardinal bound directly; it should not be confused with conventions in which the subscript is the index  $\alpha$  in  $\aleph_\alpha$ . By theorem 5.6, **No** is an  $\eta_{\text{Ord}}$ -order. Every interval is a proper class: if  $(a, b)$  were a set, a separator of  $\{a\} \cup (a, b)$  and  $\{b\}$  would be a new member of the same interval above all its members. No set is cofinal or coinital in **No**.

### 5.3 Which recursion principle is used?

Here GB has a ZF set part, elementary class comprehension, and class replacement; choice is stated separately. We use  $\text{GBC} = \text{GB} + \text{GC}$ , which includes set choice. Cardinality calculations and cardinal-valued cofinality statements throughout the article are read in ZFC, or in the set part of GBC. The explicitly definable sign code and the direct set-cut constructions retain their stated choice-free strength.

Ordinary recursion along Ord, with a set output at every stage and a rule using the set of earlier values and fixed class parameters, is available in GB. On each set ordinal perform the usual recursion with those parameters. Uniqueness makes the local solutions agree; elementary comprehension assembles their graph.

This is different from arbitrary elementary transfinite recursion, ETR, whose stages may themselves be classes. The latter supports iterated truth predicates and is stronger than GBC [22]. The prefix searches, partial permutations, and back-and-forth maps used here have set-sized stages.

[merge] The other sources fix their foundational conventions in their own sections, printed whole next. They agree with source 11's conventions, with one difference of base theory: when it analyses choice, source 12 works over  $\text{GB} + \text{AC}$  (section 1.3).

## 5.4 Source 12: the surreal carrier and the foundational conventions

### 5.4.1 Sign sequences

We use the sign-sequence presentation

$$\mathbf{No} = \bigcup_{\alpha \in \text{Ord}} \{-, +\}^\alpha.$$

Each individual sequence is a set. Its length  $\text{bd}(s) = \text{lh}(s)$  is its birthday. At the first difference, signs and termination are compared by

$$- < \text{end} < +.$$

This is the usual numerical order, not the ordinary “shorter comes first” dictionary convention. Simplicity is the separate relation of being a proper sign prefix. The standard surreal construction and its simplicity structure are treated by Gonshor and Ehrlich [12, 15].

We shall use the following standard feature, also obtainable directly from the construction: whenever  $A, B$  are *sets* of surreals with  $A < B$ , there is a surreal  $z$  with  $A < z < B$ . There is a unique such separator of minimum birthday. Moreover, if every member of  $A \cup B$  has birthday less than an ordinal  $\gamma$ , a separator can be constructed with birthday at most  $\gamma$ . This is interpolation, not Dedekind completeness: no least upper bound is being asserted.

Every set of surreals has a birthday bound, by Replacement. Every nonempty numerical interval contains a proper class of surreals. To see the latter without arithmetic, start with  $a < b$  and recursively choose  $x_\alpha$  between  $\{a\} \cup \{x_\xi : \xi < \alpha\}$  and  $\{b\}$ . The previous values form a set at each stage. Thus one obtains distinct points for all ordinals  $\alpha$ .

### 5.4.2 Well-orders and set-likeness

A class well-order on a class  $X$  is a strict linear class relation  $R$  for which every nonempty subclass has an  $R$ -least element. In GBC this agrees with the usual formulations using nonempty set subsets or absence of descending  $\omega$ -sequences; the relationship is discussed in [27, §3]. We use strict relations throughout.

It is *set-like* if

$$\text{Pred}_R(x) = \{y \in X : yRx\}$$

is a set for every  $x$ . A proper-class set-like well-order is isomorphic to  $\text{Ord}$ : map  $x$  to the ordinal type of its set of predecessors. The range is an initial segment of  $\text{Ord}$ , and cannot be a set ordinal when  $X$  is proper. This construction uses only set-sized order types.

Not all class well-orders are set-like. The ordered sums  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ , and  $\text{Ord} + \text{Ord} + 1$  are examples. Their notation means ordered sums of class orders, not new von Neumann ordinals.

### 5.4.3 Foundational levels

Our set-sized results are theorems of ZFC. Our global results are in GBC, meaning Gödel–Bernays set theory with global choice. When analyzing the necessity of choice we work over GB plus ordinary, set-level AC. The full collection of global well-orders is handled by formulas with class variables, not by pretending that a proper class is an element of another GBC class.

Kelley–Morse theory allows stronger comprehension, but its classes still have sets, not proper classes, as members. Moving from GBC to KM does not by itself create a powerclass object of all subclasses of  $\mathbf{No}$ . One can instead use a larger set-theoretic universe, a set model with a specified collection of classes, or an explicitly higher-order theory. These are distinct interpretations and will be kept distinct.

#### 5.4.4 Why an ordinal-length recursion here need not invoke ETR

A recursion on  $\text{Ord}$  that produces one *set* at each stage and uses the set of previous values is available by the ordinary recursion theorem with class parameters in GB. In contrast, ETR permits a genuinely class-valued recursive stage, represented by a class of pairs of a stage and an arbitrary set. Even a truth hierarchy brings stronger principles into play [27, §2]. Our forth constructions, block lengths, and canonical enumeration of a class with set-sized initial segments are set-valued recursions. We do not invoke a universal satisfaction predicate or unrestricted class-valued recursion.

[merge] Like source 12, source 09 works over  $\text{GB} + \text{AC}$  when it analyses choice. Its lemma 5.10 is a second route to the first clause of lemma 5.2: it adds the forbidden points inside the cut to the left side, where source 11 first splits the forbidden set at a separator. Its bound (1) is  $\text{hset:eq:cut-bound}$  of the birthday-cutoff report [4], and its definition 5.9 is definition 5.1.

### 5.5 Source 09: foundational conventions and the surreal order

#### 5.5.1 Sets, classes, and the meaning of a family

All set-sized results are in ZFC. Global results are in GBC, here meaning Gödel–Bernays class theory with global choice. Classes have sets as members. A proper class cannot be an element of another class. An expression such as “the set of class functions  $E_i$ ” is therefore replaced by a *uniform family*: a class relation

$$F \subseteq I \times \text{Ord} \times \mathbf{No}$$

whose  $i$ th section is the graph of  $E_i$ . The index  $I$  may be a set or a class of sets. If  $I$  is a set, this is a uniformly set-indexed family, not a literal set of proper classes.

This distinction does not prevent quantification over individual class variables. For example, “for every two class bijections  $E, F$ , there is a least ordinal where they differ” is a legitimate GBC assertion. What is unavailable is a class having all such bijections as members. Rangel and Mariano explicitly distinguish the set-subsets of a class from a nonexistent class of all its subclasses [17, §1.1.1].

Global choice will be used in its standard consequence that a proper class can be enumerated by  $\text{Ord}$  with set-sized initial segments. One way to obtain this consequence is to well-order each rank layer using a global choice function, concatenate the layers, and collapse the resulting set-like well-order. Restricting such an order to any proper subclass again gives order type  $\text{Ord}$ .

#### 5.5.2 Sign sequences and the cut property

Use the sign-sequence realization

$$\mathbf{No} = \bigcup_{\alpha \in \text{Ord}} \{-, +\}^\alpha.$$

Each displayed element is a set function. Its domain is its *birthday*, denoted  $\text{bd}(x)$ . Numerical order compares the first different sign using

$$- < \text{termination} < +.$$

It is different both from ordering by birthday and from the dictionary order on arbitrary surreal-valued words used later. The all-plus word of length  $\alpha$  represents the ordinal  $\alpha$ .

The standard simplicity/cut theorem says that, for sets  $A, B \subseteq \mathbf{No}$  with  $A < B$ , there is a unique simplest surreal strictly between them. Here  $A < B$  means  $a < b$  for every  $a \in A, b \in B$ , with empty sides allowed. We write this simplest separator as  $\{A \mid B\}$ . A useful birthday bound is

$$\text{bd}\{A \mid B\} \leq \sup\{\text{bd}(x) + 1 : x \in A \cup B\}. \quad (1)$$

These are standard sign-sequence facts [12]; the inspected repository also contains explicit small-cut and birthday-bound statements on its sign carrier [9].

In particular, every set of surreal numbers has strict upper and lower bounds. No set is cofinal or cointial in **No**, and no set is the whole of **No**. These assertions do not authorize a cut constructor with arbitrary proper-class option families.

**Definition 5.9.** A class linear order  $D$  has the *set-cut property* if every pair of sets  $A, B \subseteq D$  satisfying  $A < B$  has an element  $d \in D$  with  $A < d < B$ . Empty sides are allowed.

The surreal order has the set-cut property. In terminology used in the literature this is an absolute or class analogue of an  $\eta$ -order. We use the explicit definition rather than relying on potentially ambiguous subscripts such as  $\eta_{\text{Ord}}$ .

**Lemma 5.10** (Avoiding a prescribed set). *If  $D$  has the set-cut property and  $U \subseteq D$  is a set, then  $D \setminus U$  also has the set-cut property.*

*Proof.* Let  $A, B \subseteq D \setminus U$  be sets with  $A < B$ , and put

$$U_0 = \{u \in U : A < u < B\}.$$

Then  $A \cup U_0 < B$ . Choose  $x$  with  $A \cup U_0 < x < B$ . This  $x$  is in the original open cut. If it belonged to  $U$ , it would belong to  $U_0$ , giving  $x < x$ . Thus  $x \notin U$ .  $\square$

### 5.5.3 The precise recursion strength used here

We repeatedly construct a sequence of *sets* indexed by ordinals, where the next value is a uniquely specified set obtained from the set-sized previous history and fixed class parameters. This recursion is available in GBC: set recursion with class parameters constructs all set-length approximations, uniqueness makes them compatible, and elementary class comprehension joins them.

This is not the principle ETR, whose stages can themselves be proper classes. The latter is genuinely stronger than GBC and must not be silently invoked by saying “perform class recursion” [24, §2]. Every global recursion in the proofs below is explicitly of the former, set-valued kind.

[merge] Source 08’s foundational section, printed next except for its Theorem 8.2, which is recorded in [note 5.12](#). One sentence is corrected, as proposed by the review of the four archives in the repository’s Hilbert’s-tenth research tree (`Computability/HilbertTenthProblem/Papers/research-wip/native-stream-queue/review_batch80_surreal.md`, commit `c338541e3`, with the patch `surreal_research1_wellfounded_scope.patch` there). Source 08 wrote: “For non-set-like relations, the model’s class collection can matter to the well-order assertion.” Under GBC, internal well-foundedness of a fixed class relation is equivalent to the absence of a set-coded descending  $\omega$ -sequence ([27, Section 3]; source 11 makes the same distinction in [section 20](#)), so two class expansions with the same sets agree about it for a relation they share; what can change is which relations are available, and internal well-foundedness differs from external well-foundedness. The printed sentence is the patch’s text. No statement of source 08 depends on the original sentence.

## 5.6 Source 08: class foundations and set-like well-orders

From this section onward, the default theory is GBC: Gödel–Bernays class set theory with Global Choice. Sets are the objects that may be members; classes are collections of sets. A class function maps set arguments to set values. Its image of a set is a set by class replacement. Elementary class comprehension allows formulas with class parameters but only set quantifiers in the defining formula.

### 5.6.1 Why Global Choice is named explicitly

Global Choice supplies a set-like global well-order of the universe. Restricting it to any class gives a set-like well-order, and every proper class can then be enumerated by  $\text{Ord}$ . We use this to choose one baseline  $b : \text{Ord} \rightarrow \mathbf{No}$ , to enumerate class carriers during back-and-forth, and to select witnesses uniformly. Ordinary set Choice alone does not justify these global choices.

Many local results need less. Pairwise lexicographic comparison, the extension of one specified set prefix relative to a given  $b$ , and the set-cut argument use only class replacement, elementary comprehension, set Choice, and the displayed class parameters. Keeping  $b$  as an explicit parameter is therefore useful in weaker foundations.

**Definition 5.11.** A class well-order  $\prec$  is *set-like* when, for every element  $x$ , its predecessor class  $\{y : y \prec x\}$  is a set. By a class well-order here we mean a linear class relation such that every nonempty subclass available in the model has a least element.

For a set-like relation, it suffices to require well-foundedness on sets: a nonempty subclass has a witness  $x$ , and one may search the set of predecessors of  $x$  together with  $x$  for its least member. Over GBC, well-foundedness of any fixed class relation is equivalent to the absence of a set-coded descending  $\omega$ -sequence. Keeping the sets and the relation fixed while enlarging the class collection therefore does not change its internal well-foundedness. What may change is which class relations are available; internal and external well-foundedness must also be distinguished. [merge] (This replaces one sentence of source 08; see the note before this section.)

*Note 5.12* (Source 08, Theorem 8.2). *Every set-like well-order of a proper class has a unique order isomorphism from  $\text{Ord}$ . Conversely, every class bijection  $e : \text{Ord} \rightarrow \mathbf{No}$  induces a set-like well-order of  $\mathbf{No}$ .* This is the last paragraph of the proof of [theorem 13.1](#) and source 09’s [proposition 13.6](#), proved by the same rank map: the predecessors of  $x$  form a well-ordered set of ordinal type  $r(x)$ ; the range of  $r$  is downward closed, and it cannot be a set ordinal, since the inverse of  $r$  would then map a set ordinal onto a proper class, contradicting class replacement. Conversely the predecessors of  $e(\alpha)$  form the set  $e[\alpha]$ .

Thus all set-like proper-class well-orders have the same abstract order type. The interesting lexicographic structure lies in their labels, not in distinct ordinal types. It is incorrect either to introduce a set ordinal equal to “the order type of all ordinals” or to quotient away the enumerations and expect the lexicographic information to survive.

### 5.6.2 The recursion principle actually used

All transfinite constructions below have *set-valued* stages and set-sized histories at each ordinal stage. In GBC, fix the class parameters and a rule assigning a unique set to each set history. The ordinary set recursion theorem with those parameters constructs a solution through each set ordinal. Uniqueness makes these initial solutions compatible, and elementary comprehension forms their union as a class. This is the set-valued recursion needed here.

It is not the principle of elementary transfinite recursion with *class-valued* stages. For example, constructing a new truth class at each stage is a substantially different task. The distinctions among GBC, GBC + ETR, and KM are genuine; the class-recursion and class forcing literature documents their strength [23, 25]. No equivalence with those stronger principles is claimed for the constructions in this paper.

## 5.7 Universality and uniqueness of the saturated class order

**Proposition 5.13.** *In ZFC, every set linear order embeds into  $\mathbf{No}$ . In GBC, every class linear order embeds uniformly into  $\mathbf{No}$ . Any two proper-class  $\eta_{\text{Ord}}$  orders are isomorphic in GBC.*

*Proof.* Enumerate the source in a cardinal-length well-order, or in type Ord for a proper class, using global choice. At stage  $\alpha$ , the earlier images form a set. Separate the images of earlier points below the new point from those above it, and choose a separator. This extends an order embedding. Each partial map is a set.

For uniqueness, globally enumerate both class orders and alternately insert the first unused point from each enumeration. The appropriate set cut in the other order is fillable. Global choice selects a separator when none is distinguished. The union of the partial isomorphisms is a surjective class order isomorphism.  $\square$

The same construction, started from a specified set-sized partial isomorphism, gives set homogeneity. These are the order-theoretic universality and homogeneity features of  $\mathbf{No}$  [15]. The assertion that every class order embeds is made with global choice; it is not used as an unproved converse to global choice.

[merge] *Source 12's version (its Lemmas 6.5 and 6.6).* It exposes the size of the forth recursion, with a birthday bound for set orders, and proves the class isomorphism  $\mathbf{No} \setminus A \cong \mathbf{No}$  that source 11 uses in [proposition 19.25](#).

**Lemma 5.14** (Surreal universality, with the size of the recursion exposed). *In GBC, every class linear order admits a class order-embedding into  $\mathbf{No}$ . For a set order enumerated in type  $\lambda$ , one can arrange that the image of its  $\xi$ th enumerated element has birthday at most  $\xi$ , for each  $\xi < \lambda$ .*

*Proof.* Use a global-choice enumeration of the carrier, either by an ordinal or by Ord. When the next element is considered, its previously embedded predecessors and successors form two sets  $A < B$ . Send it to the simplest surreal separator. It is distinct from all previous images and preserves order. Every stage has set-sized history. Induction gives the birthday bound, because the earlier birthdays are less than the current stage. This is the standard forth argument behind surreal universality [15, 20].  $\square$

**Lemma 5.15** (Deleting a set does not change the numerical class order). *In GBC,  $\mathbf{No} \setminus A$  is order-isomorphic to  $\mathbf{No}$  for every set  $A$ . Every nonempty open numerical interval is also order-isomorphic to  $\mathbf{No}$ .*

*Proof.* Each target has interpolation for arbitrary separated sets, by [lemma 5.3](#), adding interval bounds when needed. Each is a proper class and has an Ord-enumeration by global choice. Carry out a back-and-forth between the two enumerations. At each ordinal stage, extend the partial isomorphism to the next unused domain point and then to the next unused target point. The previous partial map is a set, and the required cut can be filled while avoiding its set-sized range. At the end the class map is onto and order-preserving.  $\square$

[merge] *Source 09's route.* Source 09 proves universality into any class order with the set-cut property, uniqueness together with set-homogeneity, and the isomorphisms  $\mathbf{No} \setminus U \cong \mathbf{No}$  and  $(a, b) \cong \mathbf{No}$ ; its proofs are the forth and back-and-forth recursions of [proposition 5.13](#), stated for a general target.

## 5.8 Source 09: the classical universality mechanism, with proofs

The following facts are classical features of the surreal order; we include the arguments because the same mechanism will identify our lexicographic core. The class-universal and set-homogeneous viewpoint appears, for example, in [17].

**Theorem 5.16** (Class universality). *In GBC, every class linear order embeds into  $\mathbf{No}$ . More generally, every class linear order embeds into any class linear order with the set-cut property.*

*Proof.* For a set-sized domain, choose a well-ordering and enumerate it by an ordinal. For a proper-class domain  $L$ , use global choice to fix a class bijection  $a : \text{Ord} \rightarrow L$ . At stage  $\alpha$ , assume the values  $h(a(\xi))$  for  $\xi < \alpha$  have been selected. Form the two sets

$$A_\alpha = \{h(a(\xi)) : \xi < \alpha, a(\xi) <_L a(\alpha)\}, \quad B_\alpha = \{h(a(\xi)) : \xi < \alpha, a(\alpha) <_L a(\xi)\}.$$

Earlier choices preserve order, so  $A_\alpha < B_\alpha$ . Choose a separator in the target, using its set-cut property and a fixed global well-order for a definite choice. The new value is different from every earlier value and has exactly the required comparisons. At each stage the partial map is a set. The resulting class function is the embedding.  $\square$

**Theorem 5.17** (Uniqueness and set-homogeneity). *In GBC, any two class linear orders with the set-cut property are isomorphic. Moreover, an order isomorphism between set-sized suborders of these orders extends to a class order isomorphism.*

*Proof.* Neither order is a set: applying the set-cut property with the entire carrier on the left would otherwise be contradictory. Fix Ord-length enumerations of both carriers. Start with the given set partial isomorphism. At each ordinal stage, first put the least not-yet-mapped element of the first enumeration into the domain. Its required image is constrained by two sets of already mapped elements; the set-cut property supplies an image. Next put the least omitted element of the second enumeration into the range by the symmetric construction. Take unions at limit stages. Every initial partial map is a set, so the recursion is of the permitted kind. The final map is total and onto.  $\square$

**Corollary 5.18.** *For every set  $U \subseteq \mathbf{No}$ ,  $\mathbf{No} \setminus U \cong \mathbf{No}$ . Every nonempty open interval of  $\mathbf{No}$  is likewise isomorphic to  $\mathbf{No}$ .*

*Proof.* Use lemma 5.10 and theorem 5.17. For an interval  $(a, b)$ , add  $a$  to every lower constraint set and  $b$  to every upper constraint set.  $\square$

These isomorphisms concern numerical order alone and need not preserve simplicity or arithmetic.

[merge] Source 08's Section 12 ("The skeleton is a surreal line") contains two further statements of the classical mechanism and the skeleton theorem (note 19.17).

*Note 5.19* (Source 08, Theorem 12.1, "Uniqueness of a class saturated line"). *In GBC, any two proper-class  $\eta_{\text{Ord}}$ -orders whose elements are sets are order-isomorphic.* This is the last clause of proposition 5.13 and theorem 5.17, by the same back-and-forth. Source 08 spells out that the separator chosen in the forward step cannot be a previous image, that a fixed set-like global well-order chooses each separator uniformly among sets, and that the least-unmatched rule handles every element: after enough stages all elements of a given bounded index have been included.

*Note 5.20* (Source 08, Theorem 12.3, “Universality for class linear orders”). *Every class linear order  $L$  with set-valued elements admits a class order embedding into  $\mathbf{No}$ , and hence into  $\mathcal{P}_s(b)$ .* This is the second clause of [proposition 5.13](#) and [theorem 5.16](#), composed with [note 19.17](#). Source 08 adds: “The input order need not be set-like. A point with a proper class of predecessors is harmless because only the previously *processed* elements, rather than all its predecessors, enter a stage of the construction. This explains why  $\text{Ord} + 1$  and more complicated non-set-like class well-orders can embed into the skeleton even though each *enumeration represented by* a skeleton point induces a set-like well-order on  $\mathbf{No}$ .”

## Part I

# Sets of surreals

## 6 Well-order codes on a fixed set alphabet

Let  $X$  be an infinite linearly ordered set, and put  $\lambda = |X|$ . We work in ZFC throughout this section. A well-order on the whole carrier  $X$  has a unique increasing enumeration  $f : \alpha \rightarrow X$ , where increasing refers to that well-order, not to the native order of  $X$ . Its domain satisfies  $|\alpha| = \lambda$ , and hence  $\alpha < \lambda^+$ . Write  $\mathcal{W}(X)$  for these bijective enumeration codes, and introduce two related sets:

$$\mathcal{I}(X) = \bigcup_{\alpha < \lambda^+} \{f : \alpha \hookrightarrow X\}, \quad \mathcal{W}_\lambda(X) = \{f : \lambda \rightarrow X : f \text{ is bijective}\}.$$

Thus  $\mathcal{I}(X)$  codes well-orders of arbitrary subsets of  $X$ , including the empty subset, whereas  $\mathcal{W}(X)$  always uses the whole carrier. All three sets inherit the lexicographic order defined earlier. A proper prefix is smaller than its extension in  $\mathcal{I}(X)$ . Two distinct members of  $\mathcal{W}(X)$  cannot be proper prefixes of one another: the shorter enumeration would already have used every element of  $X$ .

The repository’s real-well-ordering report already proves the exhaustive and cardinal-length statements for arbitrary infinite alphabets [1]. We record those results together with the injective-word variant, and include a common proof to keep the size distinctions explicit. Neither density nor completeness of the native order is needed.

**Theorem 6.1** (Cardinality and exact ordinal spectrum). *Each of  $\mathcal{W}_\lambda(X)$ ,  $\mathcal{W}(X)$ , and  $\mathcal{I}(X)$  has cardinality  $2^\lambda$ , contains a copy of every linear order of cardinality at most  $\lambda$ , and contains neither  $\lambda^+$  nor  $(\lambda^+)^*$ . Consequently the ordinals embeddable in any of them are exactly the ordinals  $\alpha < \lambda^+$ .*

*Proof.* There are at most  $\lambda^+$  permitted domains. For each domain there are at most  $\lambda^\lambda = 2^\lambda$  functions, so  $|\mathcal{I}(X)| \leq \lambda^+ \cdot 2^\lambda = 2^\lambda$ . For the reverse inequality, partition  $X$  into pairs  $\{a_\xi, b_\xi\}$ ,  $\xi < \lambda$ , with  $a_\xi < b_\xi$ . The lexicographic order on  $\lambda \times \{0, 1\}$ , taking  $\xi$  first, has order type  $2 \cdot \lambda = \lambda$ . For  $\varepsilon \in 2^\lambda$ , list the  $\xi$ -th pair as  $(a_\xi, b_\xi)$  if  $\varepsilon(\xi) = 0$ , and as  $(b_\xi, a_\xi)$  otherwise. The resulting map

$$2^\lambda \rightarrow \mathcal{W}_\lambda(X)$$

is an order embedding when  $2^\lambda$  has lexicographic order. This proves all three cardinality assertions.

Let  $L$  be any linear order of cardinality at most  $\lambda$ , and fix an injection  $\iota : L \hookrightarrow \lambda$ . Associate to  $t \in L$  the binary function  $c_t$  whose value at  $\iota(s)$  is 1 precisely when  $s < t$ , and whose remaining coordinates are 0. If  $t < u$ , then  $c_t \leq c_u$  coordinatewise, and the inequality is strict at  $\iota(t)$ . Their first difference therefore has the correct direction. The preceding pair construction embeds  $L$  into  $\mathcal{W}_\lambda(X)$ .

It remains to exclude longer monotone sequences. Suppose that  $(f_\xi)_{\xi < \lambda^+}$  is strictly increasing or strictly decreasing in  $\mathcal{I}(X)$ . We recursively construct eventual common prefixes  $p_\alpha$  of length  $\alpha$ , for  $\alpha < \lambda^+$ . At a limit stage, take the union of the earlier prefixes. Regularity of  $\lambda^+$  ensures that a tail of the original sequence extends that union. At a successor step, at most one member of this tail equals  $p_\alpha$ ; discard it and all earlier indices. The values at coordinate  $\alpha$  are now monotone. A monotone sequence indexed by a tail of  $\lambda^+$ , taking at most  $\lambda$  values, is eventually constant: the first occurrence indices of all its values have a supremum below  $\lambda^+$ . Append this eventual value to  $p_\alpha$ . Every constructed prefix is injective because it occurs in members of the original sequence. The union of the prefixes through  $\lambda^+$  would therefore be an injection  $\lambda^+ \hookrightarrow X$ , a contradiction. Finally, an ordinal at least  $\lambda^+$  contains  $\lambda^+$ , whereas every smaller ordinal has cardinality at most  $\lambda$ .  $\square$

The distinction between the models also affects their elementary order topology. The order  $\mathcal{W}_\lambda(X)$  is dense. Indeed, let  $f <_{\text{lex}} g$ , with first difference at  $\xi$ . If the tail of  $f$  after  $\xi$  has an ascent, interchanging the two entries produces a point strictly between  $f$  and  $g$ . If the tail of  $g$  has a descent, the corresponding interchange works in the other direction. If neither exists, the first remaining tail is strictly decreasing and the second strictly increasing. Their common set of entries, after removing the two entries at  $\xi$ , is infinite and would be both well-ordered and reverse-well-ordered. This is impossible.

By contrast,  $\mathcal{W}(X)$  has adjacent pairs. Choose  $a < b$  in  $X$ , enumerate  $X \setminus \{a, b\}$  as a prefix  $p$ , and compare  $p \frown \langle a, b \rangle$  with  $p \frown \langle b, a \rangle$ . Any intervening enumeration would have to share  $p$ , after which only these two orders remain. Thus a cardinal-length convention changes the resulting linear order even though it does not change its cardinality or ordinal embedding spectrum.

**Proposition 6.2** (Exactly where jumps occur). *Suppose  $f <_{\text{lex}} g$  in  $\mathcal{W}(X)$ , with common prefix  $p$  up to their first difference. Put  $Y = X \setminus \text{ran}(p)$ ,  $a = f(\text{dom}(p))$ , and  $b = g(\text{dom}(p))$ , so  $a < b$ . The pair is adjacent precisely when  $Y$  is finite,  $a, b$  are consecutive in its native order, the tail of  $f$  after  $a$  lists  $Y \setminus \{a\}$  decreasingly, and the tail of  $g$  after  $b$  lists  $Y \setminus \{b\}$  increasingly.*

*Proof.* If an unused element lies strictly between  $a$  and  $b$ , start an enumeration with that element after  $p$  and complete it; this lies between  $f$  and  $g$ . Likewise, an ascent after  $a$ , or a descent after  $b$ , can be interchanged to create an intervening enumeration. Adjacency thus forces the two remaining tails to be decreasing and increasing, respectively. Their common native suborder  $Y \setminus \{a, b\}$  is then both well-ordered and reverse-well-ordered. It must be finite: an infinite well-order contains its first  $\omega$  elements, a subset with no greatest element. This proves necessity. Conversely, an intervening enumeration must share  $p$ . There is no possible next entry strictly between  $a$  and  $b$ . Among enumerations beginning with  $a$ , the displayed decreasing continuation is the largest; among those beginning with  $b$ , the increasing continuation is the smallest. Neither branch admits an intervening point.  $\square$

This description also identifies the finite components generated by adjacency. Write the domain of an enumeration uniquely as  $\theta = \delta + n$ , with  $\delta$  a limit ordinal and  $n < \omega$ . Its component consists of the  $n!$  permutations of the final  $n$  entries, keeping the prefix of length  $\delta$  fixed. In particular, words of limit length have no immediate neighbor. A jump cannot cross from one such component to another, because its common-prefix remainder would be infinite.

Endpoints can be classified just as concretely. The least element of  $\mathcal{W}(X)$ , if one exists, must always choose the least unused native element: otherwise interchanging that entry with a later smaller one decreases the enumeration. Hence a least element exists exactly when the native order on  $X$  is a well-order, and is its increasing enumeration. The greatest-element statement is the reverse assertion. For  $\mathcal{W}_\lambda(X)$ , the same argument shows that a least element exists exactly when the native

order type is the initial ordinal  $\lambda$ , not merely an arbitrary ordinal of cardinality  $\lambda$ . For example, an alphabet of native type  $\lambda + 1$  has a least full enumeration, but no least  $\lambda$ -length permutation.

## 6.1 Pointers to the reals report

[merge] The theorems of this section hold for every infinite linearly ordered set and are theorems of the repository’s reals report, which proves them in that generality. Source 11 says so (section 3); its repository audit (11-raw-orders-repository\_audit.md) adds that their application to birthday fragments “should be attributed as applications of existing repository results, not marketed as new general theorems”. All four sources re-prove them: source 08 from batch-76 manuscript 02 (now the reals report’s base source), sources 09 and 12 deliberately, and source 11 to keep the size distinctions explicit. They are printed once, here, with these pointers; no novelty is claimed for any of them.

| Adjacent pairs; finite blocks of $n!$ points                                                                                                                     | proposition 6.2 and the paragraph after it; note 6.17; notes 6.25 and 6.26 | lwo:thm:adjacency,<br>lwo:thm:blocks                                         |
| Absence of $\lambda^+$ is not a sufficient embeddability criterion                                                                                               | remark 6.9; remark 6.15                                                    | the reals report’s non-claims                                                |

The arguments are the reals report’s: pair swaps, characteristic-function cut codes, stabilization of a common prefix along a long monotone sequence, and cylinder fusion for strict cubes (the reals report credits the strict cube hierarchy to Corollary cor:strict of the point-separating game report and prints its fusion proof as a second route). Two of the sources’ routes are printed in full: source 12’s Section 9, because the singular transition of section 8 uses its lemmas, and source 09’s stabilization lemma for a regular cardinal (lemma 6.13). Source 08’s statements are recorded in notes (section 6.4).

## 6.2 Source 12’s route: a general set-sized spectrum theorem

We temporarily forget the surreal structure. Let  $X$  be any infinite linearly ordered set, and write  $|X| = \mu$ , an initial cardinal. The spectra below depend only on the cardinality, not on density,

separability, or field operations of  $X$ .

**Lemma 6.3** (Prefix-freeness of exhaustive enumerations). *Two distinct exhaustive injective ordinal enumerations of  $X$  are never proper prefixes of one another. Hence first-difference lexicography is unambiguous on  $\mathcal{W}(X)$ .*

*Proof.* An exhaustive prefix has already used every element of  $X$ . An injective proper extension would have to use a new element, which is impossible.  $\square$

For any ordinal  $\gamma$ , let  $\mathbb{B}_\gamma = (2^\gamma, <_{\text{lex}})$ . For linear orders  $L, M$ , write  $L \hookrightarrow M$  for an order-embedding and  $L \simeq_e M$  for embeddings in both directions. Define

$$\ell_2(L) = \min\{\gamma : L \hookrightarrow \mathbb{B}_\gamma\}$$

when such a binary coding ordinal exists. This is an ordinal-valued rank, not a cardinal invariant.

**Lemma 6.4** (Strict binary hierarchy). *For ordinals  $\alpha, \beta$ ,*

$$\mathbb{B}_\alpha \hookrightarrow \mathbb{B}_\beta \iff \alpha \leq \beta.$$

*In particular  $\ell_2(\mathbb{B}_\alpha) = \alpha$ .*

*Proof.* Zero-padding proves the forward construction when  $\alpha \leq \beta$ . It suffices to rule out an embedding  $f : \mathbb{B}_{\beta+1} \rightarrow \mathbb{B}_\beta$ .

Recursively construct an input prefix  $s_\xi$  of length  $\xi$  and an output prefix  $t_\xi$  of length  $\xi$ , so that every input extending  $s_\xi$  is sent to an output extending  $t_\xi$ . At a successor stage, split the input cylinder into its two next-bit halves and split the output cylinder likewise. The two input halves have strictly ordered images. They cannot both have images meeting both output halves: an image point in the upper output half from the lower input half would exceed an image point in the lower output half from the upper input half. Thus one input half has image contained in a single output half. Choose those halves to continue.

At a limit take unions; the corresponding cylinders are nonempty and the containment persists. At stage  $\beta$ , two inputs remain, differing in their last bit, but their images have the same full  $\beta$ -long output. This contradicts injectivity. For  $\alpha > \beta$ , padding embeds  $\mathbb{B}_{\beta+1}$  into  $\mathbb{B}_\alpha$ , giving the general impossibility.  $\square$

**Lemma 6.5** (Characteristic-cut coding). *Every linear order of cardinality at most  $\mu$  embeds in  $\mathbb{B}_\mu$ .*

*Proof.* Enumerate its carrier by distinct coordinates  $d_\xi$ , padding unused coordinates if necessary. Send  $x$  to the bits  $\mathbf{1}[d_\xi < x]$ . For  $x < y$ , every differing coordinate changes from 0 to 1, and the coordinate representing  $x$  does change. Thus the least difference gives the correct order.  $\square$

**Lemma 6.6** (Pair orientation coding).  $\mathbb{B}_\mu \hookrightarrow \mathcal{W}_\mu(X)$ . *More generally,  $\mathbb{B}_\gamma \hookrightarrow \mathcal{W}(X)$  for every  $\gamma < \mu^+$ .*

*Proof.* Partition  $X$  into  $\mu$  unordered pairs, sort each pair by  $X$ 's order, and orient the pair according to its bit. The ordinal sum of  $\mu$  two-element blocks has type  $2 \cdot \mu = \mu$ .

For a general  $\gamma < \mu^+$ , choose  $|\gamma|$  disjoint pairs and retain a disjoint reserve of size  $\mu$ . Such a choice is possible even when  $|\gamma| = \mu$ . List the pairs in type  $\gamma$ , then well-order all remaining labels in type  $\mu$ . The resulting enumeration has length  $2 \cdot \gamma + \mu < \mu^+$ . Its comparison is decided by the first oriented pair at which the inputs differ.  $\square$

**Lemma 6.7** (No  $\mu^+$ -long monotone chain). *Neither  $\mu^+$  nor its reverse embeds into  $\mathcal{W}(X)$ .*

*Proof.* Suppose  $(e_i)_{i < \mu^+}$  is strictly increasing. We recursively stabilize its entries on final segments of the index set. Assume that a final segment agrees on a prefix  $p$  of length  $\delta < \mu^+$ . No enumeration in a further infinite final segment can end there, by [lemma 6.3](#). Their  $\delta$ th entries form a nondecreasing  $\mu^+$ -sequence in a set of size  $\mu$ .

Such a sequence is eventually constant: choose one first occurrence for each value in its range; their at most  $\mu$  indices have supremum below  $\mu^+$  by regularity. Past that supremum no larger value can first appear. At a limit stage  $\delta < \mu^+$ , take the supremum of the earlier stabilization indices, still below  $\mu^+$ , and the union of the earlier prefixes.

This would produce an injective sequence of labels from  $X$  of length  $\mu^+$ : every set-sized earlier part is shared by a final segment of injective enumerations. That contradicts  $|X| = \mu$ . Replace nondecreasing by nonincreasing for the reverse order.  $\square$

**Theorem 6.8** (Cardinality and exact spectra). *For every infinite linearly ordered set  $X$  of cardinality  $\mu$ ,*

$$\begin{aligned} |\mathcal{W}(X)| &= |\mathcal{W}_\mu(X)| = 2^\mu, \\ \beta &\hookrightarrow \mathcal{W}(X) \iff \beta < \mu^+, \\ \beta &\hookrightarrow \mathcal{W}_\mu(X) \iff \beta < \mu^+, \\ \mathbb{B}_\gamma &\hookrightarrow \mathcal{W}(X) \iff \gamma < \mu^+, \\ \ell_2(\mathcal{W}(X)) &= \mu^+. \end{aligned}$$

*The ordinal statements also hold for reversed ordinals, and every linear order of cardinality at most  $\mu$  embeds even into  $\mathcal{W}_\mu(X)$ .*

*Proof.* Pair coding gives  $2^\mu$  elements, while all well-orders are relations on  $X$ , giving the upper bound  $2^{|X \times X|} = 2^\mu$ . The lower ordinal bounds and universality follow from [lemmas 6.5](#) and [6.6](#); [lemma 6.7](#) gives the upper bounds. The same characteristic coding applies to reversed ordinals.

For the cube spectrum use [lemma 6.6](#). If  $\gamma \geq \mu^+$ ,  $\mathbb{B}_\gamma$  contains an increasing chain of type  $\mu^+$ : use the sequences that are 1 before a moving cut and 0 afterward. Thus it cannot embed into  $\mathcal{W}(X)$ .

Embed  $X$  into  $\mathbb{B}_\mu$  using [lemma 6.5](#). Encode an exhaustive enumeration of length  $\alpha < \mu^+$  by concatenating its  $\mu$ -long entry codes, then pad with zeroes to length  $\mu^+$ . The unpadded length  $\mu \cdot \alpha$  has cardinality at most  $\mu$ , so is less than  $\mu^+$ . Distinct enumerations disagree before either ends, and their encoded first disagreement preserves the order. This proves  $\mathcal{W}(X) \hookrightarrow \mathbb{B}_{\mu^+}$ .

If it embedded in  $\mathbb{B}_\rho$  for  $\rho < \mu^+$ , then the copy of  $\mathbb{B}_{\rho+1}$  supplied by [lemma 6.6](#) would contradict [lemma 6.4](#). Hence the rank is exactly  $\mu^+$ .  $\square$

*Remark 6.9* (What the rank does not say). Although  $\ell_2(\mathcal{W}(X)) = \mu^+$ , the cube  $\mathbb{B}_{\mu^+}$  does *not* embed back into  $\mathcal{W}(X)$ . An order can first admit a binary encoding at an ordinal without containing the full cube of that ordinal. Nor is the absence of  $\mu^+$  and its reverse claimed sufficient for an arbitrary order to embed in  $\mathcal{W}(X)$ .

### 6.3 Source 09's route

[merge] Source 09's Section 4 works for any linearly ordered set. Its first statements are recorded in notes; its stabilization lemma and its proof of the ordinal spectrum are a second route and are printed in full.

*Note 6.10* (Source 09, Definition 4.1).  $\mathcal{W}_\alpha(X) = \text{Bij}(\alpha, X)$  and  $\mathcal{W}(X)$  is the union over all ordinals  $\alpha$ ; if  $|X| = \kappa$  is infinite, the possible lengths are exactly  $\kappa \leq \alpha < \kappa^+$ . This is the  $\mathcal{W}(X)$  of [section 6](#) and of the reals report.

*Note 6.11* (Source 09, Lemma 4.2, “Exhaustiveness removes the prefix ambiguity”). *Distinct members of  $\mathcal{W}(X)$  have a first unequal coordinate strictly below both of their lengths, so  $e <_{\text{lex}} f$  at that coordinate is a strict linear order (for transitivity compare the two first-disagreement ordinals of  $e < f$  and  $f < g$ ). This is `lwo:lem:prefix-free` and [lemma 6.3](#), by the same argument.*

*Note 6.12* (Source 09, Theorem 4.3, “Cardinality and universality”). *For every infinite linearly ordered set  $X$  of cardinality  $\kappa$ ,  $|\mathcal{W}_\kappa(X)| = |\mathcal{W}(X)| = 2^\kappa$ ; the lexicographic cube  $2^\kappa$  embeds into  $\mathcal{W}_\kappa(X)$ ; consequently every linear order of size at most  $\kappa$  embeds into  $\mathcal{W}_\kappa(X)$  and hence into  $\mathcal{W}(X)$ . This is [theorem 6.1](#), `lwo:prop:cardinality` and `lwo:thm:ordinal-spectrum(a)`, with the same pair-orientation and characteristic-function codes. Source 09 stresses that  $2 \cdot \kappa = \kappa$  is ordinal multiplication.*

## Second route (source 09): eventual stabilization at a regular cardinal.

**Lemma 6.13** (Eventual stabilization). *Let  $\mu$  be a regular infinite cardinal and let  $X$  have cardinality less than  $\mu$ . Every nondecreasing map  $f : \mu \rightarrow X$  is eventually constant.*

*Proof.* Some fiber must be unbounded: otherwise the union of fewer than  $\mu$  bounded fibers would be bounded. Once a value in such a fiber is reached, monotonicity and the unboundedness of the fiber prevent any subsequent strict increase.  $\square$

**Theorem 6.14** (Exact ordinal spectrum). *For  $|X| = \kappa$  infinite and any ordinal  $\beta$ ,*

$$\beta \hookrightarrow \mathcal{W}(X) \iff \beta < \kappa^+.$$

*The same equivalence holds for  $\beta^*$ , the reverse order of  $\beta$ .*

*Proof.* The positive direction follows from [note 6.12](#). For the negative direction put  $\mu = \kappa^+$  and suppose that  $(e_\xi)_{\xi < \mu}$  is strictly increasing in  $\mathcal{W}(X)$ . We construct an injective common eventual prefix of length  $\mu$ , which is impossible in the alphabet  $X$ .

Assume a prefix  $p$  of length  $\delta < \mu$  is shared by all  $e_\xi$  beyond some index  $t_\delta < \mu$ . At limits this holds by taking the supremum of the earlier cutoffs; regularity ensures that the new cutoff remains below  $\mu$ . If  $p$  exhausts  $X$ , every enumeration on this tail is exactly  $p$ , contrary to strict increase. Otherwise each tail enumeration has an entry at coordinate  $\delta$ . As the words share all earlier coordinates, these entries are nondecreasing in  $\xi$ . By [lemma 6.13](#) they eventually have one common value. Add it to  $p$ . Injectivity of the enumerations makes this a new value, not used earlier in  $p$ .

Continuing for every  $\delta < \mu$  gives  $\mu$  distinct elements of  $X$ , a contradiction. An embedding of any  $\beta \geq \mu$  would restrict to one of  $\mu$ . Reversing the alphabet proves the negative statement for  $\mu^*$  and its longer extensions.  $\square$

*Remark 6.15.* The absence of  $\kappa^+$  and its reverse is not asserted to characterize all linear orders embeddable in  $\mathcal{W}(X)$ . Indeed  $\mathcal{W}(X)$  already contains the binary cube of cardinality  $2^\kappa$ , so “size at most  $\kappa$ ” is a universality guarantee, not a necessary cardinality condition for an individual order to embed.

*Note 6.16* (Source 09, Proposition 4.7).  *$\mathcal{W}(X)$  has a least element exactly when the alphabet order on  $X$  is a well-order, and a greatest element exactly when its reverse is.* This is the paragraph on endpoints after [proposition 6.2](#) and `lwo:lem:extrema`, by the same argument (a least enumeration must take the least unused element at every position).

*Note 6.17* (Source 09, Proposition 4.8, “Finite residuals are exactly the adjacency mechanism”). *If  $e < f$  in  $\mathcal{W}(X)$  have common prefix  $p$  before their first disagreement and  $R = X \setminus \text{ran}(p)$ , they are adjacent precisely when  $R$  is finite and their remaining words are consecutive permutations of  $R$  in finite lexicographic order.* This is [proposition 6.2](#) and `lwo:thm:adjacency`, by the same argument through [note 6.16](#).

Even for a dense alphabet  $X$ , the full space  $\mathcal{W}(X)$  can therefore have adjacent points. This finite-tail phenomenon disappears for global enumerations: deleting a set prefix from **No** never leaves a finite remainder.

## 6.4 Source 08’s set-sized sections

[merge] Source 08’s Sections 3 (“All well-orderings of a fixed set”), 4 (“The exact ordinal and binary-cube spectra”) and 5 (“Adjacent pairs and finite tails”) re-prove the reals report’s general theorems by the same arguments. They are recorded here with source 08’s own remarks. Throughout,  $(X, <)$  is an infinite linearly ordered set of cardinality  $\kappa$ , its initial ordinal.

*Note 6.18* (Source 08, display (3) and Lemma 3.1, “No prefix ambiguity”). Source 08 defines

$$\mathcal{W}_\alpha(X) = \{e : \alpha \rightarrow X : e \text{ is a bijection}\}, \quad \mathcal{W}(X) = \bigcup_{\kappa \leq \alpha < \kappa^+} \mathcal{W}_\alpha(X) \quad (\text{S08.3})$$

and proves: *two distinct members  $e, f$  of  $\mathcal{W}(X)$  disagree before either one ends; consequently*

$$e <_{\text{lex}} f \iff e(\delta) < f(\delta), \quad \delta = \min\{\xi < \min(\text{dom } e, \text{dom } f) : e(\xi) \neq f(\xi)\} \quad (\text{S08.4})$$

*defines a linear order without an end-of-word convention.* This is `lwo:lem:prefix-free`. Source 08 adds: “Sorting by length *before* reading entries gives a different order. For instance, choosing one word of each possible length would produce a chain of type  $\kappa^+$  in that alternative.” [Note 6.22](#) shows this is impossible in [\(S08.4\)](#).

*Note 6.19* (Source 08, Lemma 3.2, “Pair coding”). *For every ordinal  $\theta < \kappa^+$  there is an order embedding  $\mathbb{B}_\theta \hookrightarrow \mathcal{W}(X)$ ; in particular  $\mathbb{B}_\kappa \hookrightarrow \mathcal{W}_\kappa(X)$ .* This is `lwo:lem:all-small-cubes`, `lwo:prop:cardinality` and [lemma 6.6](#), with the same blocks  $(a_\xi, c_\xi)$  and  $(c_\xi, a_\xi)$  followed by a fixed enumeration of the unused elements.

*Note 6.20* (Source 08, Lemma 3.3). *Every linear order  $L$  of cardinality at most  $\kappa$  embeds into  $\mathbb{B}_\kappa$ , by the bits  $\mathbf{1}[d < x]$  at distinct coordinates.* This is `lwo:lem:cut-code` and [lemma 6.5](#).

*Note 6.21* (Source 08, Theorem 3.4).  *$\mathcal{W}(X)$  has cardinality  $2^\kappa$  and contains every linear order of cardinality at most  $\kappa$ ; the embedding can already be made into  $\mathcal{W}_\kappa(X)$ .* This is `lwo:prop:cardinality` and `lwo:thm:ordinal-spectrum(a)`. Source 08 notes that neither the continuum hypothesis nor any regularity of  $\kappa$  occurs, so the theorem applies to arbitrary birthday cutoffs and to numerically scattered as well as dense sets of surreals.

*Note 6.22* (Source 08, Theorem 4.1, “Prefix stabilization”). *There is no strictly increasing or strictly decreasing sequence of length  $\kappa^+$  in  $\mathcal{W}(X)$ .* This is `lwo:thm:no-long`; the proof is the stabilization of [lemma 6.13](#) and [theorem 6.14](#): a monotone  $\kappa^+$ -sequence with at most  $\kappa$  values has an unbounded fibre in the regular cardinal  $\kappa^+$  and is constant from its first occurrence on.

*Note 6.23* (Source 08, Corollary 4.2, “Exact spectra”). *For every ordinal  $\beta$  and set ordinal  $\theta$ :  $\beta \hookrightarrow \mathcal{W}(X)$ ,  $\beta^{\text{op}} \hookrightarrow \mathcal{W}(X)$  and  $\mathbb{B}_\theta \hookrightarrow \mathcal{W}(X)$  each hold exactly when the ordinal is below  $\kappa^+$ .* This is `lwo:thm:ordinal-spectrum` and the cube clause of `lwo:thm:full-length`, as in [theorem 6.8](#); the chain  $f_\eta = \mathbf{1}[\xi < \eta]$  of type  $\kappa^+$  in  $\mathbb{B}_{\kappa^+}$  excludes the larger cubes.

*Note 6.24* (Source 08, Proposition 4.3, “A uniform binary upper coding”). *There is an order embedding  $\mathcal{W}(X) \hookrightarrow \mathbb{B}_{\kappa^+}$ , by concatenating cut codes of the entries and padding with zeros. This is the upper bound of `lwo:thm:full-length`, as in [theorem 6.8](#). Source 08’s remark: these results locate  $\mathcal{W}(X)$  between a long hierarchy of binary cubes without identifying it with one; the absence of a  $\kappa^+$ -chain is compatible with cardinality  $2^\kappa$  and does not mean that all suborders are small.*

*Note 6.25* (Source 08, Theorem 5.1, “Adjacency classification”). *Let  $e < f$  in  $\mathcal{W}(X)$  first disagree at  $\delta$ , with common prefix  $p$ , remaining alphabet  $Y = X \setminus \text{ran } p$ ,  $a = e(\delta)$  and  $c = f(\delta)$ . They are adjacent exactly when (i)  $Y$  is finite, (ii)  $a < c$  are consecutive in  $Y$ , and (iii) after  $a$  the word  $e$  lists  $Y \setminus \{a\}$  decreasingly and after  $c$  the word  $f$  lists  $Y \setminus \{c\}$  increasingly. This is [proposition 6.2](#) and `lwo:thm:adjacency`, by the same argument.*

*Note 6.26* (Source 08, Corollary 5.2, “Finite condensation blocks”). *If the length of  $e$  is  $\lambda + n$  with  $\lambda$  zero or a limit and  $n < \omega$ , its finite-condensation block consists of the words with the same prefix of length  $\lambda$  and all  $n!$  permutations of the remaining  $n$  values; a limit-length word has a singleton block. This is the paragraph after [proposition 6.2](#) and `lwo:thm:blocks`. Source 08 adds: “The phrase ‘singleton block’ does not assert that the point is isolated: it means that it has no finite chain of jumps to another point.”*

## 7 Birthday cutoffs and their set-sized orders

Use the sign presentation of surreal numbers:  $x \in \mathbf{No}$  is a function from an ordinal  $\text{bd}(x)$  to  $\{-, +\}$ . At the first difference, the comparison is  $- < \text{termination} < +$ . This presentation and the fundamental set-cut theorem are treated in Gonshor and in the modern account of Bagayoko and van der Hoeven [12, 14]. For an infinite cardinal  $\kappa$ , define

$$\mathbf{No}_{<\kappa} = \{x \in \mathbf{No} : \text{bd}(x) < \kappa\}.$$

This is a set. Counting sign sequences gives

$$|\mathbf{No}_{<\kappa}| = \sum_{\alpha < \kappa} 2^{|\alpha|} = 2^{<\kappa}.$$

Here  $2^{<\kappa}$  denotes the supremum of  $2^\mu$  over cardinals  $\mu < \kappa$ ; it is at least  $\kappa$ .

**Corollary 7.1.** *Put  $\lambda = 2^{<\kappa}$ . Then  $\mathcal{W}(\mathbf{No}_{<\kappa})$  has cardinality  $2^\lambda$ , is universal for linear orders of cardinality at most  $\lambda$ , and admits exactly the ordinals below  $\lambda^+$ . The same conclusions hold for its cardinal-length permutation suborder and for the injective-word order  $\mathcal{I}(\mathbf{No}_{<\kappa})$ .*

The parameter controlling this spectrum is the cardinality  $\lambda$  of the alphabet. It need not equal the birthday cutoff  $\kappa$ . For  $\kappa = \omega$ , the alphabet consists of the dyadic rationals. Its well-ordering order has cardinality  $2^{\aleph_0}$ , contains every countable linear order, and does not contain  $\omega_1$ . For  $\kappa = \omega_1$ , the alphabet consists of the surreals with countable sign expansions and has cardinality  $\mathfrak{c} = 2^{\aleph_0}$ . Its well-ordering order consequently has cardinality  $2^\mathfrak{c}$  and ordinal spectrum  $\alpha < \mathfrak{c}^+$ , without any use of the continuum hypothesis. When  $2^{<\kappa} = \kappa$ , the spectrum simplifies to  $\alpha < \kappa^+$ .

**Lemma 7.2.** *If  $\kappa$  is regular infinite,  $\mathbf{No}_{<\kappa}$  fills every cut  $A < B$  with  $|A \cup B| < \kappa$ . Such a cut can still be filled after excluding any prescribed subset of cardinality less than  $\kappa$ .*

*Proof.* The birthdays of the members of  $A \cup B$  have supremum below  $\kappa$ , by regularity. The simplest surreal between them has birthday at most the supremum of their birthdays plus one, and hence still belongs to  $\mathbf{No}_{<\kappa}$ . For the exclusion statement, let  $S$  be the forbidden set, and let  $S_0$  consist of its members that already lie strictly between  $A$  and  $B$ . Fill the cut  $A \cup S_0 < B$ . Its filler lies in the original interval but strictly above every forbidden point in that interval.  $\square$

We call this property  $\eta_\kappa$ , always allowing either side of a cut to be empty. The cardinal parameter in this notation is explicit; conventions indexing eta orders by ordinal subscripts vary in the literature. This elementary form of saturation is all that the stage arguments below require.

Regularity is necessary for this particular cutoff conclusion. If  $\kappa$  is singular, a cofinal sequence of ordinals below  $\kappa$ , of length  $\text{cf}(\kappa) < \kappa$ , is unbounded in  $\mathbf{No}_{<\kappa}$ . Indeed, a surreal of birthday  $\beta$  is at most the ordinal  $\beta$ , the all-positive sign expansion of that length. Every candidate upper bound is therefore exceeded by some member of the cofinal sequence. The cut consisting of this sequence on the left and the empty set on the right has no filler in  $\mathbf{No}_{<\kappa}$ . This failure concerns the bounded stage; it does not weaken the set-cut theorem for the full surreal class.

[merge] Source 09's Section 5 adds the stage sizes for every ordinal  $\theta$ , not only for cardinals, the density and cofinality of  $\mathbf{No}_{<\theta}$ , and a table. The cardinal clause of its [proposition 7.3](#) is source 11's count above, and (2) is [corollary 7.1](#).

## 7.1 Source 09: birthday-bounded versions of the problem

Set

$$\mathbf{No}_{<\theta} = \{x \in \mathbf{No} : \text{bd}(x) < \theta\}, \quad \kappa_\theta = |\mathbf{No}_{<\theta}|.$$

Each  $\mathbf{No}_{<\theta}$  is a set, and every set of surreal numbers is contained in one such  $\mathbf{No}_{<\theta}$ . The latter assertion follows by taking the supremum of successor birthdays.

**Proposition 7.3.** *For every ordinal  $\theta$ ,*

$$|\mathbf{No}_{<\theta}| = \sum_{\alpha < \theta} 2^{|\alpha|}.$$

*In particular, for an infinite cardinal  $\tau$ ,  $|\mathbf{No}_{<\tau}| = 2^{<\tau} := \sup_{\lambda < \tau} 2^\lambda$ . If  $\theta$  is an infinite limit ordinal,  $\mathbf{No}_{<\theta}$  is dense without endpoints and has cofinality and coinitality  $\text{cf}(\theta)$ .*

*Proof.* There are exactly  $2^{|\alpha|}$  sign words of length  $\alpha$ , and words of different lengths are distinct. For an infinite cardinal  $\tau$ , the supremum of these cardinalities is at least  $\tau$ , so multiplying it by  $\tau$  does not enlarge it.

For  $x < y$  in an infinite limit stage, the simplest cut separator has birthday at most  $\max(\text{bd}(x), \text{bd}(y)) + 1 < \theta$ . Larger positive and negative ordinals of birthday below  $\theta$  rule out endpoints. The ordinals below  $\theta$  are cofinal, and their negatives are coinital. Conversely, a subset whose birthdays are bounded below  $\theta$  is bounded in  $\mathbf{No}_{<\theta}$  by an ordinal below  $\theta$ . A cofinal subset must therefore have birthdays cofinal in  $\theta$ , establishing the lower cofinality bound.  $\square$

The fixed-set results now give the exact ordinal spectrum

$$\beta \hookrightarrow \mathcal{W}(\mathbf{No}_{<\theta}) \iff \beta < \kappa_\theta^+ \quad (\kappa_\theta \text{ infinite}). \quad (2)$$

This is a cardinal bound attached to the entire alphabet, not merely to the cofinality of its numerical order.

| Stage                                                | Alphabet size                 | Size of its well-ordering space | Ordinal spectrum         |
|------------------------------------------------------|-------------------------------|---------------------------------|--------------------------|
| $\mathbf{No}_{<\omega}$                              | $\aleph_0$                    | $2^{\aleph_0}$                  | $\beta < \omega_1$       |
| $\mathbf{No}_{<\omega_1}$                            | $2^{\aleph_0} = \mathfrak{c}$ | $2^{\mathfrak{c}}$              | $\beta < \mathfrak{c}^+$ |
| $\mathbf{No}_{<\tau}$ , $\tau$ strongly inaccessible | $\tau$                        | $2^\tau$                        | $\beta < \tau^+$         |

The second row does not identify  $\mathfrak{c}^+$  with  $\omega_2$  without an additional continuum hypothesis. At finite stages,  $|\mathbf{No}_{<n}| = 2^n - 1$ , so the number of well-orders is  $(2^n - 1)!$ .

[merge] Source 08's Section 6 begins with the same count, as (S08.5), and then treats the regular case; its statements are recorded in the notes after this extract.

## 7.2 Source 08: birthday cutoffs and the regular-cardinal model

For an ordinal  $\lambda$ , write

$$\mathbf{No}_{<\lambda} = \{x \in \mathbf{No} : \text{bd}(x) < \lambda\}.$$

Its exact cardinality is

$$|\mathbf{No}_{<\lambda}| = \sum_{\alpha < \lambda} 2^{|\alpha|}. \quad (\text{S08.5})$$

This follows directly from the disjoint birthday levels in the sign-sequence representation. If this cardinal is infinite, all the results of section 6.4 apply to  $\mathcal{W}(\mathbf{No}_{<\lambda})$ . No algebraic closure property of the cutoff is needed.

A particularly transparent case occurs at a regular infinite cardinal  $\kappa$  satisfying  $2^{<\kappa} = \kappa$ . This includes  $\kappa = \omega$  and every strongly inaccessible cardinal; it also includes successor cardinals under appropriate cardinal arithmetic hypotheses.

*Note 7.4* (Source 08, Proposition 6.1). *If  $\kappa$  is regular infinite and  $2^{<\kappa} = \kappa$ , then  $|\mathbf{No}_{<\kappa}| = \kappa$  and the numerical order of  $\mathbf{No}_{<\kappa}$  is an  $\eta_\kappa$ -order.* The second clause is lemma 7.2 (which needs only regularity), proved by the same birthday bound; it is the classical saturation of  $\mathbf{No}_{<\kappa}$  recorded in the birthday-cutoff report (`hset:rem:saturation`, through `hset:eq:cut-bound`) [4].

*Note 7.5* (Source 08, Lemma 6.2). *Replace each minus by 00 and each plus by 11 and append the terminal block 01; the resulting binary word  $d(s)$  of length  $2 \cdot \text{bd}(s) + 2$  is prefix-free and  $s < t$  exactly when  $d(s) <_{\text{lex}} d(t)$ .* This is source 12's lemma 19.33, by the same comparison  $00 < 01 < 11$ .

*Note 7.6* (Source 08, Theorem 6.3, “The initial-length cutoff order”). *If  $\kappa$  is regular infinite and  $2^{<\kappa} = \kappa$ , then*

$$\mathcal{W}_\kappa(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_\kappa, \quad |\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})| = 2^\kappa; \quad (\text{S08.6})$$

*moreover  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$  is an  $\eta_\kappa$ -order, and its ordinal and reverse-ordinal spectra consist exactly of the ordinals below  $\kappa^+$ .* The equimorphism is case 2 of source 12's theorem 8.3, proved the same way (pair coding one way, the unpadding code note 7.5 with partial sums below  $\kappa$  by regularity the other way). The  $\eta_\kappa$  clause is source 11's proposition 12.1 for  $X = \mathbf{No}_{<\kappa}$ ; source 08's set-sized cut argument is the same common-coordinate search, with fresh values from theorem 5.6 and a completion of length  $\kappa$ , and it refers to note 19.13 for the detailed invariant. The spectra are theorem 6.1.

*Note 7.7* (Source 08, Remark 6.4). Equimorphism in (S08.6) is not isomorphism: the binary cube has endpoints and adjacent pairs, whereas  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$  is dense without endpoints. Order embeddings need not preserve jumps or be continuous for the order topologies.

The regularity assumption has specific jobs: it bounds option birthdays and first-disagreement coordinates, and controls partial sums of code lengths. At a singular cutoff these steps may fail. The general cardinality and ordinal-spectrum theorems remain valid, but the  $\eta_\kappa$  and fixed-length equimorphism conclusions are not asserted without their hypotheses.

[merge] The singular case that this paragraph leaves open is settled for the coding length by source 12's dichotomy (section 8): at a singular strong limit the fixed-length order is  $\simeq_e \mathbb{B}_{\kappa \cdot \kappa}$ , not  $\mathbb{B}_\kappa$ , and it is  $\simeq_e \mathbb{B}_{2^{<\kappa}}$  when  $2^{<\kappa} > \kappa$  (section 1.7, item (c)). Source 11's remark at the end of section 7 gives the failure of  $\eta_\kappa$  at a singular cutoff.

[merge] The next section is source 12’s Section 10. Its dichotomy is new against the repository; it answers in part the reals report’s question “Other ground orders” (section 1.7). It uses source 12’s self-delimiting code (lemma 19.33, printed in part IV) and its lemmas of section 6.2. Here  $S_\kappa$  of source 12 is printed  $\mathbf{No}_{<\kappa}$ , and its “binary coding rank” is the binary coding length  $\ell_2$  of the reals report.

## 8 Birthday cutoffs and the singular transition (source 12)

Let  $\kappa$  be an infinite initial cardinal and put

$$\mathbf{No}_{<\kappa} = \{s \in \mathbf{No} : \text{bd}(s) < \kappa\}, \quad \mu = |\mathbf{No}_{<\kappa}| = 2^{<\kappa} = \sup_{\lambda < \kappa} 2^{|\lambda|}.$$

The cardinality identity follows by counting all levels. The supremum is at least  $\kappa$ , and summing  $\kappa$  levels of size at most that supremum does not increase it. The reverse inequality is supplied by the levels themselves. We do not assume  $\mathbf{No}_{<\kappa}$  is a field; none of the following proofs uses arithmetic closure.

### 8.1 A scheduler that preserves the first varying coordinate

**Lemma 8.1** (Row scheduler). *Suppose a set order  $X$  of infinite cardinality  $\kappa$  has disjoint subsets  $(X_i)_{i < \kappa}$ , each containing a copy of  $X$  and each of cardinality  $\kappa$ . Suppose their complement is either empty or has cardinality  $\kappa$ . Then*

$$X_{\text{lex}}^\kappa \hookrightarrow \mathcal{W}_\kappa(X).$$

*Proof.* Fix embeddings  $\phi_i : X \rightarrow X_i$  and a baseline enumeration of each  $X_i$  in length  $\kappa$ . For  $x \in X$ , transpose the label  $\phi_i(x)$  with the first label of that baseline, giving an enumeration  $r_{i,x}$  of  $X_i$  whose first value is  $\phi_i(x)$ . Its dependence on  $x$  is fixed and uniform. If the complement is nonempty, add a fixed filler row indexed before all variable rows. The row index order still has type  $1 + \kappa = \kappa$ .

Well-order row-stage pairs  $(i, j) \in \kappa \times \kappa$  first by  $\max(i, j)$  and then lexicographically within a level. This schedule has type  $\kappa$ : the predecessors of any pair have cardinality less than  $\kappa$ , since both coordinates there are bounded below  $\kappa$ , while the entire set of pairs has size  $\kappa$ . The first appearance of row  $i$  is  $(i, 0)$ , and these first appearances occur in increasing row order.

For an input  $(x_i)_{i < \kappa}$ , output the  $j$ th entry of  $r_{i,x_i}$  when pair  $(i, j)$  is scheduled. The output is an exhaustive bijection in type  $\kappa$ . If two inputs first differ in row  $i$ , every earlier row agrees, no later row has appeared before  $(i, 0)$ , and the first output discrepancy is  $\phi_i(x_i)$  versus  $\phi_i(y_i)$ . Its sign is exactly the sign of the input comparison.  $\square$

**Lemma 8.2** (Surreal cone decomposition). *If  $|\mathbf{No}_{<\kappa}| = \kappa$ , then*

$$\mathcal{W}_\kappa(\mathbf{No}_{<\kappa}) \simeq_e (\mathbf{No}_{<\kappa})_{\text{lex}}^\kappa.$$

*Proof.* One embedding is the inclusion of bijective sequences among all sequences. For the other, partition the sign sequences with a minus into the cones with prefixes

$$p_i = +^i \frown -, \quad i < \kappa.$$

They are disjoint, and prefixing by  $p_i$  gives a numerical order isomorphism from  $\mathbf{No}_{<\kappa}$  onto that cone. For  $i, \alpha < \kappa$ ,  $i + 1 + \alpha < \kappa$ ; this uses that  $\kappa$  is an initial cardinal and is valid even when it is singular. Removing the initial prefix also leaves a sign sequence of length less than  $\kappa$ . The complement consists of all-plus sequences, one for each length below  $\kappa$ , so has cardinality  $\kappa$ . Apply lemma 8.1.  $\square$

**Theorem 8.3** (Exact minimal-slice dichotomy). *For  $\kappa$  and  $\mu = 2^{<\kappa}$  as above,*

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \simeq_e \begin{cases} \mathbb{B}_{\kappa \cdot \kappa}, & \mu = \kappa \text{ and } \text{cf } \kappa < \kappa, \\ \mathbb{B}_\mu, & \text{otherwise.} \end{cases}$$

*Consequently its binary coding rank is respectively  $\kappa \cdot \kappa$  or  $\mu$ . The exceptional case is exactly the case of a singular strong-limit cardinal  $\kappa$ .*

*Proof.* We separate the three mechanisms.

*Case 1:  $\mu > \kappa$ .* By lemma 19.33, each member of  $\mathbf{No}_{<\kappa}$  has a prefix-free numerical binary code of length less than  $\kappa$ . Pad each such code to length  $\kappa$ . Concatenating the entry codes of a  $\mu$ -long enumeration produces a binary word of length  $\kappa \cdot \mu = \mu$ . The equality holds because  $\mu$  is an initial cardinal strictly larger than  $\kappa$ : every proper partial product  $\kappa \cdot \xi$ ,  $\xi < \mu$ , has cardinality below  $\mu$ . Thus  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \hookrightarrow \mathbb{B}_\mu$ . Pair coding gives the reverse embedding.

*Case 2:  $\mu = \kappa$  and  $\kappa$  is regular.* Use the unpadded, self-delimiting code  $c(s)$ . In a sequence of  $\kappa$  entries, the sum of code lengths before any stage  $\xi < \kappa$  is less than  $\kappa$ , by regularity. The full sum is  $\kappa$ , since every length is positive. Consequently concatenation embeds even  $(\mathbf{No}_{<\kappa})_{\text{lex}}^\kappa$  into  $\mathbb{B}_\kappa$ . Pair coding again supplies the reverse embedding for  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$ .

*Case 3:  $\mu = \kappa$  and  $\delta = \text{cf } \kappa < \kappa$ .* The padded single-entry code embeds  $\mathbf{No}_{<\kappa}$  into  $\mathbb{B}_\kappa$ , whence

$$\mathcal{W}_\kappa(\mathbf{No}_{<\kappa}) \hookrightarrow (\mathbf{No}_{<\kappa})_{\text{lex}}^\kappa \hookrightarrow \mathbb{B}_{\kappa \cdot \kappa}.$$

Choose increasing nonzero ordinals  $(\lambda_j)_{j < \delta}$  cofinal in  $\kappa$ . Their ordinal sum is  $\kappa$ . As  $\delta \cdot \kappa = \kappa$ , partition the  $\kappa$  input coordinates into  $\kappa$  consecutive blocks of length  $\delta$ . In each block, restrict its  $j$ th coordinate to sign sequences of exactly length  $\lambda_j$ . The lexicographic product of those coordinates is the binary cube of the sum of their lengths. Thus, over all the blocks, this restricted product is

$$\mathbb{B}_{\sum_{\xi < \kappa} \sum_{j < \delta} \lambda_j} = \mathbb{B}_{\kappa \cdot \kappa}.$$

It embeds into  $(\mathbf{No}_{<\kappa})_{\text{lex}}^\kappa$ , which embeds into  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$  by lemma 8.2. This gives the claimed equimorphism. The rank assertions follow from lemma 6.4.

Finally, a singular strong limit satisfies  $2^{<\kappa} = \kappa$ . Conversely, suppose  $\kappa$  is singular and  $2^{<\kappa} = \kappa$ . If  $2^\lambda = \kappa$  for some  $\lambda < \kappa$ , choose  $\rho < \kappa$  with  $\rho \geq \lambda, \text{cf } \kappa$ . Then  $\kappa \leq 2^\rho \leq 2^{<\kappa} = \kappa$ , so  $2^\rho = \kappa$ , contradicting König's inequality  $\text{cf}(2^\rho) > \rho$ . Thus  $2^\lambda < \kappa$  for every  $\lambda < \kappa$ .  $\square$

**Corollary 8.4** (A complete cube test for the minimal slice). *Let  $\rho = \kappa \cdot \kappa$  in the exceptional case of theorem 8.3, and let  $\rho = \mu$  otherwise. Then*

$$\mathbb{B}_\gamma \hookrightarrow \mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \iff \gamma \leq \rho.$$

*In every case its ordinal embedding spectrum is still precisely  $\{\beta : \beta < \mu^+\}$ .*

**Example 8.5** (An unconditional singular example). Let  $\kappa = \beth_\omega = \sup_{n < \omega} \beth_n$ . It is a singular strong-limit cardinal of cofinality  $\omega$ , independently of GCH. Thus

$$\ell_2(\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})) = \kappa \cdot \kappa > \kappa, \quad \ell_2(\mathcal{W}(\mathbf{No}_{<\kappa})) = \kappa^+.$$

All three displayed ordinals must be distinguished. The first two have the same cardinality, but are different coding lengths; the successor cardinal is larger still.

**Example 8.6** (Regular cutoffs). For  $\kappa = \omega$ ,  $\mathbf{No}_{<\kappa}$  is the order of finite-birthday surreals, and the minimal slice is equimorphic with  $\mathbb{B}_\omega$ . For  $\kappa = \omega_1$ , its cardinality is  $2^{\aleph_0}$ , and the minimal slice is equimorphic with  $\mathbb{B}_{2^{\aleph_0}}$ , whether or not CH holds. At a strongly inaccessible  $\kappa$ , it is equimorphic with  $\mathbb{B}_\kappa$ .

## 8.2 Why the singular phenomenon is genuinely ordinal

A set of  $\kappa$  coordinates does not license arbitrary reordering of those coordinates in a lexicographic product. In the singular case, a short cofinal block of coordinate lengths can already consume ordinal length  $\kappa$ ; repeating that event  $\kappa$  times consumes  $\kappa \cdot \kappa$ . Replacing this ordinal sum by its cardinality would incorrectly collapse the rank back to  $\kappa$ . The strict-cube lemma shows that the lost information is mathematically detectable.

The row scheduler addresses a separate possible error: an arbitrary bijection  $\kappa \times \kappa \rightarrow \kappa$  need not preserve the first varying row. Bounding by the maximum coordinate ensures that all earlier observable output is independent of later varying rows. This is why the product-to-permutation embedding is valid even at singular  $\kappa$ .

[merge] The last sentence of [corollary 8.4](#) is [corollary 7.1](#) for the minimal slice. The dichotomy computes binary coding length only; source 11's question on the exact cut spectrum and point characters of  $\mathcal{W}_\lambda(\mathbf{No}_{<\kappa})$  without  $2^{<\kappa} = \kappa$  ([research question 113.7](#)) stays open.

[merge] Dated note, 3 October 2026 (batch 81): that question is now answered by sources 17, 15 and 18 in Part VI: point characters  $(q, q)$  with  $q = \text{cf } \mu$ , the exact gap spectrum and its multiplicities, and the saturation threshold  $\eta_{\text{cf } \kappa}$  of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$ , for every infinite cardinal  $\kappa$  ([sections 30](#) and [33](#)). Source 15 extends the dichotomy itself to the strata  $\mu \cdot \gamma + n$  ([theorem 31.2](#)).

## Part II

# Set-length words

## 9 Set-length surreal words embed explicitly in the surreal line

Let  $\mathcal{T}$  be the class of all set-length words  $f : \alpha \rightarrow \mathbf{No}$ , and let  $\mathcal{I}$  be its injective subclass. The latter codes well-orders of set-sized subsets of  $\mathbf{No}$ . Both are ordered lexicographically with proper prefixes smaller. Their members are sets, so these are ordinary definable classes in  $\mathbf{GB}$ , not collections whose members are proper classes. They should not be confused with all global well-orders of the entire surreal class.

In particular, a word cannot exhaust  $\mathbf{No}$ : its range is a set by Replacement. Passing from fixed alphabets to  $\mathcal{I}$  consequently changes which carrier is being well-ordered from one point of the lexicographic order to another. This is a mathematically natural extension, but it answers a different question from ordering all class well-orders on a single proper-class carrier. Making this distinction before forming any collection of codes is what prevents a hidden ascent from classes to collections of classes.

The following construction uses neither a global enumeration of  $\mathbf{No}$  nor Global Choice. It uses only ordinal concatenation of sign expansions, whose general properties are discussed in [\[14, Section 3.2\]](#).

**Theorem 9.1** (Explicit sign coding). *There is an explicitly defined order embedding  $\mathcal{E} : \mathcal{T} \rightarrow \mathbf{No}$ . It maps the empty word to 0, maps every nonempty word to a positive surreal, and restricts to an order embedding of  $\mathcal{I}$ . Singleton words give embeddings in the opposite direction.*

*Proof.* For a sign expansion  $s$ , let  $D(s)$  duplicate each sign: replace  $-$  by  $(-, -)$ , and  $+$  by  $(+, +)$ . For  $x \in \mathbf{No}$ , put

$$C(x) = (+) \frown D(s_x) \frown (+, -).$$

The length here is the ordinal  $1 + 2 \cdot \text{bd}(x) + 2$ . If  $s_x, s_y$  first differ at a sign, their doubled blocks have the same comparison. If  $s_x$  is a proper prefix of  $s_y$ , the terminal block  $(+, -)$  of  $C(x)$  is compared with the next doubled block of  $C(y)$ . We have

$$(-, -) < (+, -) < (+, +).$$

This is precisely the comparison of a missing sign with a negative or positive continuation. Thus  $C$  preserves the surreal order. Moreover, two distinct values of  $C$  cannot be prefixes of one another: the same first differing block supplies an actual differing sign before either code ends.

For  $f : \alpha \rightarrow \mathbf{No}$ , concatenate these blocks in domain order:

$$\mathcal{E}(f) = \bigcap_{i < \alpha} C(f(i)).$$

Replacement and ordinal summation make this a set-length sign expansion. If two words first differ at  $i$ , their preceding blocks coincide and their blocks at  $i$  have a first differing sign. Prefix freedom prevents that difference from being displaced into a subsequent block. The comparison therefore agrees with the comparison of the original entries. If  $f$  is a proper prefix of  $g$ , the expansion  $\mathcal{E}(g)$  continues  $\mathcal{E}(f)$  with the initial  $+$  of the next block, so  $\mathcal{E}(f) < \mathcal{E}(g)$ . This also proves the assertions about empty and nonempty words. Finally,  $x \mapsto \langle x \rangle$  embeds  $\mathbf{No}$  into both word classes.  $\square$

Accordingly,  $\mathcal{T}$ ,  $\mathcal{I}$ , and  $\mathbf{No}$  are pairwise equimorphic as class linear orders. This conclusion asserts embeddings both ways, not isomorphism. Section 10 exhibits an obstruction to isomorphism that persists after the empty word is removed.

**Proposition 9.2** (Birthday bounds). *The coding has the following bounds.*

1. If  $\kappa$  is regular infinite,  $\alpha < \kappa$ , and  $f(i) \in \mathbf{No}_{<\kappa}$  for every  $i < \alpha$ , then  $\mathcal{E}(f) \in \mathbf{No}_{<\kappa}$ .
2. For any infinite cardinal  $\kappa$ , put  $\lambda = 2^{<\kappa}$ . If  $f$  is an arbitrary injective word over  $\mathbf{No}_{<\kappa}$ , then  $\mathcal{E}(f) \in \mathbf{No}_{<\lambda^+}$ .

*Proof.* The birthday of the image is

$$\text{bd}(\mathcal{E}(f)) = \sum_{i < \alpha} (1 + 2 \cdot \text{bd}(f(i)) + 2),$$

with ordinal addition and multiplication. For the first assertion, this sums fewer than  $\kappa$  ordinals below  $\kappa$ , and regularity keeps the sum below  $\kappa$ . For the second, injectivity gives  $|\alpha| \leq \lambda$ ; each block has cardinality at most  $\lambda$ . The whole sign expansion has cardinality at most  $\lambda$ , so its ordinal length is below  $\lambda^+$ .  $\square$

The first bound need not hold at a singular cutoff. Choose distinct ordinals  $\gamma_i < \kappa$ ,  $i < \text{cf}(\kappa)$ , cofinal in  $\kappa$ , and regard them as surreal entries. The word has length less than  $\kappa$ , but the lengths of its code blocks are unbounded in  $\kappa$ , so its encoded birthday is at least  $\kappa$ . Also, injectivity is essential to the unrestricted second bound: constant words over a one-element alphabet can have every ordinal length.

## 10 Local characters and set suprema of word orders

In this section  $\mathcal{W}$  denotes either  $\mathcal{T}$  or  $\mathcal{I}$ . Deleting the set of entries of an existing prefix causes no difficulty when choosing a new coordinate: apply Lemma 5.2. We say that a segment has no set cofinal subset rather than assigning it a cardinal cofinality that does not exist.

**Theorem 10.1** (Exact local character). *Let  $f \in \mathcal{W}$  have domain  $\alpha$ .*

1. *If  $\alpha$  is a nonzero limit ordinal, then  $\text{cf}(\mathcal{W}_{<f}) = \text{cf}(\alpha)$ .*
2. *If  $\alpha$  is a successor ordinal, then  $\mathcal{W}_{<f}$  has no set cofinal subset.*
3. *For every  $\alpha$ , the segment  $\mathcal{W}_{>f}$  has no set coinitial subset.*

*The empty word is the minimum of  $\mathcal{W}$ .*

*Proof.* Suppose first that  $\alpha$  is a nonzero limit. Its proper prefixes  $f \upharpoonright \beta$ ,  $\beta < \alpha$ , are cofinal below  $f$ . A word  $g < f$  is either a proper prefix, or differs from  $f$  first at some coordinate  $\xi$ ; in the latter case it lies below every prefix long enough to include coordinate  $\xi$ . A cofinal sequence of indices in  $\alpha$  therefore supplies a cofinal subset of size  $\text{cf}(\alpha)$ . Conversely, to each  $g < f$  assign a prefix length strictly large enough that the corresponding prefix exceeds  $g$ . Fewer than  $\text{cf}(\alpha)$  such lengths are bounded below  $\alpha$ , so the corresponding words cannot be cofinal.

Next let  $\alpha = \beta + 1$ , write  $p = f \upharpoonright \beta$ , and take a set  $A < f$ . For each member  $a$  properly extending  $p$ , its next coordinate satisfies  $a(\beta) < f(\beta)$ . Choose an unused surreal  $d$  strictly above all these coordinates and strictly below  $f(\beta)$ . Then  $h = p \frown \langle d \rangle$  is below  $f$ . It exceeds every member of  $A$  extending  $p$ ; the remaining members are at most  $p$ , so they also lie below  $h$ . Thus  $A$  is not cofinal.

Finally, take a set  $B > f$ . Collect  $b(\alpha)$  for those  $b \in B$  properly extending  $f$ , and choose an unused  $d$  below all these coordinates. The word  $h = f \frown \langle d \rangle$  lies above  $f$ . It lies below the members of  $B$  extending  $f$ . Every other member of  $B$  first differs earlier with a larger coordinate, and consequently exceeds every extension of  $f$ , including  $h$ . Hence  $f < h < B$ .  $\square$

**Corollary 10.2.** *Neither  $\mathcal{T}$  nor  $\mathcal{I}$ , with or without its empty word, is order-isomorphic to  $\mathbf{No}$ . Each has nontrivial set suprema, but a set with no minimum cannot have an infimum in either word order.*

*Proof.* Take an injective word  $f$  of length  $\omega$ . Its nonempty finite prefixes increase to  $f$ , and  $f$  is their supremum by the preceding theorem. No surreal can be the supremum of a set lying strictly below it: the surreal set-cut property would insert a smaller upper bound. This distinguishes the orders even after deleting their minimum. If  $f$  were the infimum of a set  $B$  not containing  $f$ , part (3) would produce  $h$  with  $f < h < B$ , contradicting the definition of infimum.  $\square$

These local obstructions coexist with very rich intervals. Given  $f <_{\text{lex}} g$  with a first differing coordinate, vary that coordinate through a surreal interval strictly between the two values and disjoint from the set of preceding entries. If  $f$  is a proper prefix of  $g$ , vary a new coordinate below the next entry of  $g$  instead. The surreal set-cut property provides such an interval after excluding the preceding entries. Every surreal interval  $(u, v)$  is order-isomorphic to  $\mathbf{No}$ , for example by

$$t \mapsto u + \frac{v - u}{2} \left( 1 + \frac{t}{1 + |t|} \right).$$

Thus every open word interval contains a copy of  $\mathbf{No}$ , and Theorem 9.1 then places a copy of the entire word order inside it. Interval universality therefore does not imply that set cuts are filled.

## 11 The complete obstruction to filling a set cut

The preceding prefix example is the only nontrivial obstruction. Here and below,  $A < B$  means that every member of  $A$  is strictly below every member of  $B$ ; either set may be empty.

**Theorem 11.1** (Word-cut classification). *A set cut  $A < B$  in  $\mathcal{W}$  has no interpolant if and only if one of the following holds:*

1.  *$B$  contains the empty word;*
2.  *$B$  has a minimum  $b$  of nonzero limit length, and  $A$  is cofinal in  $\mathcal{W}_{<b}$ .*

*If neither obstruction occurs, an interpolant can be chosen to have nonzero successor length.*

*Proof.* Either displayed obstruction plainly prevents an interpolant. For the converse, perform the following common-prefix search. Start with  $p$  empty. Maintain these invariants: members of  $A$  not extending  $p$  lie below  $p$ ; members of  $B$  not extending  $p$  lie above every extension of  $p$ . Here extending allows equality.

If  $p \in B$ , stop. Otherwise, with  $\delta = \text{dom}(p)$ , form the sets of next coordinates

$$A(p) = \{a(\delta) : a \in A, p \text{ is a proper prefix of } a\}, \quad B(p) = \{b(\delta) : b \in B, p \text{ is a proper prefix of } b\}.$$

Every member of  $A(p)$  is at most every member of  $B(p)$ , since the corresponding words satisfy  $a < b$ . If these coordinate sets are disjoint, all these inequalities are strict. Choose a surreal  $c$  strictly between them, outside  $\text{ran}(p)$ . Then  $p \frown \langle c \rangle$  interpolates the original cut by the invariants, and the construction is complete.

If the two coordinate sets meet, their intersection consists of a unique element  $c$ : two distinct common elements would violate the preceding inequalities. Replace  $p$  by  $p \frown \langle c \rangle$ . The invariants persist because the discarded  $A$ -branches have smaller next coordinates and the discarded  $B$ -branches have larger ones. In the injective-word case,  $c$  is unused, since it is witnessed by an injective word extending the previous prefix. At a limit stage take the union of the prefixes. It is a set word, is injective when required, and satisfies the same invariants. A member of  $B$  cannot have become a proper prefix of this union: the search would already have stopped upon reaching that member.

This procedure requires only set recursion. Choose an ordinal strictly above the domains of all words in  $A \cup B$ . The search cannot continue taking common next coordinates up to that length, because there would be no words supplying those coordinates. It therefore terminates. The remaining possibility is termination at  $p \in B$ . The invariants show that  $p = \min B$ . If its length is zero, the first obstruction holds.

Termination cannot occur at a successor length  $\delta + 1$ . The last appended coordinate was chosen from the intersection, so some member of  $A$  extends this successor prefix. Such a word is at least  $p$ , contrary to  $A < B$ . Hence a nonzero terminal length  $\alpha$  is a limit. For every  $\beta < \alpha$ , a member of  $A$  witnessed the common coordinate at stage  $\beta$ ; it extends  $p \upharpoonright (\beta + 1)$  and lies below  $p$ . These witnesses exceed prefixes of arbitrarily large length. Since the proper prefixes are cofinal below  $p$ ,  $A$  is cofinal below  $p$ . This is exactly the second obstruction.  $\square$

**Corollary 11.2** (Successor words). *The suborder of  $\mathcal{W}$  consisting of words of nonzero successor length fills every set cut. In GBC, it is order-isomorphic to **No**.*

*Proof.* Neither obstruction in Theorem 11.1 can occur when the upper set consists of successor words. The construction returns another successor word, proving the set-cut property. Under Global Choice, enumerate each of the two proper classes by a set-like class well-order and perform back-and-forth. At every ordinal stage the previously matched elements form a set; their images specify a set cut, and an unused filler extends the partial order isomorphism. The union is an isomorphism. This is the class analogue of the usual eta-order back-and-forth, with its choice assumption made explicit; compare the class framework in [15].  $\square$

The distinction is precise. Deleting the empty word alone does not remove the prefix-supremum obstruction. Restricting to successor lengths does remove it. The explicit embeddings of Theorem 9.1 require no Global Choice, while the back-and-forth identification just given uses it.

[merge] Source 09’s class of set-length injective words is  $\mathcal{I}$  (its  $\mathcal{T}$ ). Its proposition 11.3 obtains the equimorphism with **No** from class universality in GBC; source 11’s theorem 9.1 gives explicit embeddings in ZF, and corollary 10.2 the non-isomorphism.

## 11.1 Source 09: allowing the underlying set to vary

### 11.1.1 The set-word class

Every well-order on a set of surreals has a unique injective exhaustive enumeration of its range. Thus all such labeled set well-orders are represented by the genuine proper class

$$\mathcal{I} = \{p : p \text{ is an injective function } \alpha \rightarrow \mathbf{No} \text{ for some ordinal } \alpha\}.$$

Every member of  $\mathcal{I}$  is a set. The collection is proper because it contains every singleton word  $(x)$  with  $x \in \mathbf{No}$ .

For  $p, q \in \mathcal{I}$ , compare at the first unequal entry when one exists; otherwise the proper prefix is smaller. This is a strict linear order. One can verify transitivity by padding words with a formal termination symbol below every surreal, but this symbol is *not itself a surreal number*. It is simply part of the definition of word order.

**Proposition 11.3.** *The dictionary order on  $\mathcal{I}$  is dense, has the empty word as its least element, and has no greatest element. In GBC it is equimorphic with **No**, but it is not isomorphic to **No**, even after removing the empty word.*

*Proof.* If  $p < q$  differ at coordinate  $\delta$ , their common prefix has set range. By lemma 5.10, choose a fresh surreal between the two entries at  $\delta$  and append it to this prefix. The resulting word lies strictly between  $p$  and  $q$ . If  $p$  is a proper prefix of  $q$ , append to  $p$  a fresh value smaller than  $q(\text{dom } p)$ ; this also gives an intermediate word. Every word has a proper injective extension, so there is no greatest word.

The singleton map  $x \mapsto (x)$  embeds **No** into  $\mathcal{I}$ . Conversely,  $\mathcal{I}$  is a class linear order and embeds into **No** by theorem 5.16. The final nonisomorphism assertion follows from the next proposition.  $\square$

*Note 11.4* (Source 09, Proposition 6.2, “Limit prefixes create small one-sided character”). *If  $p \in \mathcal{I}$  has nonzero limit length  $\lambda$ , its proper prefixes are cofinal in the open initial segment below  $p$ , the cofinality of that segment is exactly  $\text{cf}(\lambda)$ , and  $p = \sup_{\mathcal{T}}\{p \restriction \xi : \xi < \lambda\}$ .* This is part (1) of theorem 10.1 and the first step of the proof of corollary 10.2, by the same argument.

In **No**, the set-cut property forbids a set cofinal immediately below any fixed point. Thus the difference in note 11.4 is intrinsic, not just an artifact of the empty word. An embedding into **No** does not contradict this: the image need not preserve suprema in the ambient order.

### 11.1.2 Labeled objects versus order types

There is only one increasing exhaustive enumeration of a set already well-ordered by the numerical surreal order. In contrast,  $\mathcal{W}(X)$  allows all well-orders on the labeled set  $X$ . If one instead quotients all set well-orders by abstract order isomorphism, only their ordinal types remain. Lexicographic comparison of their numerical entries does not descend to that quotient: two distinct two-letter words can have identical abstract order type and different positions in dictionary order. The distinctions between labels, inherited order, and order type must be retained.

[merge] Source 08’s Section 7 (“Varying set-sized subsets: a different class order”) uses the same class  $\mathcal{I}(\mathbf{No}) = \mathcal{I}$  with proper prefixes first.

*Note 11.5* (Source 08, Proposition 7.1). *The prefix-small lexicographic order on  $\mathcal{I}(\mathbf{No})$  is linear; its empty word is a minimum, its nonempty part is dense without endpoints, and it contains a copy of  $\mathbf{No}$  through one-entry words. Nevertheless its nonempty part is not an  $\eta_{\text{Ord}}$ -order: for an injective word  $p$  of length  $\omega$ , the set of its nonempty finite prefixes and  $\{p\}$  have no separator. This is [corollary 10.2](#) with the obstruction (2) of [theorem 11.1](#), by the same argument. Its last paragraph is printed next.*

More generally, for a word  $p$  of nonzero limit length  $\lambda$ , its proper prefixes are cofinal below it, and the left cofinality at  $p$  is  $\text{cf}(\lambda)$ . For the lower bound, a family of fewer than  $\text{cf}(\lambda)$  words below  $p$  has its first disagreement or termination coordinates bounded below  $\lambda$ , and so is bounded by a proper prefix. Thus even very large numerical alphabets do not erase cofinalities created by termination conventions.

If “well-orders of subsets” is instead required to mean *numerically increasing* enumerations, it defines a further subclass of  $\mathcal{I}(\mathbf{No})$ . The singleton embedding of  $\mathbf{No}$  still works, and the limit-prefix obstruction persists using an increasing  $p$ . We do not identify that subclass with the arbitrary-enumeration class. Likewise a numerically well-ordered *proper subclass* of  $\mathbf{No}$  need not be set-like: a bounded increasing copy of  $\text{Ord}$  followed by its upper endpoint has type  $\text{Ord} + 1$ . Such copies also follow from the universality theorem in [section 5.8](#).

## 12 Saturation at a regular stage

For regular infinite  $\kappa$ , restrict to successor-length injective words of length below  $\kappa$ , with entries in  $\mathbf{No}_{<\kappa}$ . This order is  $\eta_\kappa$ . Indeed, a cut with fewer than  $\kappa$  words has all its word lengths bounded below  $\kappa$ . The common-prefix search in the preceding proof consequently stops below  $\kappa$ , and [Lemma 7.2](#) supplies the last coordinate while excluding the fewer than  $\kappa$  entries already used. [Proposition 9.2](#) embeds this order into  $\mathbf{No}_{<\kappa}$ ; singleton words embed  $\mathbf{No}_{<\kappa}$  back. When  $2^{<\kappa} = \kappa$ , both orders have cardinality  $\kappa$ , and the ordinary back-and-forth of length  $\kappa$  makes them isomorphic.

A related saturation statement applies to full permutations.

**Proposition 12.1.** *Let  $X$  be an  $\eta_\kappa$ -order of cardinality  $\kappa$ , where  $\kappa$  is regular infinite. Then  $\mathcal{W}_\kappa(X)$  is  $\eta_\kappa$ . Its global and local cofinalities and coinitalities are all exactly  $\kappa$ .*

*Proof.* For a cut  $A < B$  of total cardinality below  $\kappa$ , apply the common-coordinate search to its permutations. If both sides are nonempty, the first-disagreement indices of the pairs in  $A \times B$  have supremum below  $\kappa$ . The search cannot continue sharing a coordinate past this bound; if either active side becomes empty, it stops sooner. The common prefix therefore has length below  $\kappa$ . The  $\eta_\kappa$  property chooses an unused coordinate strictly between the active coordinate sets. Complete the resulting prefix to a  $\kappa$ -permutation: its remaining entries and remaining positions both have cardinality  $\kappa$ , and its remaining interval of positions has order type  $\kappa$ . The completed permutation fills the cut.

Saturation excludes cofinal or coinital subsets of size below  $\kappa$ , both globally and on either side of a point. Conversely, [Theorem 6.1](#) excludes monotone sequences of length  $\kappa^+$ . If one of these segments had no cofinal subset of size at most  $\kappa$ , recursively choosing a point above all earlier choices would produce such an increasing sequence. The decreasing argument is identical. Thus each of the stated characters equals  $\kappa$ .  $\square$

In particular this proposition applies to  $\mathbf{No}_{<\kappa}$  when  $2^{<\kappa} = \kappa$ . The resulting permutation order has cardinality  $2^\kappa$ , so it is substantially larger than its alphabet while retaining the same local characters. It is not  $\eta_{\kappa^+}$ : that stronger cut property would construct an increasing  $\kappa^+$ -sequence, contrary to Theorem 6.1.

## Part III

# Global choice and all class well-orders

## 13 Global choice and well-ordering the surreal class

The distinction between a set of surreal numbers and the entire surreal class changes the existence question. Here GB has the sets of ZF, without a choice axiom, and GC asserts the existence of a class function choosing an element of every nonempty set. A class well-order is a strict linear class relation for which every nonempty available subclass has a least element. Its underlying objects are still sets. The relation itself can be a proper class, and its predecessor classes need not be sets. These are the size distinctions emphasized in the repository's foundations discussion [3].

Throughout this section,  $\mathfrak{W}_{\text{all}}$ ,  $\mathfrak{W}_{\text{sl}}$ , and  $\mathcal{W}(X)$  when  $X$  is a proper class are metanotation for the indicated collections of class relations. We quantify over their members as class variables; we do not assert that those collections are GB classes. When  $X$  is a set,  $\mathcal{W}(X)$  retains its ordinary set meaning from the preceding section. All constructions below are uniform formulas in the stated class parameters. In particular, restricting such a construction to an already given uniformly indexed family produces an ordinary class relation on the indexing domain.

Concretely, a family indexed by a class  $I$  is supplied by one class  $\mathcal{R} \subseteq I \times \mathbf{No} \times \mathbf{No}$ , whose slice at  $i$  defines the relation  $R_i$ . Writing this family does not make  $R_i$  a set or a member of  $I$ : the index  $i$  is a set, and the slice is a class defined with that parameter. This distinction permits uniform families of proper class relations while preserving the usual GB typing rules. No exhaustive indexing family is assumed in this section.

**Theorem 13.1** (Existence and global choice). *Over GB, the following statements are equivalent:*

1. GC holds;
2. there is a class well-order of  $\mathbf{No}$ ;
3. there is a set-like class well-order of  $\mathbf{No}$ ;
4. there is a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ .

Here set-like means that the predecessors of every element form a set.

*Proof.* We give the implication from an arbitrary well-order to global choice in detail. It also explains why set choice need not be assumed in the base theory. Let  $W$  be a class well-order of the sign-sequence presentation of  $\mathbf{No}$ . By ordinary set-valued transfinite recursion, with the fixed class parameter  $W$ , construct a set relation  $w_\alpha$  well-ordering  $V_\alpha$ , for every ordinal  $\alpha$ .

Set  $w_0 = \emptyset$ . Suppose  $w_\beta$  has been constructed. There is a unique ordinal  $\theta$  and a unique order isomorphism

$$e : \theta \longrightarrow (V_\beta, w_\beta).$$

For  $A \subseteq V_\beta$ , let  $s_A$  be the sign sequence of length  $\theta$  whose value at  $\xi$  is  $+$  exactly when  $e(\xi) \in A$ . The map  $A \mapsto s_A$  is a bijection between  $\mathcal{P}(V_\beta)$  and the set of all sign sequences of length  $\theta$ . Define

$$A w_{\beta+1} B \iff s_A W s_B.$$

This is a set relation by separation with a class parameter, and it well-orders  $V_{\beta+1} = \mathcal{P}(V_\beta)$ . No selection of an enumeration is involved: the enumeration of an already specified set well-order is unique.

At a nonzero limit  $\lambda$ , order  $V_\lambda$  first by rank, and within rank  $\gamma$  by the restriction of  $w_{\gamma+1}$ :

$$x w_\lambda y \iff \text{rank}(x) < \text{rank}(y) \text{ or } (\text{rank}(x) = \text{rank}(y) = \gamma \text{ and } x w_{\gamma+1} y).$$

Since  $\lambda$  is a limit, every required  $\gamma + 1$  is below  $\lambda$ . A nonempty subset of  $V_\lambda$  has a least occurring rank; the specified well-order on that rank then supplies its least member. Thus the recursion continues. Its stages are sets, even though their union over all ordinals is a class. This is precisely the ordinary GB recursion theorem, rather than a recursion whose individual values are proper classes.

For a nonempty set  $A$ , every element of  $A$  belongs to  $V_{\text{rank}(A)}$ . Choose the  $w_{\text{rank}(A)}$ -least element of  $A$ . The recursion and this prescription define a single class choice function, establishing GC.

Conversely, global choice implies choice for sets. For each ordinal  $\alpha$ , the set of well-orders of the birthday layer  $S_\alpha = \{-, +\}^\alpha$  is nonempty. Apply the global choice function to this set, and order **No** first by birthday and then by the selected order within the birthday layer. This is a class well-order. Every predecessor class is contained in  $\bigcup_{\beta \leq \alpha} S_\beta$  for some  $\alpha$ , hence is a set. This proves the set-like version directly.

Finally, for any set-like well-order  $R$  of the proper class **No**, assign to  $x$  the ordinal order type of its predecessor set. These ranks form an initial subclass of Ord. That subclass cannot be a set: otherwise the inverse rank map, by class replacement on a set domain, would make **No** a set. It is therefore all of Ord, and the inverse rank map is the required bijection. Conversely, a class bijection from Ord transports its well-order to a set-like well-order of **No**.  $\square$

The connection between surreal enumerations and global choice is discussed by Hamkins [18]; the general equivalences for global choice are collected in [19]. The explicit rank recursion above proves the assertion over the stated choiceless GB base. It does not assert that a global choice class is definable without parameters in the first-order language of set theory. Definability is an additional requirement.

[merge] (3 October 2026, batch 89.) Source 31 (Part XV) shows where the base theory enters. The full-class rank models  $\mathcal{M}_\lambda = (V_\lambda, \mathcal{P}(V_\lambda))$ , for limit  $\lambda > \omega$ , satisfy ZC with Foundation, elementary class comprehension and global choice, but Class Replacement only at strongly inaccessible  $\lambda$  (proposition XV.6.1 and theorem XV.9.3). In every one of them the sign carrier  $S_\lambda$  has a set-like, even birthday-monotone, class well-order (proposition XV.6.2), while a class bijection between Ord and  $S_\lambda$  exists exactly when  $\lambda$  is a cardinal  $\kappa$  with  $2^{<\kappa} = \kappa$  (theorem XV.7.2). At  $\lambda = \omega + \omega$ , for example, clauses 1–3 above hold for  $S_\lambda$  and clause 4 fails (section XV.11): the equivalence uses the class Replacement of GB. Source 31's theorem XV.5.1 localizes global choice over Zermelo set theory instead: selection from countable sets alone, with Separation for the selector, is not conservative over ZC, by Glazer's countermodels through an interface not reviewed here (section XV.5.1).

[merge] *Second proof over GB + AC (source 12).* Source 12 proves the equivalence by coding transitive closures on ordinals; set choice is used only to code each  $\text{TC}(\{x\})$  on an ordinal. Its equivalence includes non-set-like well-orders, as source 11's does. Its subsection on birthday order follows its theorem.

### 13.1 Source 12's route over GB with set choice

**Theorem 13.2** (Choice equivalence). *Over GB plus set-level AC, the following are equivalent:*

- (i) *global choice;*

- (ii) a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ ;
- (iii) a set-like class well-order of  $\mathbf{No}$ ;
- (iv) a class well-order of  $\mathbf{No}$ , not necessarily set-like.

*Proof.* Global choice supplies a set-like global well-order of the universe, and hence of the proper class  $\mathbf{No}$ . A proper set-like well-order has type  $\text{Ord}$ , giving (i) $\Rightarrow$ (iii) $\Rightarrow$ (ii). A bijection in (ii) pulls back ordinal order, giving (iii), and (iii) $\Rightarrow$ (iv) is immediate.

We prove the substantive reverse implication by coding sets. Suppose  $R$  well-orders  $\mathbf{No}$ . Let  $x$  be a nonempty set and let  $T_x = \text{TC}(\{x\})$ ; it contains  $x$  and all its elements. By set choice, there is a least initial ordinal  $\lambda$  equinumerous with  $T_x$ . There is a fixed definable ordinal  $\tau_\lambda$  large enough to code a binary relation on  $\lambda$ , together with one distinguished index, by a binary sequence of length  $\tau_\lambda$ . For example, concatenate a  $\lambda \cdot \lambda$ -long relation table and a  $\lambda$ -long singleton marker.

Consider the *set* of codes for well-founded extensional relations on  $\lambda$  whose Mostowski collapse has range  $T_x$ , and whose marked index collapses to  $x$ . This set is nonempty. Convert 0, 1 to  $-$ ,  $+$ , view the codes as surreals, and take its  $R$ -least member. Decode it, and choose the element of  $x$  represented by the least ordinal index that belongs to the marked node in the coded membership relation.

The result is an element of  $x$ , uniquely determined by  $x$  and the class parameter  $R$ . Elementary class comprehension gives the graph of this choice operation on all nonempty sets. It is a global choice function. Notice that only a set of codes for each  $x$  was minimized: set-likeness of  $R$  was not needed.  $\square$

*Remark 13.3* (The explicit set-choice hypothesis). The converse proof uses set choice to code  $T_x$  on an ordinal. We do not claim the same equivalence over GB with no set-level choice. A purported stronger choice equivalence must address that missing coding step.

### 13.1.1 Birthday is not a canonical global well-order

Ordering first by birthday and then by numerical value does not work. For  $n < \omega$ , let  $s_n$  be the length- $\omega$  sign sequence consisting of  $n$  minuses followed by pluses forever. Then

$$\text{bd}(s_n) = \omega, \quad s_{n+1} < s_n.$$

The whole descending sequence lies in one birthday level. Simplicity itself is well-founded but is only a partial order; two incompatible sign sequences need not be comparable by simplicity.

With global choice one may choose a well-order on every birthday level and concatenate them in birthday order. The result is set-like because all earlier levels, and every initial part of the current level, form a set. The noncanonical choices have not disappeared: they are exactly the kind of information accounted for by [theorem 13.2](#).

*Remark 13.4* ([merge]; source 12's question answered). Dated note, 2 October 2026. Source 12's [remark 13.3](#) declines the choiceless case, and its research question on the exact weak-choice strength ([remark 113.15](#)) asks which principle is equivalent to a class well-order of the sign-sequence surreals over GB without set choice. Source 11's [theorem 13.1](#) answers it: global choice itself. The “missing coding step” that [remark 13.3](#) names is avoided, not supplied: the well-orders  $w_\alpha$  of  $V_\alpha$  are built by set-valued recursion from the given well-order of the sign sequences of length  $\theta = \text{otp}(V_\beta, w_\beta)$ , a subset  $A \subseteq V_\beta$  being coded by the sign sequence  $s_A$  of length exactly  $\theta$ , so no ordinal coding of a transitive closure has to be chosen. The proof thus produces a uniformly defined sequence of well-orders of the sets  $V_\alpha$ , in particular of the power sets of ordinals, which is the comparison the question suggests. The same mechanism, at the level of sets, is the ordinal-graph coding of the birthday-cutoff report

(`hset:thm:choice`, whose range over ZF is the class of sets with well-orderable transitive closure) [4]; that theorem concerns a different statement and is unchanged. Hamkins’s question whether surreal universality implies global choice [21] is not affected. (Corrected in place on 3 October 2026, following the Hilbert’s-tenth programme’s review `Computability/HilbertTenthProblem/Papers/research-wip/native-stream-queue/review_surreal_synthesis_0be9b9134.md` (commit 280583d2f): this note had called the sequence “coherent”. The orders  $w_\alpha$  are uniformly defined, but a later one need not restrict to an earlier one. If  $W$  puts  $-$  before  $+$  among the sign sequences of length one and  $+-$  before  $--$  among those of length two, then  $w_2$  puts  $\emptyset$  before  $\{\emptyset\}$  (codes  $-$  and  $+$ ), while  $w_3$  puts  $\{\emptyset\}$  before  $\emptyset$  (codes  $+-$  and  $--$ ). The proof of [theorem 13.1](#) needs only the uniform definition: it selects the  $w_{\text{rank}(A)}$ -least element of each nonempty set  $A$ . Ordering all sets by rank and then, within rank  $\gamma$ , by  $w_{\gamma+1}$ , as at the limit stages, does give a class well-order whose restrictions to the sets  $V_\alpha$  cohere; the proof does not use it.)

[merge] Dated note, 4 October 2026 (batch 89): a set-level, choiceless calibration. Part VII of the birthday-cutoff report [4] (batch-89 manuscript 04; AI-assisted, unrefereed, not formalized) proves over ZF that a set injects into **No** iff it injects into the power set of an ordinal (its Theorem 42.1, `hset:kw:thm:coding`), and that embedding the free real rational-function fields on all sets into **No** is exactly the first Kinna–Wagner principle, strictly weaker than choice (its Theorem 43.5, `hset:kw:thm:equivalences`). For a *prescribed* order it proves only that well-orderable linear orders embed (`hset:kw:prop:wellordered`), characterizes order embeddability by convex resolutions (`hset:kw:thm:resolution`), and exhibits, in a ZFA permutation model, an ordered field all of whose finitely generated coordinate subfields embed but which has no field homomorphism into the internal **No** (`hset:kw:thm:orderedcounter`). Hamkins’s question whether surreal universality implies global choice [21], about the class **No** over GB, is therefore still not affected.

[merge] *Third proof over GB + AC, for set-like orders (source 09)*. Source 09’s [proposition 13.6](#) is the last paragraph of the proof of [theorem 13.1](#) (and source 08’s [note 5.12](#)); its [proposition 13.7](#) recovers global choice from a class bijection  $\text{Ord} \rightarrow \mathbf{No}$  through a definable class surjection of **No** onto  $V$ , using set choice only to prove surjectivity. By [theorem 13.1](#) that hypothesis is unnecessary ([remark 13.4](#)). Its last subsection leads to source 08’s relation codes ([section 17](#)).

## 13.2 Source 09: global well-orders and global enumerations

**Definition 13.5.** A class well-order  $\prec$  on a class  $D$  is *set-like* when the predecessors of every  $d \in D$  form a set. We take “class well-order” to mean that every nonempty subclass has a least element.

**Proposition 13.6.** *Set-like class well-orders on **No** correspond bijectively to class bijections  $E : \text{Ord} \rightarrow \mathbf{No}$ .*

*Proof.* Given  $E$ , transfer the ordinal order to its values. Every predecessor set is the image of a set ordinal, so this order is set-like and is a class well-order.

Conversely, for a set-like well-order, assign to  $x$  the ordinal order type of its set of predecessors. This assignment is an order isomorphism onto a downward-closed class of ordinals. Its range cannot be a set: otherwise its inverse, a class function on a set, would have set range **No**. A proper downward-closed class of ordinals is all of  $\text{Ord}$ . Invert the assignment.  $\square$

Global choice supplies at least one such bijection; fix one and call it  $b$ . None of these enumerations is increasing in the numerical order on **No**. The numerical order is dense and has descending sequences, so it is not a well-order.

**Proposition 13.7** (The baseline already entails global choice). *Over GB with ordinary choice for sets, the following are equivalent: global choice; a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ ; and a set-like class well-order of  $\mathbf{No}$ .*

*Proof.* Global choice gives the bijection as explained in [section 5.5](#), and [proposition 13.6](#) identifies the last two conditions without using global choice. It remains to recover global choice from  $b$ .

There is an elementary definable class surjection  $d : \mathbf{No} \rightarrow V$ , using only ordinary set choice to prove surjectivity. Here is the coding argument. A set code consists of a nonzero ordinal  $\gamma$ , a well-founded extensional relation  $R \subseteq \gamma \times \gamma$ , and a distinguished root  $r < \gamma$ . Its decoded value is the image of  $r$  under the Mostowski collapse of  $(\gamma, R)$ . Every set  $x$  has such a code: well-order a transitive set containing  $x$ , transport its membership relation to an ordinal, and mark the index corresponding to  $x$ .

These triples have a uniform injective encoding by sign sequences. Write  $\gamma$  plus signs, then one minus sign as a header. Append a binary word of length  $\gamma \cdot \gamma$  recording  $R$ , with  $(u, v)$  assigned to position  $\gamma \cdot v + u$ , and then a word of length  $\gamma$  whose unique plus sign marks  $r$ . The first minus sign recovers  $\gamma$ ; the prescribed block lengths recover  $R$  and  $r$ . Decode valid codes by their set Mostowski collapses and send invalid codes to  $\emptyset$ . Everything in this decoder concerns set-sized relations, so it defines a class function by elementary comprehension, not a class truth predicate.

The composite  $d \circ b : \text{Ord} \rightarrow V$  is a class surjection. Assign to each set  $x$  the least ordinal  $\alpha$  with  $d(b(\alpha)) = x$ . These indices define a set-like global well-order of  $V$ : predecessors of  $x$  occur among the set of decoded values before its index. Taking the least member of each nonempty set in that well-order gives a global choice function.  $\square$

Thus existence of the global baseline is not a choice-free substitute for global choice. The equivalence is a standard well-founded-coding argument, included to make the axiomatic cost explicit. It says nothing similar about merely well-ordering one birthday-bounded set.

### 13.2.1 Why non-set-like global well-orders are different

Not every class well-order is set-like. For example,  $\text{Ord} + 1$  and  $\text{Ord} + \text{Ord}$  are class well-orders; the final point in the first example, and every point in the second block of the second example, has a proper class of predecessors. Global choice permits transfer of these orders to the underlying class  $\mathbf{No}$ .

Such orders have no exhaustive enumeration by ordinal positions alone. They are deliberately excluded from  $\mathfrak{W}_{\text{sl}}$ . Even two presentations of orders with a full first block of type  $\text{Ord}$  can agree throughout that block and differ later; there is then no ordinal position at which their full presentations first differ.

There is a different, fully explicit way to compare all class well-order *relations*, including non-set-like ones: fix a class bijection  $c : \text{Ord} \rightarrow \mathbf{No} \times \mathbf{No}$  and compare the binary characteristic classes of the relations at their first differing  $c$ -coordinate. This is a legitimate comparison formula on class variables. However, it depends on the auxiliary coordinate enumeration and is not the exhaustive-enumeration lexicographic order analyzed here. Its collection of objects remains of the same higher logical level.

[merge] The relation-code comparison of source 09's last paragraph is source 08's [proposition 17.1](#), which computes its equimorphism type. Source 09's research direction on it ([section 113.3](#)) asks for more: a dense set-coded core and the representation of its cuts.

## 14 Lexicographic comparison without class ordinals

The set-sized enumeration method studied for the real numbers [1] suggests comparing the first unequal labels. Arbitrary class well-orders require a formulation that also permits a proper class of common earlier labels. No ordinal enumeration of that entire common prefix is needed.

For a strict class well-order  $R$  on a fixed class  $X$ , write

$$P_R(x) = \{y \in X : yRx\}.$$

A common labeled prefix of  $R, S$  is a subclass initial in both orders on which their restrictions agree. The adjective labeled matters: agreement here is equality of the actual elements and relations, rather than the existence of an abstract order isomorphism.

**Lemma 14.1** (Unique first disagreement). *If  $R \neq S$  are class well-orders of the same class  $X$ , there are unique distinct  $a, b \in X$  such that*

$$P_R(a) = P_S(b) = C, \quad R \upharpoonright C = S \upharpoonright C.$$

*The subclass  $C$  is their maximal common labeled prefix.*

*Proof.* The class  $D = \{x : P_R(x) \neq P_S(x)\}$  is nonempty, since predecessor classes determine a strict order. Let  $a$  be its  $R$ -least element and put  $C = P_R(a)$ . For every  $y \in C$ ,  $P_R(y) = P_S(y)$ . In particular,  $ySa$ : otherwise  $aSy$ , which would imply  $aRy$ , contradicting  $yRa$ . Thus  $C \subseteq P_S(a)$ . Also, if  $zSy$  with  $y \in C$ , then  $zRy$ , so  $z \in C$ . Therefore  $C$  is  $S$ -initial as well as  $R$ -initial, and the restrictions of the orders to it agree.

The inclusion  $C \subseteq P_S(a)$  is strict because  $a \in D$ . Let  $b$  be the  $S$ -least element outside  $C$ . The strict inclusion shows that  $bSa$ , hence  $b \neq a$ . Initiality and the minimality of  $b$  give  $P_S(b) = C$ .

For uniqueness, suppose  $a', b', C'$  satisfy the displayed conditions with  $a' \neq b'$ . Every element of  $C'$  has identical predecessor classes in the two orders. But  $b'Sa'$ , so the predecessor classes of  $a'$  differ. Consequently  $a'$  is exactly the  $R$ -least element of  $D$ ; hence  $a' = a$ ,  $C' = C$ , and  $b' = b$ . Any common prefix properly extending  $C$  would have to include incompatible next labels, so  $C$  is maximal.  $\square$

Fix now a native linear order  $<_X$  on the labels. For distinct  $R, S$ , define  $R <_{\text{lex}} S$  when the labels supplied by Lemma 14.1 satisfy  $a <_X b$ .

**Theorem 14.2** (Raw lexicographic order). *This rule is a strict linear order on the class well-orders of  $X$ , understood as a definable relation on class variables. In particular it defines  $\mathfrak{W}_{\text{all}}$  for  $X = \mathbf{No}$  with its native numerical order.*

*Proof.* Existence and uniqueness of first disagreement give totality and asymmetry; the relation is irreflexive by definition. To verify transitivity, suppose  $R <_{\text{lex}} S <_{\text{lex}} T$ . Write  $(a, b)$  for the first unequal labels of  $R, S$ , and  $(c, d)$  for those of  $S, T$ . Their common prefixes are  $C = P_S(b)$  and  $D = P_S(c)$ , respectively, and  $a <_X b$ ,  $c <_X d$ .

If  $bSc$ , then  $C \subsetneq D$ . The orders  $S, T$  agree through the label  $b$ , so the first unequal labels of  $R, T$  are  $a, b$ , with common prefix  $C$ . Thus  $R <_{\text{lex}} T$ . If  $cSb$ , then  $D \subsetneq C$ ; now  $R, S$  agree through  $c$ , and the first unequal labels of  $R, T$  are  $c, d$ , again giving the conclusion. If  $b = c$ , the prefixes coincide and the next labels of  $R, T$  are  $a, d$ . Since  $a <_X b = c <_X d$ , the conclusion follows in this case as well.  $\square$

This proof compares labeled relations directly. It does not compare arbitrary class well-orders up to isomorphism, and makes no appeal to a collection of class ordinal types. The defining conditions use only set quantifiers with the given class relations as parameters: equality of predecessor classes means a universal statement about their set elements.

For example, the predicate that  $a, b$  are the first unequal labels can be written without quantifying over a common-prefix class:

$$\begin{aligned} a \neq b \quad \wedge \quad & \forall z (zRa \leftrightarrow zSb) \\ & \wedge \quad \forall x \forall y ((xRa \wedge yRa) \longrightarrow (xRy \leftrightarrow xSy)). \end{aligned}$$

Adding  $a <_X b$  and existentially quantifying the two labels gives the lexicographic predicate. Consequently its restriction to the indexed family  $\mathcal{R}$  described above is a GB class of pairs of indices. If the indexing contains duplicate orders, this relation orders the distinct relations, and becomes a strict linear order on indices whenever the indexing is injective. Passing instead to abstract isomorphism types would discard exactly the label information on which the construction depends.

**Proposition 14.3** (Convex prefix cones). *Fix a well-ordered subclass  $(C, P)$  of  $X$ . The collection of all class well-orders of  $X$  extending  $(C, P)$  as an initial labeled segment is convex in the raw lexicographic order.*

*Proof.* Suppose  $R, S$  extend the prefix and  $R <_{\text{lex}} T <_{\text{lex}} S$ . Let  $D$  be the first-disagreement prefix of  $R, T$ . The subclasses  $C, D$  are initial in  $R$ , and therefore inclusion-comparable. If  $C \subseteq D$ , then  $T$  extends  $(C, P)$ , as required. If  $D \subsetneq C$ , the next  $R$ -label lies in  $C$ ; it is also the next  $S$ -label after  $D$ . Accordingly,  $T$  compares with  $R$  and  $S$  in the same direction, contradicting the strict inequalities. This reasoning permits  $C$  and  $D$  to be proper classes.  $\square$

[merge] *Second route (source 12): the largest common labelled prefix.* Source 12's Section 3 proves lemma 14.1 and theorem 14.2 differently. Instead of the class  $D$  of points whose predecessor classes differ, it defines the largest common labelled prefix  $C(R, S)$  by an elementary formula and proves directly that it is initial in both orders and contains every common labelled initial segment. Source 11's shipped check compares its predecessor rule with finite lexicographic order on all 266,272 pairs of permutations of at most six points (data/11-raw-orders-finite\_checks\_results.txt); source 12's checks the common-prefix formula on 15,017 finite pairs (data/12-singular-finite\_checks.json).

## 14.1 Source 12's route: the largest common labelled prefix

The central observation is that comparing two *labelled* well-orders is easier than comparing arbitrary abstract class order types. Fix a class  $X$  equipped with an ambient strict linear order  $<$ , and let  $R, S$  be class well-orders of the same carrier  $X$ .

**Definition 14.4** (Common labelled prefix). Define  $C(R, S) \subseteq X$  by putting  $x \in C(R, S)$  if

$$\begin{aligned} \text{Pred}_R(x) &= \text{Pred}_S(x), \\ \forall u, v \in \text{Pred}_R(x), \quad & uRv \iff uSv. \end{aligned}$$

Equality of the predecessor classes is expanded as a quantification over sets  $u \in X$ . Thus this is an elementary formula with class parameters  $R, S$ ; it is not a quantification over all possible common prefixes.

**Lemma 14.5** (Maximal-prefix lemma).  *$C(R, S)$  is an initial segment of both well-orders, their restrictions to it agree, and it contains every common labelled initial segment. If  $R \neq S$ , it is proper, and the least elements*

$$a = \min_R(X \setminus C(R, S)), \quad b = \min_S(X \setminus C(R, S))$$

*exist and are distinct.*

*Proof.* Suppose  $x \in C(R, S)$  and  $yRx$ . Equality of the predecessor classes puts  $y$  before  $x$  in  $S$  as well. For  $zRy$ , transitivity gives  $zRx$ ; agreement of  $R, S$  below  $x$  then gives  $zSy$ . Conversely,  $zSy$  implies  $zSx$ , hence  $zRx$ , and agreement below  $x$  yields  $zRy$ . The orders agree below  $y$  because they agree below  $x$ . Therefore  $y \in C(R, S)$ . The symmetric argument proves initiality in  $S$ .

If  $u, v \in C(R, S)$  and  $uRv$ , equality of the predecessor classes of  $v$  gives  $uSv$ . Thus the restrictions agree. If  $D$  is any common labelled initial segment and  $x \in D$ , both predecessor classes of  $x$  lie in  $D$  and agree, as do the restricted relations. Hence  $D \subseteq C(R, S)$ . If  $C(R, S) = X$ , equality of every predecessor class implies  $R = S$ .

For  $R \neq S$ , class well-foundedness supplies  $a, b$ . By initiality and minimality,  $\text{Pred}_R(a) = C(R, S)$  and  $\text{Pred}_S(b) = C(R, S)$ . If  $a = b$ , these predecessor classes agree and the two relations agree on them. The defining formula would put  $a$  in  $C(R, S)$ , a contradiction.  $\square$

**Definition 14.6** (Full lexicographic comparison). For distinct  $R, S$ , put  $R <_{\text{lex}} S$  precisely when  $a < b$ , with  $a, b$  from lemma 14.5. Identical relations are equal in this order.

**Theorem 14.7** (Full class lexicographic order). *In GBC, the preceding comparison is a strict linear ordering of the predicate of all class well-orders of a fixed linearly ordered class  $X$ . Its definition uses only elementary class comprehension. In particular, ETR and the comparability of abstract class well-order types are not required.*

*Proof.* Irreflexivity and trichotomy follow from the maximal-prefix lemma and trichotomy in  $X$ . For transitivity suppose  $R <_{\text{lex}} S <_{\text{lex}} T$ . The classes  $C(R, S)$  and  $C(S, T)$  are initial segments of the same well-order  $S$ , so they are comparable by inclusion.

If  $C(R, S)$  is a proper subset of  $C(S, T)$ , the first  $S$ -element  $b$  after  $C(R, S)$  belongs to  $C(S, T)$ . Thus  $T$  agrees with  $S$  through that element. The first disagreement of  $R, T$  is exactly the earlier  $R, S$  disagreement, with the same two labels  $a < b$ . Consequently  $R <_{\text{lex}} T$ . The opposite proper-inclusion case uses the earlier  $S, T$  disagreement and is identical in form.

If the two common prefixes are equal to  $C$ , let  $a, b, c$  be the first labels after  $C$  in  $R, S, T$ . The hypotheses give  $a < b < c$ . Hence  $R, T$  also first disagree after  $C$ , and  $R <_{\text{lex}} T$ . Every construction of  $C$ , and every assertion about its next elements, expands into set quantifiers with the given class relations as parameters.  $\square$

*Remark 14.8* (Why this does not prove class order-type comparability). In general one asks whether two arbitrary class well-orders admit an initial-segment isomorphism. ETR is a sufficient hypothesis for that principle [27, Theorem 6]. Here no such isomorphism is constructed. Only their *identical labelled* portions are compared. As soon as the labels disagree, the fixed ambient order decides the answer. Confusing these two tasks would impose an unnecessary stronger axiom.

**Example 14.9** (A disagreement after every ordinary ordinal). Fix  $a < b$  in **No**. Well-order **No**  $\setminus \{a, b\}$  in type Ord. Append first  $a, b$ , and in a second order append  $b, a$ . The orders agree throughout their initial Ord-block and differ only after it. No ordinary ordinal indexes that first disagreement, but theorem 14.7 compares them immediately: their common labelled prefix is **No**  $\setminus \{a, b\}$ .

**Corollary 14.10** (Agreement with enumeration lexicography). *For set-sized exhaustive ordinal enumerations, and for class bijections  $\text{Ord} \rightarrow X$ , the common-prefix definition agrees with first-difference lexicography.*

*Proof.* Before the first unequal entry, exactly the same labels occur in exactly the same order. Their ranges form the common labelled initial segment. No later label can belong to that segment by initiality and the distinct next labels. In the  $\text{Ord}$  case the disagreement is a nonempty class of ordinals; restricting it below any one witness gives its least member.  $\square$

[merge] Source 12’s [remark 14.8](#) is source 11’s remark after [theorem 14.2](#) and in [section 20](#): comparability of abstract class well-orders by initial-segment isomorphisms follows from ETR [27], and neither labelled comparison needs it. Its [example 14.9](#) is source 11’s [example 16.3](#), and its [corollary 14.10](#) is the corresponding sentence after [definition 19.1](#).

## 15 The canonical initial set-like part

Every class well-order of  $\mathbf{No}$  has a canonical initial segment of type  $\text{Ord}$ , even when its entire order is not set-like. This gives a structural description of all well-orders using ordinary class functions.

**Theorem 15.1** (Canonical initial part). *For  $R \in \mathfrak{W}_{\text{all}}$ , let*

$$I_R = \{x \in \mathbf{No} : P_R(x) \text{ is a set}\}.$$

*Then  $I_R$  is a proper initial subclass of the domain or is the entire domain; in either case it is a proper class. Its induced order is set-like and has a unique order enumeration*

$$F_R : \text{Ord} \longrightarrow I_R.$$

*The order  $R$  is the concatenation of this enumeration with its induced well-order on  $\mathbf{No} \setminus I_R$ .*

*Proof.* If  $x \in I_R$  and  $yRx$ , then  $P_R(y) \subseteq P_R(x)$ , so separation makes  $P_R(y)$  a set. Thus  $I_R$  is initial. Suppose it were a set. Since  $\mathbf{No}$  is proper, there would be an  $R$ -least element  $x$  outside it. Every predecessor of  $x$  would then belong to  $I_R$ , and initiality would place every member of  $I_R$  before  $x$ . Hence  $P_R(x) = I_R$ , a contradiction.

The induced order on  $I_R$  has the same predecessor sets as  $R$ . The ordinal-rank map therefore identifies it with an initial subclass of  $\text{Ord}$ . As in [Theorem 13.1](#), a set-sized range would make  $I_R$  a set by replacement. Its range is consequently all of  $\text{Ord}$ . The inverse map is unique, and initiality gives the asserted concatenation.  $\square$

**Example 15.2** (Two proper blocks). Under GBC, fix  $e : \text{Ord} \rightarrow \mathbf{No}$  bijective. The disjoint classes  $A = \{e(2\alpha) : \alpha \in \text{Ord}\}$  and  $B = \{e(2\alpha + 1) : \alpha \in \text{Ord}\}$  partition  $\mathbf{No}$ , where the product is ordinal multiplication  $2 \cdot \alpha$ . Order each block by its displayed ordinal index and place all of  $A$  before all of  $B$ . The resulting well-order has class type  $\text{Ord} + \text{Ord}$ . Its canonical initial part is exactly  $A$ : a point of  $B$  has the whole proper class  $A$  among its predecessors. Hence an  $\text{Ord}$ -enumeration of the canonical part is not, in general, an enumeration of the entire well-order. Both blocks consist of ordinary surreal labels; their size affects their positions in the chosen well-order, not the status of individual surreal numbers as sets.

Let  $\mathfrak{J}$  denote the metacollection of injective class functions  $F : \text{Ord} \rightarrow \mathbf{No}$ , with lexicographic comparison at their first ordinal of disagreement. Such a first disagreement exists for distinct functions: after choosing any witness, minimize within the set of earlier ordinals. Put  $Y_F = \mathbf{No} \setminus \text{ran}(F)$ .

**Proposition 15.3** (Convex fibers). *Assume GBC. Every  $F \in \mathfrak{J}$  occurs as  $F_R$  for some  $R \in \mathfrak{W}_{\text{all}}$ . The fiber over  $F$  is a convex copy of  $\mathcal{W}(Y_F)$ . Distinct fibers are ordered by the first unequal values of their functions  $F$ .*

*Proof.* The range of an injection from Ord is proper, since a set could not contain an injective image of all ordinals. Choose a well-order  $Q$  of  $Y_F$ , using the restriction of any fixed global well-order, and put the sequence  $F$  before  $Q$ . Each  $F(\alpha)$  has exactly the set  $F^{\alpha}$  of predecessors. Each residual point, however, has the proper class  $\text{ran}(F)$  among its predecessors. Thus the resulting order has canonical function exactly  $F$ .

All orders with that function extend the same initial labeled order on  $\text{ran}(F)$ , and conversely every extension has that canonical function. Proposition 14.3 proves convexity. Restriction to  $Y_F$  and concatenation with  $F$  are inverse operations; first disagreement inside the residual orders proves that they preserve lexicographic comparison. Finally, if  $F \neq G$ , their first ordinal disagreement occurs before either residual order begins. It therefore determines the comparison of every member of one fiber with every member of the other.  $\square$

We may summarize this result as the lexicographic-sum description

$$\mathfrak{W}_{\text{all}} \cong \sum_{F \in (\mathfrak{J}, <_{\text{lex}})} \mathcal{W}(Y_F).$$

This is uniform metanotation for the preceding theorem, not the assertion that its indexing hyperclass or all its fibers have been collected into a GB class. The set-like fragment  $\mathfrak{W}_{\text{sl}}$  consists exactly of the fibers with  $Y_F = \emptyset$ , or equivalently the exhaustive enumerations. For finite  $Y_F$  of size  $m$ , its fiber is a convex block of  $m!$  orders, with the usual lexicographic order on permutations.

*Remark 15.4* (Singleton fibers and iteration). A singleton fiber need not be set-like. If  $F$  omits exactly one surreal  $z$ , its unique completion puts  $z$  after the entire Ord-sequence; it has class order type  $\text{Ord} + 1$ . Conversely, every exhaustive  $F$  gives a singleton set-like fiber. Extracting the initial part once also does not justify transfinite iteration of this operation through class-sized tails. Such an iteration would require a separate specification of its indexing order, its objects, and its recursion principle; none is asserted here.

## 16 All jumps arise from finite residual permutations

The full order has jumps despite the extreme density of the native surreal line. A proper common prefix can already have used every label between the two labels at which comparison is decided.

**Lemma 16.1** (Extreme enumerations). *For a class  $Z$  with a native linear order, a class well-order is lexicographically greatest among all well-orders of  $Z$  exactly when it is the native reverse order. It is lexicographically least exactly when it is the native forward order.*

*Proof.* If a well-order places  $y$  before  $z$  with  $y < z$ , transpose these two labels throughout the order. The result is another class well-order. Its first changed label is  $z$  in place of  $y$ , so it is lexicographically greater. A greatest order must therefore be strictly decreasing in the native order, which determines the entire relation. Conversely, in the reverse native order the next label at any first disagreement is the greatest remaining label, so every different well-order is smaller. The least-order assertion follows by reversing the native order. The argument includes empty and singleton domains.  $\square$

The lemma is an existence criterion as well as a characterization: a greatest enumeration exists only when the native reverse order itself is well-founded. It is therefore not permissible to use “list

the remaining labels in decreasing order” as an unconditional completion rule. For example, on a copy of the natural numbers with its usual native order, the increasing enumeration is least, but there is no greatest well-order. Finite residual domains have both extrema, and the adjacency theorem shows that precisely such domains can support a jump after a common prefix.

**Theorem 16.2** (Exact adjacency criterion). *Let  $R <_{\text{lex}} S$  be class well-orders of  $X$ . Let  $C$  be their first-disagreement prefix, let  $a < b$  be their respective next labels, and put  $Y = X \setminus C$ . They are adjacent if and only if all three conditions hold:*

1. *there is no  $y \in Y$  with  $a < y < b$ ;*
2. *the  $R$ -tail on  $Y \setminus \{a\}$  is the native reverse order;*
3. *the  $S$ -tail on  $Y \setminus \{b\}$  is the native forward order.*

*These conditions force  $Y$  to be finite. Thus adjacency is exactly ordinary finite permutation adjacency after a possibly proper class common prefix.*

*Proof.* Suppose first that the pair is adjacent. A label  $y \in Y$  strictly between  $a, b$  could be placed immediately after  $C$ , followed by the restriction of  $R$  to the other remaining labels. This would give a well-order strictly between  $R, S$ ; thus condition 1 holds.

Any lexicographically greater replacement of the  $R$ -tail after  $a$  would also give an intermediate order: its next label after  $C$  would still be  $a < b$ . Hence this tail is greatest, and Lemma 16.1 gives condition 2. A lexicographically smaller replacement of the  $S$ -tail after  $b$  similarly gives condition 3. These modifications use restrictions and finite transpositions of existing class relations; they require no new choice principle.

The overlap  $Z = Y \setminus \{a, b\}$  is now well-ordered both forward and backward in the native order. If  $Z$  were not finite, repeatedly take its least element after deleting the finitely many already selected. Ordinary recursion on  $\omega$  and replacement produce a set of strictly increasing selected elements. That set has no greatest member, contradicting reverse well-ordering. Thus  $Z$ , and hence  $Y$ , is finite. This argument does not assume that  $Z$  was a set in advance.

Conversely, suppose the three conditions hold and let  $R <_{\text{lex}} T <_{\text{lex}} S$ . Convexity of the prefix cone forces  $T$  to extend  $C$ . Let  $t \in Y$  be its next label. A label below  $a$  makes  $T < R$ , and a label above  $b$  makes  $T > S$ ; condition 1 excludes intermediate labels. If  $t = a$ , its remaining tail cannot exceed the greatest tail of  $R$ , so  $T \leq R$ . If  $t = b$ , its tail cannot precede the least tail of  $S$ , so  $T \geq S$ . Every possibility contradicts strict betweenness.  $\square$

**Example 16.3** (An adjacent pair of type  $\text{Ord} + 2$ ). Assume GBC, choose surreal labels  $a < b$ , and give  $C = \mathbf{No} \setminus \{a, b\}$  a set-like well-order  $P$ . Consider

$$R = P + (a, b), \quad S = P + (b, a).$$

Each has class order type  $\text{Ord} + 2$ , and  $R, S$  are adjacent. They have the same canonical initial enumeration, and constitute its entire two-point fiber. The notation  $\text{Ord} + 2$  describes a class concatenation; it is not a set ordinal.

For  $X = \mathbf{No}$ , every adjacent pair has a cofinite, hence proper class, common prefix. Neither endpoint can be set-like. Moreover, if two set-like orders are given, their common prefix is a set. The deletion property of the surreal line leaves an unused label strictly between their next labels, and that set prefix can be completed to a set-like well-order. For completeness, this extension does not require an additional recursion principle. Retain the prescribed set prefix, put the new intermediate label next, and then append the restriction of a fixed set-like global well-order of  $\mathbf{No}$  to the unused labels. A predecessor class in the appended part is contained in the union of the prescribed set

prefix and a predecessor set of the fixed order, together with the one inserted label. It is therefore a set. Every label occurs once, and the concatenation is a well-order, so the completion belongs to  $\mathfrak{W}_{\text{sl}}$ . Thus the induced order  $\mathfrak{W}_{\text{sl}}$  is dense, while  $\mathfrak{W}_{\text{all}}$  has the finite terminal blocks classified above. Allowing all well-orders changes the local order structure in a concrete and unavoidable way.

[merge] *Second route (source 12): residual decomposition and adjacency.* Source 12's Section 8 proves [theorem 16.2](#) in the form “the residual class is finite and the residual permutations are consecutive”; the two criteria are equivalent, since a tail that is both well-ordered and reverse well-ordered is finite. Its [proposition 16.5](#) is the description of one prefix cone given by [propositions 14.3](#) and [15.3](#). Its [corollary 16.7](#) adds that interior points of the finite blocks with  $n \geq 3$  are isolated in the order topology and that the set-like suborder is not dense in the full order, and its last paragraph adds the order-reversing involution induced by negation.

### 16.1 Source 12's route: unrestricted class well-orders and finite-tail geometry

The full order  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  contains  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  as an ordered subcollection, but it is not dense. The effect is not a failure of density of the surreal alphabet; it is exhaustion of almost all labels by a proper-class prefix.

**Definition 16.4** (A prefix cylinder in the full order). Let  $C \subsetneq X$  carry a fixed well-order  $P$ . Consider all class well-orders of  $X$  that have  $(C, P)$  as a labelled initial segment. Write this cylinder as  $[P]_X$  and put  $D = X \setminus C$ .

**Proposition 16.5** (Residual-order decomposition).  *$[P]_X$  is convex and is order-isomorphic to the lexicographic order of all well-orders of the residual carrier  $D$ , with its inherited ambient order. If  $D$  is a set, this is the ordinary set order  $\mathcal{W}(D)$ , with the same notation extended to finite carriers. If  $|D| = n < \omega$ , the cylinder has exactly  $n!$  elements.*

*Proof.* Restriction to  $D$  and ordered concatenation with  $P$  are inverse operations. Concatenation of two class well-orders is a class well-order: a nonempty subclass has its minimum in the first part if it meets that part, and otherwise in the second. The maximal common prefix after  $P$  is exactly the common prefix of the tails, so comparisons are preserved.

If a third order differs before completing  $P$ , its first discrepancy with every extension of  $P$  is the same and places it on the same side of all of them. This proves convexity. The last assertion counts permutations of a finite carrier.  $\square$

**Theorem 16.6** (Exact adjacency criterion). *Let  $R <_{\text{lex}} S$  be two class well-orders of  $X$ , and let  $C = C(R, S)$ ,  $D = X \setminus C$ . They are adjacent in the full order if and only if  $D$  is finite and their residual permutations are consecutive in the ordinary finite lexicographic order.*

*Proof.* Let  $a < b$  be their first residual labels. If some  $d \in D$  satisfies  $a < d < b$ , begin the residual order with  $d$  and well-order the remaining labels by a restriction of  $R$ . This gives an order strictly between. So an adjacent pair can have no such  $d$ .

If the tail of  $R$  after  $a$  has two labels  $u$  before  $v$  with  $u < v$  in the ambient order, interchange the labels  $u, v$  at their two positions. The new well-order is larger than  $R$ , and still smaller than  $S$  because its first residual label remains  $a$ . Thus adjacency forces the  $R$  tail to be numerically decreasing. Dually, the tail of  $S$  after  $b$  must be numerically increasing.

On  $D \setminus \{a, b\}$ , both the ambient numerical order and its reverse are therefore well-orders. Such a carrier is finite: an infinite well-order contains an increasing  $\omega$ -sequence, contradicting well-foundedness of its reverse. Hence  $D$  is finite.

Conversely, if  $D$  is finite, convexity in [proposition 16.5](#) says that every order between  $R, S$  must be another permutation of  $D$  after  $C$ . There is none exactly when the two permutations are consecutive.  $\square$

**Corollary 16.7** (Proper-class prefixes are responsible). *Adjacent pairs in  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  share a proper-class prefix. There are convex blocks of every factorial size  $n!$ . For  $n \geq 3$ , interior elements of such blocks are isolated in the order topology. The set-like suborder is not dense in the full order.*

*Proof.* A set prefix cannot exhaust all but finitely many surreals. Conversely, well-order  $\mathbf{No} \setminus D$  in type Ord for any finite  $D$ , and append all its permutations. For  $|D| \geq 3$ , choose two nonconsecutive permutations in the resulting finite convex block. Their nonempty open interval contains only orders with a proper-class predecessor segment, so it contains no set-like order.  $\square$

The full order still has no endpoints and no set-indexed cofinal or cointial family, by the first-entry argument of [note 19.28](#). It contains every class linear order, by [note 19.21](#). But neither global density nor interpolation for all set-indexed cuts survives: an adjacent pair already gives a two-sided cut that cannot be filled.

Pointwise surreal negation gives an order-reversing involution on both global orders: transport a well-order by the bijection  $x \mapsto -x$ . This preserves enumeration type and set-likeness while reversing the ambient comparison of the first unequal labels.

[merge] Source 08’s Section 14 proposes two alternatives to the labelled comparison of [section 14](#): a fixed larger index order, and relation-code lexicography.

## 17 Non-set-like well-orders and alternative coding (source 08)

The restriction to set-like well-orders is substantive, not cosmetic. Choose distinct surreals  $a < c$ , and enumerate  $\mathbf{No} \setminus \{a, c\}$  by Ord. Append  $a, c$  at the end in one well-order and  $c, a$  in another. These are legitimate class well-orders of type Ord + 2, but they are not set-like: the final points have a proper class of predecessors.

The two enumerations agree at every *set ordinal* position. Their first disagreement occurs only after a proper-class initial segment, at the first appended point. Thus ([S08.7](#)), whose index is Ord, does not compare them. Treating “Ord” as one more set ordinal would conceal precisely the error.

### 17.1 A fixed larger index order

One can fix a class well-order  $J$ , such as Ord + 2, and compare class bijections  $J \rightarrow \mathbf{No}$  at their first difference, using the order on  $J$  and the numerical order on  $\mathbf{No}$ . For the indicated concrete  $J$  this is entirely rigorous. For a general  $J$ , the existence of least members for the disagreement subclasses must be part of the specified class well-order property.

What does not follow is a canonical single comparison for all bijections having all possible non-set-like class well-order domains. Unlike set ordinals, the domains do not automatically come with a common set-ordinal coordinate system. A comparison theorem for all such domains, or a recursive alignment of their proper-class initial segments, needs an explicit formulation and an axiomatic audit. We do not assume an unproved class analogue of every set well-order theorem.

### 17.2 Relation-code lexicography works, but changes the question

There is an alternative that does not align enumeration domains. Fix a class bijection

$$q : \text{Ord} \longrightarrow \mathbf{No} \times \mathbf{No}.$$

Encode each strict class relation  $R$  on  $\mathbf{No}$  by  $\chi_R(\xi) = 1$  iff  $q(\xi) \in R$ . Compare these characteristic functions lexicographically. This gives a comparison of *all* class well-order relations, set-like or not. It depends on  $q$ , and is not generally the numerical lexicographic comparison of their exhaustive enumerations.

**Proposition 17.1.** *For every fixed  $q$ , the virtual order of all class well-order relations under relation-code comparison is equimorphic with  $\mathbb{B}_{\text{Ord}}$ . The lower embedding can be chosen to use only set-like well-order relations.*

*Proof.* The upper embedding is the characteristic-function code itself. For the lower embedding, partition  $\mathbf{No}$  into disjoint two-element blocks using a baseline  $b$ . For each block  $\{a, c\}$ , let  $m$  be the smaller of the two positions where  $q$  lists  $(a, c)$  and  $(c, a)$ . The positions  $m$  are distinct and form a proper subclass of  $\text{Ord}$ ; they have a unique increasing enumeration by  $\text{Ord}$ . Order the blocks by this enumeration.

Within each block, choose its orientation so that the relation value at its first listed directed pair is the prescribed input bit. Order all elements in earlier blocks before all elements in later blocks. This is a set-like well-order, consisting of an  $\text{Ord}$ -sequence of two-element blocks. Reversing a block changes only the two directed relations internal to that block, not any relations between blocks. At the first differing input bit, its associated  $m$  is therefore the first changed coordinate of the characteristic function. The code preserves order. All selections and enumerations are uniform relative to  $q, b$ .  $\square$

This supplies two coherent meanings of “lexicographic ordering of all well-orders”: numerical enumeration comparison on the set-like part, and relation-code comparison on all class well-orders. They have uniform embeddings into one another through the binary class order, but their definitions, canonicity properties, and possible topological invariants should not be conflated.

[merge] Dated note, 2 October 2026. Source 08 says (its Section 14.1) that a canonical single comparison for all bijections from all non-set-like class well-order domains does not follow without an explicit alignment of proper-class initial segments, and asks (its question 11) for a comparison principle for arbitrary class well-orders and its recursion requirements. Sources 11 and 12 supply one without aligning domains: compare the two relations on their largest common labelled prefix, then compare the next labels ([theorems 14.2](#) and [14.7](#)); its definition uses elementary comprehension only, not ETR and not comparability of abstract class order types. For the pair of type  $\text{Ord} + 2$  displayed at the start of this section, the comparison is decided at the first appended point ([example 16.3](#), [example 14.9](#)). Source 08’s warning stands for the alignment of abstract domains, and relation-code lexicography remains a different order ([section 18](#) makes the same point on three points).

## 18 Numerically well-ordered subclasses and other interpretations (source 12)

The positive surreal ordinals form a numerically increasing class copy of  $\text{Ord}$ , but this is not a well-order of all of  $\mathbf{No}$ . More generally, [lemma 5.14](#) implies that every class well-order is isomorphic to a numerically well-ordered subclass of  $\mathbf{No}$ . That subclass need not be set-like in its inherited numerical order.

For an explicit example, the class

$$\left\{ -\frac{1}{\alpha + 1} : \alpha \in \text{Ord} \right\} \cup \{0\}$$

has numerical order type  $\text{Ord} + 1$ . The arithmetic here is surreal arithmetic on the embedded ordinal values; the reciprocal reverses positive order and the minus sign reverses it back. The final point has a proper class of predecessors. Putting a positive ordinal block after this negative block gives a numerical copy of  $\text{Ord} + \text{Ord}$ .

For a set  $A \subseteq \mathbf{No}$ , numerical well-ordering has the usual ordinal order type. Its birthday bound places it inside some  $\mathbf{No}_{<\kappa}$ . The class of all such set-sized well-ordered subsets is a legitimate class of sets. Its members are not exhaustive enumerations of a fixed carrier, however, so one must specify what happens when one enumeration is a prefix of another. The “shorter first” convention and the surreal  $- < \mathbf{end} < +$  convention are different choices; neither can be silently borrowed from the prefix-free exhaustive setting.

Finally, ordering binary relation tables rather than enumerations is another legitimate but different construction. If one fixes a set-like well-order of  $\mathbf{No} \times \mathbf{No}$ , compares the characteristic functions of relations at the first unequal table entry, and restricts to well-orders, one gets a table-dependent order. A first changed relation bit is not generally the first changed enumerated label. Even on three points the two lexicographic orders can differ. The present article uses labelled initial segments, not relation-table lexicography.

[merge] Source 12’s shipped check records a three-point example on which relation-table lexicography and enumeration lexicography differ (`data/12-singular-finite_checks.json`, key `relation_table_vs_enumeration_example`).

## Part IV

# Set-like global well-orders

## 19 The lexicographic structure of global enumerations

The set-like case has a particularly strong structure theorem. Although the full collection of global enumerations is a higher-order object, one ordinary class of set codes already meets every cut specified by set-indexed families. That class, with its induced order, is isomorphic to the surreal line. The distinction between a set-indexed family and an ordinal-indexed class family is essential: an explicit omitted-range construction shows exactly where the interpolation theorem stops.

Throughout this section we work in GBC and fix a class bijection

$$e_0 : \text{Ord} \longrightarrow \mathbf{No}.$$

The existence of such a baseline is supplied by global choice; the relevant equivalences are discussed in [19]. We use the surreal set-cut property, its preservation under deleting a set (Lemma 5.2), and the universality and uniqueness statements of Proposition 5.13. These are order-theoretic properties; the field operations on  $\mathbf{No}$  play no role in the main construction.

### 19.1 Class parameters and uniform families

**Definition 19.1.** For this section,  $\mathfrak{J}$  denotes the collection of class injections  $F : \text{Ord} \rightarrow \mathbf{No}$ , and  $\mathfrak{W}_{\text{sl}}$  denotes the subcollection of class bijections. For distinct  $F, G \in \mathfrak{J}$ , put

$$d(F, G) = \min\{\alpha \in \text{Ord} : F(\alpha) \neq G(\alpha)\}, \quad F <_{\text{lex}} G \iff F(d(F, G)) < G(d(F, G)).$$

A *uniformly set-indexed family*  $(F_i)_{i \in I}$  is given by a set  $I$  and one class relation whose  $i$ th row is the graph of  $F_i$ .

These notations are interpreted relationally in two-sorted class theory. An individual  $F$  is a class, not a possible element of a GB class. Thus “for all  $F \in \mathfrak{W}_{\text{sl}}$ ” abbreviates quantification over class functions with the stated property. Likewise, a uniformly indexed family is a single class of triples  $(i, \alpha, x)$ , not a literal set containing proper classes. The first-difference definition is legitimate: choose any coordinate of disagreement and minimize within the set of preceding ordinals. The usual first-difference proof gives a strict linear comparison on these objects.

Uniformity matters whenever a set bound is taken. For example, if two uniformly set-indexed families have different rows across every pair, Class Replacement makes their cross first-difference ordinals a set. No principle of choosing an arbitrary family of classes is being assumed. Finite lists of given class parameters are automatically uniform, and the families of set-coded objects constructed below have a fixed evaluation formula, so their set-indexed subfamilies are uniform as well.

[merge] Sources 09 and 08 define the same comparison of global enumerations (source 09 in [section 19.3](#); source 08 in its Section 9, “The virtual order of global enumerations”).

*Note 19.2* (Source 08, display (7) and Proposition 9.1). For two different global enumerations  $e, f$ ,

$$\delta(e, f) = \min\{\alpha \in \text{Ord} : e(\alpha) \neq f(\alpha)\}, \quad e <_{\text{lex}} f \iff e(\delta(e, f)) < f(\delta(e, f)), \quad (\text{S08.7})$$

and *this comparison satisfies trichotomy and transitivity; it defines a linear comparison in the two-sorted sense*. This is [definition 19.1](#) and the paragraph after it, by the same argument. Source 08’s Section 9.1 makes source 11’s point about uniform families: a family indexed by  $J$  is one class relation  $T \subseteq J \times \text{Ord} \times \mathbf{No}$ ; for a set  $J$ , class replacement bounds all cross first-disagreement coordinates; “merely saying ‘choose one class for every member of a set’ would not supply the uniform relation, and could hide an additional class-choice principle”; with repeated rows one works with the comparison preorder or an injective subfamily.

## 19.2 A class of bounded-support codes

**Definition 19.3.** A *normalized bounded-support code* is a set permutation  $\sigma : \lambda \rightarrow \lambda$  of an ordinal  $\lambda$  satisfying

$$\lambda = \sup\{\xi + 1 : \xi < \lambda \text{ and } \sigma(\xi) \neq \xi\}.$$

The empty permutation is allowed. Extend  $\sigma$  to a class permutation  $\hat{\sigma}$  of  $\text{Ord}$  by the identity outside  $\lambda$ , and evaluate the code as

$$E_\sigma = e_0 \circ \hat{\sigma}.$$

Write  $\mathcal{P}_{\text{bd}} = \mathcal{P}_{\text{bd}}(e_0)$  for the ordinary class of these codes, ordered by the lexicographic comparison of their evaluations.

Normalization removes the otherwise harmless duplication obtained by adding fixed points to the end of a code. Every class permutation with bounded support has exactly one normalized code: restrict it to the supremum of one plus its moved coordinates. Its support is invariant under the permutation, so this restriction is a permutation of the indicated ordinal. Consequently distinct normalized codes evaluate to distinct enumerations, and the induced order on  $\mathcal{P}_{\text{bd}}$  is a genuine class linear order. The class is proper, since the transpositions of 0 with arbitrary nonzero ordinals have distinct codes.

Here and below, identifying a code with its evaluated enumeration is a notational convenience. It does not convert the evaluated proper-class graph into a set. In particular, the assertion that  $\mathcal{P}_{\text{bd}}$  is an ordinary class refers to the codes, while assertions comparing its members with arbitrary members of  $\mathfrak{W}_{\text{sl}}$  use the common evaluation relation.

**Lemma 19.4** (Completion of an arbitrary set prefix). *Every injective set function  $p : \delta \rightarrow \mathbf{No}$ , with  $\delta$  an ordinal, is the initial segment of an enumeration represented in  $\mathcal{P}_{\text{bd}}$ . The completion can be chosen uniformly in  $p$ .*

*Proof.* Let  $q = e_0^{-1} \circ p$ . This is a set injection from  $\delta$  into  $\text{Ord}$ . Choose an infinite initial cardinal  $\gamma$  strictly larger than  $\delta$  and than  $\sup \text{ran}(q)$ . Both complements

$$\gamma \setminus \delta \quad \text{and} \quad \gamma \setminus \text{ran}(q)$$

have cardinality  $\gamma$ , since fewer than  $\gamma$  elements were removed. A bijection between the complements therefore extends  $q$  to a permutation of  $\gamma$ . Extend that permutation by the identity above  $\gamma$ , and normalize its code. Its evaluation agrees with  $p$  at every coordinate below  $\delta$ . To make the construction uniform, fix the least permissible  $\gamma$  and then the least complement bijection under a fixed global well-order. These choices select sets; they do not require a choice principle for families of proper classes.  $\square$

The lemma is stronger than merely extending  $p$  to some global well-order. Even an arbitrarily long set-sized prefix can be realized by changing the baseline only on a bounded set of coordinates. The bound need not be small: it must contain the baseline indices of all values prescribed by  $p$ .

**Source 12’s prefix extension.** [merge] Source 12’s Section 6 (“Set-like global well-orders: interpolation and universality”) proves the results of this section by the same arguments, except for its prefix extension, printed next, which is a different construction: it appends the restriction of the baseline order to the complement of the prefix, so its completion need not have bounded support. Source 12’s interpolation theorem, local characters and local universality are recorded in notes below; its avoidance lemma and its universality lemmas are printed in [section 5](#).

We now restrict to  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$ , the class-bijection predicate. All statements about set- or class-indexed collections of its members mean uniform families, unless a larger ambient universe is explicitly specified.

**Lemma 19.5** (Extending a set prefix). *Every injective set sequence  $p : \alpha \rightarrow \mathbf{No}$  extends to a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ . The extension can be chosen uniformly from  $p$  and one fixed baseline bijection  $B$ .*

*Proof.* Let  $A = \text{ran}(p)$ . Restrict the baseline order to  $\mathbf{No} \setminus A$ . It is a proper-class set-like well-order, so it has its canonical increasing enumeration in type  $\text{Ord}$ . Append that enumeration to  $p$ . The class order  $\alpha + \text{Ord}$  is canonically isomorphic to  $\text{Ord}$ . The construction is set-valued recursion with  $B$  as a parameter.  $\square$

[merge] *Source 09’s coding of the core.* Source 09 codes the core by fixed-point-free support permutations ([section 1.3](#)). Its prefix completion [lemma 19.6](#) has the proof of [lemma 19.4](#), and its [remark 19.7](#) warns why a larger cardinal is needed.

## 19.3 Source 09’s coding: canonical support codes and prefix completion

### 19.3.1 Lexicographic comparison of global enumerations

If  $E, F : \text{Ord} \rightarrow \mathbf{No}$  are distinct, choose an ordinal  $\gamma$  where they differ. Their disagreement class intersected with  $\gamma + 1$  is a nonempty set and has a least member. Thus

$$\Delta(E, F) = \min\{\alpha : E(\alpha) \neq F(\alpha)\}$$

is a set ordinal. Define

$$E <_{\text{lex}} F \iff E(\Delta(E, F)) < F(\Delta(E, F)).$$

The same first-disagreement argument as before proves trichotomy and transitivity. This proof quantifies over individual classes, not over a new class whose members would be enumerations.

### 19.3.2 Canonical set codes for eventual perturbations

A *support code* is a set function  $\sigma : S \rightarrow S$ , where  $S \subseteq \text{Ord}$  is a set,  $\sigma$  is bijective, and  $\sigma(\alpha) \neq \alpha$  for every  $\alpha \in S$ . The empty code is allowed. Extend it by the identity outside  $S$ :

$$\hat{\sigma}(\alpha) = \begin{cases} \sigma(\alpha), & \alpha \in S, \\ \alpha, & \alpha \notin S. \end{cases}$$

The code determines a global enumeration

$$E_\sigma = b \circ \hat{\sigma}. \quad (3)$$

Let  $\mathcal{P}_s(b)$  be the class of these codes, ordered by the corresponding  $E_\sigma$ . Because fixed points are omitted, distinct codes yield distinct enumerations. The carrier of  $\mathcal{P}_s(b)$  genuinely consists of sets.

A class enumeration  $E$  occurs this way exactly when it agrees with  $b$  at every sufficiently large ordinal. Indeed any set of ordinals is bounded. Conversely, if  $E$  equals  $b$  beyond a bound, then  $b^{-1} \circ E$  has set support, and that support is invariant under the permutation and its inverse. This gives its unique support code.

**Lemma 19.6** (Bounded-support prefix completion). *Every injective set word  $p : \alpha \rightarrow \mathbf{No}$  is a prefix of some  $E_\sigma$  with  $\sigma \in \mathcal{P}_s(b)$ . More precisely, choose any infinite initial cardinal  $\nu$  strictly above  $\alpha$  and every ordinal in  $b^{-1}[\text{ran } p]$ . Then  $\sigma$  can be chosen with support contained in  $\nu$ .*

*Proof.* Let  $r = b^{-1} \circ p : \alpha \rightarrow \nu$ . Since  $\alpha < \nu$ , both  $\nu \setminus \alpha$  and  $\nu \setminus \text{ran } r$  have cardinality  $\nu$ . Choose a bijection between them. Together with  $r$ , this gives a permutation  $\pi : \nu \rightarrow \nu$ . Extend  $\pi$  by the identity outside  $\nu$  and remove fixed points from its set code. Then  $b \circ \pi \upharpoonright \alpha = p$ .  $\square$

*Remark 19.7* (Why extra unused positions matter). A partial injection need not extend to a permutation on the union of its domain and range. For example,  $n \mapsto n + 1$  on  $\omega$  cannot extend to a permutation of  $\omega$  while retaining every prescribed value. The proof avoids this defect by moving to a larger cardinal  $\nu$ , where both complements have the same cardinality. Merely saying “complete the partial permutation” would leave a genuine gap.

For each ordinal  $\gamma$ , permutations of  $\gamma$  extended by the identity form a set-sized suborder of the core. Increasing  $\gamma$  gives compatible embeddings. Therefore

$$\mathcal{P}_s(b) = \bigcup_{\gamma \in \text{Ord}} \{\text{support codes of permutations of } \gamma\}.$$

Unlike naive unions of  $\mathcal{W}(\mathbf{No}_{<\theta})$ , this is a coherent direct system: the same global enumeration is retained when the support bound is increased.

[merge] Source 08’s Section 10 (“Set-supported permutations and prefix extension”) uses source 09’s support codes, writes  $\mathcal{P}_s$  for their class and  $\mathcal{P}_s(b)$  for the class ordered by

$$s <_b t \iff b \circ \hat{s} <_{\text{lex}} b \circ \hat{t}, \quad (\text{S08.8})$$

an ordinary class relation since codes are sets, and calls  $O_b = \{b \circ \hat{s} : s \in \mathcal{P}_s\}$  the virtual orbit of  $b$ .

*Note 19.8* (Source 08, Lemma 10.1, “Prefix extension inside one orbit”). *Every injective set word  $p : \alpha \rightarrow \mathbf{No}$  is an initial segment of  $b \circ \widehat{s}$  for some  $s \in \mathcal{P}_s$ .* This is [lemma 19.4](#) and [lemma 19.6](#), by the same proof through an initial cardinal  $\theta$  above  $\alpha$  and  $\sup \text{ran}(b^{-1} \circ p)$ , where both complements have cardinality  $\theta$ . Source 08 notes that set choice supplies the complement bijection; that a support below any such  $\theta$  suffices; that an arbitrary partial permutation of a fixed infinite set need not extend to a permutation of that set; and that under global choice the extension can be selected uniformly as the least valid code in a fixed set-like global well-order, “a choice of *sets*, not an invocation of choice among arbitrary classes”.

*Note 19.9* (Source 08, Corollary 10.2). *There is a uniform order embedding  $j_b : \mathbf{No} \hookrightarrow \mathcal{P}_s(b)$  for which  $b \circ \widehat{j_b(x)}$  has first entry  $x$ ; its image is cofinal and cointial in  $\mathfrak{W}_{\text{sl}}$  in the uniform-family sense.* The code is the transposition of 0 and  $b^{-1}(x)$ . This is [proposition 19.20](#) (source 11’s  $E_x$ ) and the first part of source 12’s [note 19.28](#). Source 08: the images of the positive and of the negative ordinals are cofinal and cointial, so there are uniform class-indexed cofinal families although there are no set-indexed ones; “cofinality must not be confused with exhaustive parametrization”.

## 19.4 Interpolation of every uniformly set-indexed cut

**Theorem 19.10** (Prefix interpolation). *Let  $(A_i)_{i \in I}$  and  $(B_j)_{j \in J}$  be uniformly set-indexed families in  $\mathfrak{J}$ , with*

$$A_i <_{\text{lex}} B_j \quad (i \in I, j \in J).$$

*Either index set may be empty. There is an injective set prefix  $p$  such that every member of  $\mathfrak{J}$  extending  $p$  is strictly above every  $A_i$  and strictly below every  $B_j$ . In particular, a member of  $\mathcal{P}_{\text{bd}}$  lies between the two families.*

*Proof.* If both index sets are nonempty, Class Replacement gives a set of ordinals  $d(A_i, B_j)$ . Choose  $\beta$  so that

$$d(A_i, B_j) < \beta \quad (i \in I, j \in J).$$

If one side is empty, put  $\beta = 0$ . We build an injective prefix  $p$ , keeping track of the rows that still agree with it. Call these rows *active*. The invariant is that every discarded  $A_i$  is below every extension of  $p$ , and every discarded  $B_j$  is above every extension of  $p$ .

Suppose  $p$  has length  $\alpha$  and the construction has not stopped. Let

$$L = \{A_i(\alpha) : A_i \text{ is active}\}, \quad R = \{B_j(\alpha) : B_j \text{ is active}\}.$$

These are sets. Since active cross pairs agree before  $\alpha$ , the hypothesis implies  $\ell \leq r$  whenever  $\ell \in L$  and  $r \in R$ . Thus  $L \cap R$  has at most one member: two distinct common values, taken in reverse order as a left and a right value, would contradict this inequality.

If  $L \cap R$  is empty, all cross inequalities are strict. By [Lemma 5.2](#), choose

$$z \in \mathbf{No} \setminus \text{ran}(p), \quad L < z < R.$$

This notation includes an empty left or right side; if both are empty, choose any fresh value. Append  $z$  and stop. Every previously active left row is now strictly below every extension of the new prefix, and every previously active right row is strictly above it. The invariant handles the already discarded rows, proving the desired conclusion.

If  $L \cap R = \{z\}$ , append  $z$  and retain as active exactly the rows whose next value is  $z$ . The new value is fresh because each surviving row is injective. A discarded left value is strictly below  $z$ , since  $z \in R$ ; a discarded right value is strictly above  $z$ , since  $z \in L$ . Hence the invariant is preserved.

At a limit stage take the union of the preceding prefixes; its length is a set ordinal and it remains injective.

The procedure cannot continue with both sides active through a prefix of length  $\beta$ . Such active rows would agree below  $\beta$ , contrary to the bound on every cross first difference. Therefore it stops no later than the next step, giving a set prefix. Lemma 19.4 supplies a bounded-support completion. Notice that surjectivity of the input rows was never used; this is why the theorem was stated for  $\mathfrak{J}$ .  $\square$

All recursion histories in this proof are sets. Even when the input rows are proper classes, their restrictions to a set ordinal are sets, and their next values form sets because the index sets are sets. The proof therefore uses ordinary set-valued transfinite recursion with class parameters, not ETR. The same observation applies to the back-and-forth argument below.

*Note 19.11* (Source 12, Theorem 6.3, “Set-indexed interpolation”). *If  $I, J$  are sets and  $(E_i)_{i \in I}, (F_j)_{j \in J}$  are uniform families in  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  with  $E_i <_{\text{lex}} F_j$  for all  $i, j$ , there is  $G \in \mathfrak{W}_{\text{sl}}(\mathbf{No})$  with  $E_i <_{\text{lex}} G <_{\text{lex}} F_j$ ; empty sides are allowed, so  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  is dense without endpoints in the indexed-family sense. This is theorem 19.10, by the same forced-prefix construction; source 12 completes the prefix by lemma 19.5, so its interpolant need not lie in the bounded-support core.*

[merge] Sources 09 and 08 prove the same theorem with their support codes (source 09’s Section 9, “The interpolation theorem”, and source 08’s Section 11, “The set-cut interpolation theorem”).

*Note 19.12* (Source 09, Theorem 9.1, “Uniform set-indexed interpolation”). *For uniformly set-indexed families  $(E_i) <_{\text{lex}} (F_j)$  of global enumerations ( $I, J$  possibly empty) and every fixed baseline  $b$ , there is  $\sigma \in \mathcal{P}_s(b)$  with  $E_i <_{\text{lex}} E_\sigma <_{\text{lex}} F_j$ . This is theorem 19.10, by the same construction; source 09 bounds the forced prefix by  $\lambda + 1$ ,  $\lambda = \sup\{\Delta(E_i, F_j) + 1\}$ , and notes that the theorem “permits constraints from outside the chosen core, and the interpolant can be required to come from any specified baseline’s eventual-agreement class”.*

*Note 19.13* (Source 08, Theorem 11.1, “Orbit interpolation”). *For fixed  $b$  and uniform families  $(l_i)_{i \in I}, (r_j)_{j \in J}$  of global enumerations,  $I, J$  sets, with  $l_i <_{\text{lex}} r_j$ , there is  $s \in \mathcal{P}_s$  with*

$$l_i <_{\text{lex}} b \circ \hat{s} <_{\text{lex}} r_j \quad (i \in I, j \in J); \quad (\text{S08.9})$$

*either family may be empty.* This is theorem 19.10, by the same active-row invariant (its display (S08.10) is the inequality  $a \leq b$  between active next entries). Source 08 stresses that the separator lies in one fixed orbit “regardless of the supports, or lack of supports, of the input enumerations”.

*Note 19.14* (Source 08, Corollary 11.2). *The virtual order  $\mathfrak{W}_{\text{sl}}$  is dense without endpoints and has no uniformly set-indexed cofinal or coinital family; every orbit  $O_b$  is dense in  $\mathfrak{W}_{\text{sl}}$  and realizes every uniformly set-sized separated cut; the class order  $\mathcal{P}_s(b)$  is an  $\eta_{\text{Ord}}$ -order. This is corollary 19.15 and proposition 19.27, by specializing the interpolation theorem.*

**Corollary 19.15.** *The class order  $\mathcal{P}_{\text{bd}}$  is an  $\eta_{\text{Ord}}$  order and is order-isomorphic to  $(\mathbf{No}, <)$ . Moreover, it meets every strict cut in  $\mathfrak{W}_{\text{sl}}$  specified by uniformly set-indexed families.*

*Proof.* A set of codes is uniformly evaluable, so Theorem 19.10 applies to every separated pair of sets in  $\mathcal{P}_{\text{bd}}$ . Empty sides give the absence of endpoints, and singleton sides give density. We already know that  $\mathcal{P}_{\text{bd}}$  is a proper class. Proposition 5.13 therefore identifies it with  $\mathbf{No}$ .

Explicitly, global choice enumerates each of the two classes by ordinals. Alternately extend a set-sized partial isomorphism to cover the next element of one enumeration and then the next element of the other. The lower and upper images at either step are sets, so the cut property supplies the new point. The union of this ordinary set-valued recursion is an isomorphism. The last assertion is the direct specialization of Theorem 19.10 to bijective input rows.  $\square$

This is an isomorphism of the class of bounded-support codes with the surreal line. It is not an isomorphism between  $\mathbf{No}$  and the full higher-order collection  $\mathfrak{W}_{\text{sl}}$ . Different baselines produce classes with the same abstract order type, but the argument does not single out a canonical isomorphism.

*Note 19.16* (Source 09, Corollary 9.2, “The surreal core theorem”). *In GBC,  $\mathcal{P}_s(b) \cong \mathbf{No}$ . In particular  $\mathcal{P}_s(b)$  is dense without endpoints, every set-sized partial order isomorphism between its suborders extends to an automorphism, and every class linear order embeds into it.* This is [corollary 19.15](#) (with the coding of [section 1.3](#)), with homogeneity from [theorem 5.17](#). Source 09 adds that no set family is cofinal or coinital among all global enumerations, or immediately on either side of a fixed global enumeration, while proper-class cofinal and coinital families exist, with first entries running through cofinal positive and coinital negative ordinals.

*Note 19.17* (Source 08, Theorem 12.2, “Surreal-sized skeleton”). *For every fixed global enumeration  $b$ ,  $\mathcal{P}_s(b) \cong \mathbf{No}$ ; the code order is a proper class, is dense in  $\mathfrak{W}_{\text{sl}}$  through its represented enumerations, and realizes every uniform set cut of  $\mathfrak{W}_{\text{sl}}$ .* This is [corollary 19.15](#), by the same uniqueness theorem ([note 5.19](#)); properness comes from [note 19.9](#). Source 08 adds: “The isomorphism is an isomorphism of *linear orders*, not of fields, of simplicity trees, of birthday filtrations, or of permutation groups. No canonical isomorphism independent of Global Choice and  $b$  is asserted. One could transport a field structure along a selected isomorphism, but it would be additional, choice-dependent structure, not an arithmetic operation naturally defined by lexicographic comparison of enumerations.”

#### 19.4.1 Eventual agreement and interleaved orbits (source 08)

Two enumerations  $e, f$  differ on a set of coordinates exactly when  $e = b \circ \hat{s}$ ,  $f = b \circ \hat{t}$  for some common orbit, equivalently when  $e^{-1} \circ f$  has set support. Any set of ordinal coordinates is bounded, so this is also eventual equality: there is an ordinal  $\alpha$  such that  $e(\xi) = f(\xi)$  for every  $\xi \geq \alpha$ . The equivalence between the support conditions follows from injectivity of the baseline enumeration and class replacement.

Distinct orbits are disjoint as collections of enumerations, but every one is dense in  $\mathfrak{W}_{\text{sl}}$ . Hence these equivalence classes are not convex, and the quotient by eventual equality does not inherit a linear order by simply comparing representatives. This is a concrete obstruction, not merely a size warning.

**Corollary 19.18** (The class of realizations of a set cut). *Under the hypotheses of Theorem 19.10, the ordinary class*

$$K = \{p \in \mathcal{P}_{\text{bd}} : (\forall i \in I \ A_i <_{\text{lex}} p) \text{ and } (\forall j \in J \ p <_{\text{lex}} B_j)\}$$

*is itself order-isomorphic to  $\mathbf{No}$ .*

*Proof.* It is an ordinary class by comprehension with the two uniform input relations as parameters. Suppose  $C, D \subseteq K$  are sets with  $C < D$ . Add the evaluated codes of  $C$  to the lower input family and those of  $D$  to the upper input family. All cross inequalities remain strict: members of  $K$  already lie between the original sides. Theorem 19.10 supplies a member of  $K$  between  $C$  and  $D$ . Thus  $K$  has the set-cut property, including empty sides. It cannot be a set, since applying that property with lower side all of  $K$  would give a member above itself. The uniqueness statement of Proposition 5.13 now gives the isomorphism.  $\square$

Thus the interpolation theorem produces a full proper-class order of available choices, even when the input constraints are numerous and occur at arbitrarily complicated set-ordinal coordinates. In particular, no set of codes can be order-dense in  $\mathfrak{W}_{\text{sl}}$ . Given such a set, choose a point strictly above

all its evaluations, and then a second, larger point. The open interval between the two contains no code from the proposed dense set. The same argument applies within  $K$ : a set cannot be dense even in the class of realizations of one specified set cut. The ordinary class  $\mathcal{P}_{\text{bd}}$  is therefore a natural scale for density here, while an exhaustive class of set codes will be ruled out by a separate diagonal argument.

*Note 19.19* (Source 09, Corollary 9.3, “Dense copies in every interval”). *For global enumerations  $E < F$ , the class  $\{\sigma \in \mathcal{P}_s(b) : E < E_\sigma < F\}$  is isomorphic to  $\mathbf{No}$ ; the core meets every open interval of the global order and supplies a copy of every class linear order inside it.* This is [corollary 19.18](#) with  $I = \{E\}$  and  $J = \{F\}$ , by the same argument.

## 19.5 Universality, cylinders, and local cofinality

**Proposition 19.20.** *The surreal line embeds explicitly into  $\mathcal{P}_{\text{bd}}$ . Consequently every ordinary class linear order embeds into  $\mathcal{P}_{\text{bd}}$  and hence into  $\mathfrak{W}_{\text{sl}}$ , in the uniform evaluation sense.*

*Proof.* For  $x \in \mathbf{No}$ , transpose the values  $e_0(0)$  and  $x$  in  $e_0$ , and denote the resulting enumeration by  $E_x$ . Its coordinate permutation has support contained in  $\{0, e_0^{-1}(x)\}$ , so it has a code in  $\mathcal{P}_{\text{bd}}$ , and

$$E_x(0) = x, \quad x < y \iff E_x <_{\text{lex}} E_y.$$

For the general assertion, compose this embedding with the class-order universality of  $\mathbf{No}$  from [Proposition 5.13](#).  $\square$

Thus all set ordinals, the class order  $\text{Ord}$ , its reverse, and class orders such as  $\text{Ord} + \text{Ord}$  occur as suborders of the lexicographic comparison. This statement concerns the order *between* enumerations. Each individual enumeration in  $\mathfrak{W}_{\text{sl}}$  still presents a well-order of type  $\text{Ord}$ ; its lexicographic environment need not be well-ordered.

*Note 19.21* (Source 12, Theorem 6.7, “Local class universality and cylinders”). *Every class linear order has a uniform order-embedding into  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  and into every nonempty open interval of  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$ ; for a set-sized injective prefix  $p$ , the cylinder  $[p]$  is convex and isomorphic to  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  by uniform transformations.* This is [proposition 19.20](#) and [proposition 19.25](#), by the same constructions ( $x \mapsto E_x$  composed with [lemma 5.14](#); a cylinder through  $\mathbf{No} \setminus \text{ran}(p) \cong \mathbf{No}$ , [lemma 5.15](#)). Source 12 lists the examples “all set ordinals, their reverses,  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ , all set-sized lexicographic powers of  $\mathbf{No}$  formed as class orders” and adds that “every class linear order” still means an order whose elements are sets; it does not include an unrestricted higher collection such as all class well-orders themselves.

*Note 19.22* (Source 09, Theorem 10.2). *Every set ordinal, every reverse set ordinal and every class linear order embeds as a uniformly class-indexed family of global enumerations; all these embeddings can be taken in  $\mathcal{P}_s(b)$ , or within any specified nonempty global open interval.* This is [proposition 19.20](#) with [corollary 19.18](#). Source 09 lists  $\text{Ord}$ ,  $\text{Ord}^*$ ,  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ , set-sized lexicographic powers of  $\mathbf{No}$  and every class linear order on a class of set codes, and stresses that “the class order *being embedded* need not be set-like, although each well-order represented by a target global enumeration is set-like. These are two entirely different orders.” Its direct embedding  $x \mapsto T_x \circ b$  (exchange  $b(0)$  and  $x$ ) is source 11’s  $E_x$ ; it “does not by itself give the surjectivity of the isomorphism”.

*Note 19.23* (Source 08, Corollary 12.4). *The skeleton contains copies of every ordinal and its reverse, every class well-order,  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ ,  $\mathbf{No} \times_{\text{lex}} \mathbf{No}$ , and  $(\mathbf{No}^\alpha, <_{\text{lex}})$  for every set ordinal  $\alpha$ ; every injectively parametrized uniform class family of global enumerations, with its induced lexicographic order, also embeds into  $\mathcal{P}_s(b)$ .* The first part is [proposition 19.20](#); the last clause is

source 09's [proposition 19.24](#), printed next. Source 08: this concerns a uniform class-indexed family, not all class enumerations simultaneously, and replacing the set ordinal  $\alpha$  by  $\text{Ord}$  in  $\mathbf{No}^\alpha$  changes the size level of the elements and is not covered.

**Proposition 19.24** (Representable suborders do not exceed surreal universality). *Every uniformly class-indexed family of global enumerations, modulo equal rows, has a class-coded linear order that embeds into  $\mathbf{No}$ .*

*Proof.* For a family with class index  $I$ , choose the least representative of each equal-row class in a fixed set-like global well-order of  $I$ . Equality of rows is the first-order condition  $\forall \alpha E_i(\alpha) = E_j(\alpha)$ , with the family as a class parameter. The representatives form a class of sets. Their first-disagreement order is a class linear order, to which [theorem 5.16](#) applies.  $\square$

This does not say that the full higher-level totality  $\mathfrak{W}_{\text{sl}}$  embeds into  $\mathbf{No}$ ; it says that every *uniformly class-coded portion* does.

**Proposition 19.25** (Prefix cylinders). *For an injective set prefix  $p$ , let*

$$C_p = \{E \in \mathfrak{W}_{\text{sl}} : E \upharpoonright \text{dom}(p) = p\}.$$

*The cylinder  $C_p$  is convex and order-isomorphic to  $\mathfrak{W}_{\text{sl}}$ , with the isomorphism interpreted as a uniform transformation of class parameters. Every nonempty open interval in  $\mathfrak{W}_{\text{sl}}$ , and every interval specified by a uniformly set-indexed strict cut, contains a whole such cylinder.*

*Proof.* An enumeration that first departs from  $p$  at a coordinate of  $p$  lies on the same side of all its extensions. This proves convexity. Put  $S = \text{ran}(p)$  and  $\delta = \text{dom}(p)$ . By [Lemma 5.2](#) and [Proposition 5.13](#), fix an order-isomorphism  $h : \mathbf{No} \rightarrow \mathbf{No} \setminus S$ . The ordinal tail  $[\delta, \text{Ord})$  has order type  $\text{Ord}$ , with its canonical increasing parametrization  $\xi \mapsto \delta + \xi$ . Given  $E \in \mathfrak{W}_{\text{sl}}$ , prepend  $p$  to the enumeration  $h \circ E$  on this tail. The result is a bijection onto  $\mathbf{No}$ , since its prefix covers  $S$  and its tail covers exactly the complement. Conversely, restrict an element of  $C_p$  to its tail and apply  $h^{-1}$ . These transformations are inverse and preserve first-difference comparisons. The final assertion follows from [Theorem 19.10](#).  $\square$

In particular, every such interval contains a copy of the entire comparison structure  $\mathfrak{W}_{\text{sl}}$ , not merely a copy of an arbitrarily large set order. This self-similarity does not invoke a class whose members are the cylinders; for each set prefix the displayed construction gives the required transformation, using the indicated class parameters.

*Note 19.26* (Source 09, [Proposition 10.4](#), “Cylinder self-similarity”). *Each cylinder  $[p]$  (the global enumerations extending an injective set word  $p$ ; convex, and nonempty by [lemma 19.6](#)) is isomorphic to the full global comparison order by an explicit invertible transformation of class enumerations preserving lexicographic order and having exactly  $[p]$  as its image. This is [proposition 19.25](#), by the same construction  $H_E \upharpoonright \alpha = p$ ,  $H_E(\alpha + \xi) = h(E(\xi))$  with  $h : \mathbf{No} \cong \mathbf{No} \setminus \text{ran } p$  ([corollary 5.18](#)). Source 09's paragraph on two baselines follows; source 08 makes the same observation in its subsection printed after [corollary 19.15](#).*

For two baselines  $b, c$ , their eventual-agreement collections are either identical or disjoint. They are identical exactly when  $b, c$  agree beyond some set ordinal. Otherwise no global enumeration can be eventually equal to both. Nevertheless, *each* such collection has a genuine set-coded presentation isomorphic to  $\mathbf{No}$  and is dense in the entire global comparison order. Eventual agreement is therefore not a convex relation, and its quotient does not inherit a lexicographic linear order by comparing arbitrary representatives.

**Proposition 19.27** (Approximants at every point). *For each  $F \in \mathfrak{J}$  there are uniformly ordinal-indexed families  $(a_\alpha)$  and  $(b_\alpha)$  of codes in  $\mathcal{P}_{\text{bd}}$  such that, whenever  $\alpha < \beta$ ,*

$$a_\alpha <_{\text{lex}} a_\beta <_{\text{lex}} F <_{\text{lex}} b_\beta <_{\text{lex}} b_\alpha.$$

*The lower family is cofinal among the global enumerations below  $F$ , and the upper family is coinital among those above  $F$ . Neither side admits a uniformly set-indexed cofinal or coinital family, respectively.*

*Proof.* Choose a fresh value below  $F(\alpha)$ , append it to  $F \upharpoonright \alpha$ , and use Lemma 19.4 to obtain  $a_\alpha$ . Choose a fresh value above  $F(\alpha)$  to obtain  $b_\alpha$ . Lemma 5.2 supplies the fresh values, and the fixed global well-order makes all choices uniform. For  $\alpha < \beta$ , the comparison between  $a_\alpha$  and  $a_\beta$  is decided at  $\alpha$ , giving the asserted inequality; the other comparisons are identical arguments.

If  $E <_{\text{lex}} F$ , choose  $\alpha > d(E, F)$ . Then  $a_\alpha$  agrees with  $F$  at the decisive coordinate, so  $E <_{\text{lex}} a_\alpha <_{\text{lex}} F$ . This proves cofinality, and the upper assertion is symmetric. Finally, given any uniformly set-indexed family below  $F$ , Theorem 19.10 applied with upper side  $\{F\}$  supplies a larger lower approximant in  $\mathcal{P}_{\text{bd}}$ . Hence the original family was not cofinal. The dual argument proves the coinitality assertion.  $\square$

For  $F \in \mathfrak{W}_{\text{sl}}$ , these are the local cofinality and coinitality statements at an actual point of the order. It is appropriate to say that ordinal-length class families suffice and set-sized families do not; assigning an ordinary set cardinal to these proper-class cofinalities would obscure the distinction.

*Note 19.28* (Source 12, Proposition 6.4, “Cofinality and local character”). *No set-indexed uniform family is cofinal or coinital in  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$ ; there are increasing cofinal and decreasing coinital families indexed by Ord; at every point neither side has a set-indexed cofinal, respectively coinital, family, but both have Ord-indexed ones.* This is proposition 19.27 together with the remark that first entries of a set-indexed family are bounded, by the same argument; the cofinal family is  $(E_\alpha)_{\alpha \in \text{Ord}}$  for the positive ordinals  $\alpha$ .

**Corollary 19.29** (Set saturation is not Dedekind completeness). *A nonempty uniformly set-indexed family in  $\mathfrak{W}_{\text{sl}}$  with no greatest member has no supremum in  $\mathfrak{W}_{\text{sl}}$ . Dually, a family with no least member has no infimum. Both statements also hold in the ordinary class order  $\mathcal{P}_{\text{bd}}$ .*

*Proof.* Suppose that  $E$  is the supremum of a family  $(A_i)$  with no greatest member. Every  $A_i$  is then strictly below  $E$ . By Theorem 19.10, there is a bounded-support enumeration  $p$  with  $A_i < p < E$  for every  $i$ . This makes  $p$  a smaller upper bound, a contradiction. The infimum argument reverses the inequalities, and the same bounded-support interpolant proves the assertions internal to  $\mathcal{P}_{\text{bd}}$ .  $\square$

For example, take the enumerations  $E_n$  from the transposition construction, so that  $E_n(0) = n$  for  $n \in \mathbb{N}$ . They form an increasing sequence of bounded-support codes. The enumeration whose first value is the surreal ordinal  $\omega$  is an upper bound, but there is no least upper bound in either  $\mathcal{P}_{\text{bd}}$  or  $\mathfrak{W}_{\text{sl}}$ . The obstruction is not a failure to find bounds: Theorem 19.10, with one input side empty, bounds every uniformly set-indexed family above and below. Rather, whenever a proposed bound is strictly beyond every member, there remains room to move the bound closer. This distinction will also matter when the full order of Dedekind cuts is embedded below. An order embedding preserves comparisons, but does not automatically preserve the role of a point as the least upper bound of a specified family.

[merge] Source 08’s Section 11.2, “Saturation is not Dedekind completeness”, proves corollary 19.29 by the same argument (a strictly smaller upper bound from note 19.13) and adds that the same assertion holds in  $\mathcal{P}_s(b)$  and in  $\mathbf{No}$ : “Set-cut saturation supplies abundant *strict* separators; it is not the Dedekind completeness familiar from the real line.”

[merge] Bounded reflection is proved only by source 09.

## 19.6 Source 09: bounded reflection

### 19.6.1 Every set family reflects into one bounded permutation stage

**Theorem 19.30** (Bounded reflection). *Let  $(E_i)_{i \in I}$  be a uniformly set-indexed family of pairwise distinct global enumerations. For any baseline  $b$ , there are a set ordinal  $\lambda$ , an infinite initial cardinal  $\nu$ , and support codes  $\sigma_i \subseteq \nu \times \nu$  such that*

$$E_{\sigma_i} \upharpoonright \lambda = E_i \upharpoonright \lambda, \quad E_i < E_j \iff E_{\sigma_i} < E_{\sigma_j}.$$

The family order also embeds into  $\mathcal{W}_\kappa(\mathbf{No}_{<\theta})$  for some birthday bound  $\theta$ , where  $\kappa = |\mathbf{No}_{<\theta}|$ .

*Proof.* Choose  $\lambda \geq 1$  strictly greater than every first-disagreement ordinal of a pair of distinct rows. This is possible by Replacement because  $I \times I$  is a set. The set

$$U = \bigcup_{i \in I} \text{ran}(E_i \upharpoonright \lambda)$$

is a set of surreals. Choose one infinite initial cardinal  $\nu$  strictly above  $\lambda$  and every ordinal in  $b^{-1}[U]$ . Apply lemma 19.6 to every row prefix at this same bound. All comparisons were resolved before  $\lambda$ , so they are preserved. Choice for this set family of completions suffices.

For the birthday version, take  $\theta$  large enough that  $U \subseteq \mathbf{No}_{<\theta}$  and its cardinality  $\kappa$  is strictly larger than the ordinal  $\lambda$ . Each prefix then removes fewer than  $\kappa$  letters from  $\mathbf{No}_{<\theta}$ . Enumerate the remainder in type  $\kappa$  and append it. The total ordinal length is  $\lambda + \kappa = \kappa$ . The resulting exhaustive words preserve all first disagreements.  $\square$

Thus no counterexample involving a *uniform set family* needs unboundedly many coordinates in an essential way. But the bound depends on the family, and there is no single set bound working for every family. For each  $\kappa$ , the global core contains  $\kappa^+$ , whereas theorem 6.14 rules it out of any fixed alphabet of size  $\kappa$ .

[merge] The failure of finite support is proved only by source 08; it shows why the core must allow set support.

## 19.7 Why finite support is insufficient (source 08)

Let  $F_b$  be the suborder of  $\mathcal{P}_s(b)$  consisting of finite support codes. The explicit transpositions in note 19.9 show that  $F_b$  already contains a copy of  $\mathbf{No}$  and hence every class linear order. Nevertheless it does not have the saturation or ambient density of the full set-supported skeleton.

**Proposition 19.31.** *The order  $F_b$  is not an  $\eta_{\text{Ord}}$ -order, and its represented enumerations are not dense in  $\mathfrak{W}_{\text{sl}}$ .*

*Proof.* Put  $p(n) = b(n+1)$  for  $n < \omega$ . This injective prefix differs from  $b$  at every natural-number coordinate. Every finite injective prefix extends to a finite perturbation of  $b$ : after applying  $b^{-1}$ , its partial injection extends to a permutation of the finite union of its domain and range, because the two remaining finite complements have equal size.

For each  $n$ , choose fresh values  $a_n < p(n) < c_n$  outside  $\text{ran}(p \upharpoonright n)$ , and extend  $(p \upharpoonright n) \frown (a_n)$  and  $(p \upharpoonright n) \frown (c_n)$  to finite perturbations  $l_n, r_n$  of  $b$ . These choices can be made uniformly. For all  $n, m$  one has  $l_n < r_m$ : at the earlier of their altered coordinates one sees either  $a_n < p(n)$  or  $p(m) < c_m$ , and when  $n = m$  one sees  $a_n < c_n$ .

A separator of these two countable families must agree with  $p$  at every finite coordinate. Otherwise at its first disagreement  $k$ , the rows  $l_m, r_m$  for  $m > k$  both agree with  $p$  there, forcing the candidate

below a left row or above a right row. Such a separator moves every natural-number coordinate of  $b$  and cannot have finite support. This proves failure of set-cut saturation.

Finally choose  $u < v$  in  $\mathfrak{W}_{\text{sl}}$  with common prefix  $p$  of length  $\omega$  and distinct fresh entries immediately afterward, using [note 19.8](#). Every enumeration between them must share that prefix, so none is a finite perturbation of  $b$ . Hence  $F_b$  is not dense in  $\mathfrak{W}_{\text{sl}}$ .  $\square$

Thus containing every ordinary class order is weaker than being a surreal line or being a dense skeleton of the virtual ambient order. Set support, not merely finite support, is what permits arbitrary set-length prefixes to be imposed.

## 19.8 Binary class words, cuts, and diagonalization

**Theorem 19.32.** *The lexicographic orders  $\mathfrak{W}_{\text{sl}}$  and  $\{0,1\}^{\text{Ord}}$  are order-bi-embeddable, where a binary word of length  $\text{Ord}$  means a class characteristic function. Both embeddings have uniform relational definitions in GBC.*

*Proof.* Partition the coordinate ordinals into successive pairs  $2 \cdot \xi, 2 \cdot \xi + 1$ . Here the multiplication is ordinal multiplication with 2 on the left; every ordinal has a unique such pair position. Sort the corresponding baseline values as

$$u_\xi = \min\{e_0(2 \cdot \xi), e_0(2 \cdot \xi + 1)\}, \quad v_\xi = \max\{e_0(2 \cdot \xi), e_0(2 \cdot \xi + 1)\}.$$

For a class  $D \subseteq \text{Ord}$ , put these two values in the order  $(u_\xi, v_\xi)$  if  $\xi \notin D$ , and in the order  $(v_\xi, u_\xi)$  if  $\xi \in D$ . Denote the resulting enumeration by  $T_D$ . Each pair retains exactly its original two values, so  $T_D$  is a bijection onto  $\mathbf{No}$ . At the least differing bit of two characteristic functions, 0 chooses the smaller first value and 1 the larger one. Thus  $D \mapsto T_D$  preserves and reflects lexicographic comparison.

For the converse, fix an ordinal enumeration  $(p_\xi)_{\xi \in \text{Ord}}$  of the set codes in  $\mathcal{P}_{\text{bd}}$ . Associate with  $E \in \mathfrak{W}_{\text{sl}}$  the class

$$D_E = \{\xi \in \text{Ord} : p_\xi <_{\text{lex}} E\}.$$

If  $E <_{\text{lex}} F$ , then  $D_E \subseteq D_F$ , and the inclusion is strict: [Corollary 19.15](#) supplies a code strictly between  $E$  and  $F$ . At the least ordinal belonging to  $D_F \setminus D_E$ , the characteristic functions therefore have values 0 and 1, respectively. This proves the second order embedding. Both constructions use elementary class comprehension with the input word or enumeration as a class parameter.  $\square$

Bi-embeddability must not be replaced by isomorphism. Binary class words have a least and a greatest word and have adjacent pairs: after a set prefix, the word with next bit 0 and all subsequent bits 1 immediately precedes the word with next bit 1 and all subsequent bits 0. By contrast,  $\mathfrak{W}_{\text{sl}}$  is dense and has no endpoints.

[merge] *Second route (source 12).* Source 12's Section 7 embeds  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  into binary class words by concatenating self-delimiting codes of the entries, instead of source 11's characteristic function of a dense class; the other embedding is source 11's pair swap.

## 19.9 Source 12's route to the binary-class representation

Let  $\mathbb{B}_{\text{Ord}}$  denote the predicate of class subsets of  $\text{Ord}$ , regarded as binary functions on  $\text{Ord}$  and compared at their least disagreement. This is again notation for a predicate and relation on classes, not a powerclass object.

**Lemma 19.33** (A self-delimiting numerical code). *Replace every minus in a sign sequence by 00, every plus by 11, and append the terminal block 01. The resulting binary ordinal word  $c(s)$  has length  $2 \cdot \text{bd}(s) + 2$ . Distinct codewords are prefix-incomparable, and their first-difference comparison agrees with numerical comparison of the surreals.*

*Proof.* The three two-bit blocks have order  $00 < 01 < 11$ , exactly matching  $- < \text{end} < +$ . At a sign disagreement the first different block decides. When one sign sequence ends, its terminal block differs from the next sign block of the other. Hence neither complete codeword can be a prefix of another, and the numerical comparison is preserved.  $\square$

**Theorem 19.34** (Binary-class equimorphism). *In the sense of uniform class transformations,*

$$\mathfrak{W}_{\text{sl}}(\mathbf{No}) \simeq_e \mathbb{B}_{\text{Ord}}.$$

*Proof.* For  $E : \text{Ord} \rightarrow \mathbf{No}$ , concatenate  $c(E(\alpha))$  over all ordinals. The cumulative length before each stage is a set ordinal. All blocks are nonempty, so the cumulative lengths are unbounded in  $\text{Ord}$  and the result is a binary class on all of  $\text{Ord}$ . If  $E, F$  first disagree at  $\alpha$ , their earlier block lengths and bits agree, and the code of that entry decides the same inequality by lemma 19.33.

For the converse, use the disjoint pairs  $a_\alpha < b_\alpha$  in the proof of theorem 19.38. For a binary class  $A$ , list the pair in ascending order if its bit is 0, and descending order if its bit is 1. Put pair blocks in ordinal order. The first different bit gives the first different pair orientation and the correct lexical inequality. All labels occur exactly once.  $\square$

This is not an isomorphism assertion. The binary-class order has least and greatest elements and adjacent pairs, such as a zero followed by all ones versus a one followed by all zeros. By note 19.11,  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  has no endpoints or adjacent pairs. The distinction between equimorphism and isomorphism is already visible at this level.

[merge] Source 08’s Section 13 (“Binary class sequences and the size obstruction”) defines an embedding between virtual collections as a *uniform operator*: “a formula, with displayed class parameters, assigning a unique output class to every input class, with class existence proved in the base theory. It is not a new class whose members are ordered pairs of proper classes.”

*Note 19.35* (Source 08, Theorem 13.1, “Virtual binary equimorphism”). *Relative to a baseline  $b : \text{Ord} \rightarrow \mathbf{No}$ , there are uniform order embeddings*

$$\mathbb{B}_{\text{Ord}} \hookrightarrow \mathfrak{W}_{\text{sl}} \hookrightarrow \mathbb{B}_{\text{Ord}}; \tag{S08.11}$$

*thus these virtual orders are equimorphic in the uniform-operator sense; they are not order-isomorphic.* This is theorem 19.32. The first embedding is source 11’s pair swap; the second is source 12’s concatenation (theorem 19.34), with the code of note 7.5 and block endpoints  $D_0 = 0$ ,  $D_{\xi+1} = D_\xi + (2 \cdot \text{bd}(e(\xi)) + 2)$ ,  $D_\lambda = \sup_{\xi < \lambda} D_\xi$  defined by set-valued recursion. Source 08 adds that the jump “ $p \cap 0$  followed by constant 1” below “ $p \cap 1$  followed by constant 0” in  $\mathbb{B}_{\text{Ord}}$  ceases to be adjacent in the image, because  $\mathfrak{W}_{\text{sl}}$  is dense: “equimorphism does not preserve order topology”.

**Corollary 19.36.** *The higher-order order of all class initial segments of  $\mathbf{No}$ , ordered by inclusion, embeds into  $\mathfrak{W}_{\text{sl}}$ . In particular, this holds for any specified convention of Dedekind cuts. Conversely, each  $E \in \mathfrak{W}_{\text{sl}}$  determines the initial segment  $\{p \in \mathcal{P}_{\text{bd}} : p <_{\text{lex}} E\}$ , and these initial segments separate distinct enumerations.*

*Proof.* For a class initial segment  $C \subseteq \mathbf{No}$ , form  $e_0^{-1}[C] \subseteq \text{Ord}$  and apply the pair-swap embedding of Theorem 19.32. Proper inclusion of initial segments gives proper inclusion of their inverse images, which implies the correct lex comparison of their characteristic functions. The converse is the dense-class construction in the second half of that theorem.  $\square$

This corollary does not form a GB class of all Dedekind cuts of  $\mathbf{No}$ . Each individual cut is an allowed class parameter; the rule associates an enumeration to it and compares any two such results. An encompassing object belongs to a higher type or to an explicitly larger ambient universe. Nor does the corollary assert that the natural inclusion of  $\mathcal{P}_{\text{bd}}$  in  $\mathfrak{W}_{\text{sl}}$  is a Dedekind completion: an order embedding of cuts need not preserve their intended suprema or their original positions relative to the embedded line.

There is a useful description of the natural cuts produced by an enumeration outside the bounded-support family. If  $E \in \mathfrak{W}_{\text{sl}}$  has no code in  $\mathcal{P}_{\text{bd}}$ , then

$$L_E = \{p \in \mathcal{P}_{\text{bd}} : p <_{\text{lex}} E\}, \quad U_E = \{p \in \mathcal{P}_{\text{bd}} : E <_{\text{lex}} p\}$$

partition  $\mathcal{P}_{\text{bd}}$  into two nonempty classes. Proposition 19.27 shows that  $L_E$  has no set-sized cofinal subset and  $U_E$  has no set-sized coinital subset, while ordinal-indexed class families suffice on both sides. This cut is unfilled in  $\mathcal{P}_{\text{bd}}$ : a putative filling code and  $E$  would be separated by another bounded-support code. Transporting the cut through an isomorphism  $\mathcal{P}_{\text{bd}} \cong \mathbf{No}$  therefore exhibits a surreal class cut with neither side controlled by a cofinal or coinital set. This is a description of individual additional enumerations relative to the fixed dense class, rather than a classification of all surreal class cuts.

**Theorem 19.37** (No exhaustive uniform class of codes). *There is no ordinary class of set codes with a single class evaluation relation whose evaluated rows include every member of  $\mathfrak{W}_{\text{sl}}$ .*

*Proof.* If such a coding existed, global choice would enumerate its codes by ordinals, with repetitions if the class of codes were a set. Write the resulting row relation as  $\text{Eval}(\xi, \alpha, x)$ . Use the sorted pairs  $u_\xi < v_\xi$  from Theorem 19.32, and define the class

$$D = \{\xi : \text{Eval}(\xi, 2 \cdot \xi, u_\xi)\}.$$

The associated pair-swap enumeration  $T_D$  differs from row  $\xi$  on the pair  $(2 \cdot \xi, u_\xi)$ . If that pair belongs to the old row, it does not belong to the graph of  $T_D$ , whose value there is  $v_\xi$ . If it does not belong to the old row, it belongs to the new graph, whose value there is  $u_\xi$ . Thus  $T_D$  is a member of  $\mathfrak{W}_{\text{sl}}$  omitted by the proposed exhaustive list. The argument even permits invalid or nonfunctional rows in the evaluator.  $\square$

The theorem explains why class universality of  $\mathbf{No}$  cannot simply be applied to the full collection  $\mathfrak{W}_{\text{sl}}$ . It also pinpoints the limitation of coding only bounded modifications, or any other one uniformly evaluable family of set codes: such a family may be order-dense and may realize all set-indexed cuts, while still omitting global enumerations by diagonalization.

[merge] *Strengthening (source 12)*. Source 12's Section 5 proves that no uniform family of class well-orders indexed by a class of sets contains every class well-order of  $\mathbf{No}$ , and that the missing one can be chosen set-like; its corollary 19.39 is theorem 19.37. Its subsection on definable classes explains why enumerating formulas does not evade the theorem.

## 19.10 Source 12's strengthening: why the collection of all global well-orders is not a class

The formal obstacle is not that individual class relations are illegal. They are legitimate class variables. The obstacle is attempting to make them the elements of an ordinary class of the same theory.

A useful legal replacement is a *uniform family*. For example,  $F \subseteq I \times \text{Ord} \times \mathbf{No}$  is a class of triples of sets, and its section  $F_i$  can be a class bijection for every  $i \in I$ . Similarly a class of triples

$(i, x, y)$  can code a family of class order relations. The index class  $I$  may be proper. These are single classes, not functions whose values are class objects.

**Theorem 19.38** (No exhaustive class-coded family). *In GBC, no uniform family of class well-orders of  $\mathbf{No}$  indexed by a class of sets contains every class well-order of  $\mathbf{No}$ . In fact, for every such family there is a set-like class well-order not among its sections.*

*Proof.* Global choice permits the family to be reindexed by an ordinal or by  $\text{Ord}$ . Extend an ordinal-indexed family to an  $\text{Ord}$ -indexed one by repeating an arbitrary default well-order; an empty family is trivial. Write the resulting relations as  $R_\alpha$ .

Fix a bijection  $B : \text{Ord} \rightarrow \mathbf{No}$  and partition its range into the pairs

$$\{B(2 \cdot \alpha), B(2 \cdot \alpha + 1)\} = \{a_\alpha, b_\alpha\}, \quad a_\alpha < b_\alpha.$$

Here multiplication is ordinal multiplication. The blocks of length two partition  $\text{Ord}$ . Define a new enumeration  $E$  by placing the two labels of pair  $\alpha$  in the order *opposite* to their relative order in  $R_\alpha$ . Keep the pair blocks in increasing  $\alpha$  order.

This is a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ , defined elementarily from the family and  $B$ . Its induced well-order disagrees with  $R_\alpha$  on the relative order of  $a_\alpha, b_\alpha$ . Thus it is not any section of the family.  $\square$

**Corollary 19.39** (No uniform set-code solution). *There is no class  $D$  of set codes together with a uniform class decoder whose decoded relations are exactly all class well-orders of  $\mathbf{No}$ .*

This diagonal theorem applies equally to an attempted exhaustive coding of all class subsets of  $\text{Ord}$  through the pair construction. It does not say that an externally specified set model has too many classes to form an external set. It says that the corresponding exhaustive decoder is not available *internally at the same size level*.

### 19.10.1 Definable classes and the truth-predicate trap

Formula codes and set parameters are sets, but the semantic map “formula plus parameters  $\mapsto$  its extension in the universe” is not a uniformly available truth predicate for the universe. For each fixed formula one may define a class. One may also work externally with all definable classes of a chosen model. Neither maneuver supplies an internal universal decoder defeating [theorem 19.38](#). The same caution applies to quantifying over all possible Lean universe levels: universe polymorphism is not an internal type of all universes.

[merge] Sources 09 and 08 prove the diagonal theorem for families of global enumerations (source 09’s Section 12, “Why all global well-orders cannot be uniformly coded by sets”).

*Note 19.40* (Source 09, Theorem 12.1, “Uniform no-coding theorem”). *There is no class of set indices  $I$  and no uniform class relation  $F \subseteq I \times \text{Ord} \times \mathbf{No}$  whose rows are exactly, or even include, all global enumerations of  $\mathbf{No}$ . This is [theorem 19.37](#), by the same diagonal class  $D = \{\alpha : (c(\alpha), 2 \cdot \alpha, a_\alpha^-) \in F\}$  along a class surjection  $c : \text{Ord} \rightarrow I$ , valid with nonfunctional rows. Source 09’s preceding paragraph defines the switches  $E_A$  that list the pair  $\{a_\alpha^-, a_\alpha^+\} = \{b(2 \cdot \alpha), b(2 \cdot \alpha + 1)\}$  increasingly for  $\alpha \notin A$  and decreasingly for  $\alpha \in A$ ; they embed the binary-class comparison into the global one, “the proper-class counterpart of the pair construction” of [note 6.12](#), as in the first half of [theorem 19.32](#).*

*Note 19.41* (Source 08, Theorem 13.2, “No class-uniform exhaustive list”). *If a class relation  $T \subseteq \text{Ord} \times \text{Ord} \times \mathbf{No}$  uniformly gives a global enumeration  $T_\alpha$  for each ordinal  $\alpha$ , there is a global enumeration  $e^*$  different from every  $T_\alpha$ ; consequently no uniform family indexed by an ordinary set*

or class of sets exhausts  $\mathfrak{W}_{\text{sl}}$ . This is [theorem 19.37](#), by the same switch at the even coordinate  $2 \cdot \alpha$ ; families indexed by sets or proper classes are reindexed by  $\text{Ord}$ . Source 08 adds: “the class of set-supported perturbation codes does not parametrize the full collection. The isomorphism  $\mathcal{P}_s(b) \cong \mathbf{No}$  is compatible with the much larger size of  $\mathfrak{W}_{\text{sl}}$ : each orbit is a dense copy of the surreal line, not all global enumerations”, and “an assertion about an embedding of the entire virtual order into a class must first specify a higher-type notion of mapping; it cannot be inferred from ordinary class universality.”

### 19.10.2 What the theorem does and does not say

The theorem rules out a uniform master list by set parameters, including one indexed by a proper class of such parameters. It does not rule out large useful coded subfamilies such as  $\mathcal{P}_s(b)$ ; indeed the latter is dense and class-universal.

It also does not mean that class functions cannot be discussed in **GBC**, nor that stronger foundations are inconsistent. They can be discussed one or several at a time, in uniform families, or as elements of a higher-level collection in a suitably stratified theory. What fails is compression of *all* of them into one same-level, set-indexed evaluation relation.

Enumerating formula strings does not evade this issue. A putative uniform evaluation of all formulas over the set universe would require an appropriate truth predicate; it is not obtained from syntax alone. Definitions with additional class parameters also need not remain in the original parameter collection. One must distinguish a metatheoretic list of formulas, individual definable classes, and an internal uniform family of their extensions.

## 19.11 Omitted ranges and the transition to raw well-orders

**Theorem 19.42** (An omitted-range cut). *Fix  $r \in \mathbf{No}$  and a class bijection  $F : \text{Ord} \rightarrow \mathbf{No} \setminus \{r\}$ . There are increasing and decreasing ordinal-indexed families  $(a_\alpha)$  and  $(b_\alpha)$  in  $\mathcal{P}_{\text{bd}}$  such that*

$$a_\alpha <_{\text{lex}} b_\beta \quad (\alpha, \beta \in \text{Ord}),$$

*but no member of  $\mathfrak{W}_{\text{sl}}$  lies strictly between both entire families. The raw well-order that lists  $F$  and then  $r$  has type  $\text{Ord} + 1$  and is the unique member of  $\mathfrak{W}_{\text{all}}$  between these families.*

*Proof.* Use the approximants from [Proposition 19.27](#). They satisfy  $a_\alpha <_{\text{lex}} F <_{\text{lex}} b_\beta$  for every pair of indices. If a global bijection  $E$  lay between both families and differed from  $F$  first at  $\delta$ , an approximant with index greater than  $\delta$  would place  $E$  on the wrong side. Therefore  $E$  would equal  $F$  at every ordinal, which contradicts its surjectivity.

Let  $R$  be the raw order obtained by appending  $r$  after the enumeration  $F$ . Its set-like initial part is precisely  $F$ : every point listed by  $F$  has set-sized predecessors, whereas  $r$  has a proper class of predecessors. Its comparisons with the approximants are decided at their prescribed ordinal first differences, so it lies between both families. Conversely, the same first-difference argument forces the core  $F_S$  of any raw order  $S$  between the families to equal  $F$ . By the core decomposition of [Theorem 15.1](#), its residual order must be the unique order on the singleton  $\{r\}$ . Thus  $S = R$ .  $\square$

The lower and upper families here are indexed by all ordinals, not by sets. Accordingly, the missing interpolant does not contradict [Theorem 19.10](#). It gives a concrete boundary between the set-cut saturation of the set-like comparison and the additional points provided by non-set-like global well-orders.

[merge] *Source 09’s route.* Source 09’s Section 11 gives a concrete instance of [theorem 19.42](#), with the nonexhaustive word  $\xi \mapsto \xi$  and the fresh values  $-1$  and  $\alpha + 1$ ; its [remark 19.44](#) is the general mechanism, which is source 11’s theorem for an arbitrary omitted range.

### 19.12 Source 09's route: a proper-class cut with no interpolant

The interpolation theorem has an exact and visible size limitation. The following construction uses only ordinal-valued prefixes and the single nonordinal value  $-1$ .

**Theorem 19.43** (An explicit unfilled  $(\text{Ord}, \text{Ord})$  configuration). *For any baseline  $b$ , there are uniformly class-indexed families  $(L_\alpha)_{\alpha \in \text{Ord}}$  and  $(U_\alpha)_{\alpha \in \text{Ord}}$  lying in  $\mathcal{P}_s(b)$  such that*

$$\alpha < \beta \implies L_\alpha < L_\beta < U_\beta < U_\alpha, \quad L_\alpha < U_\beta \quad \text{for all } \alpha, \beta,$$

*but there is no global enumeration  $E$  with  $L_\alpha < E < U_\beta$  for every  $\alpha, \beta$ .*

*Proof.* Let  $g : \text{Ord} \rightarrow \mathbf{No}$  be  $g(\xi) = \xi$ . This is an injective class word but not an exhaustive enumeration of  $\mathbf{No}$ . For each  $\alpha$ , use [lemma 19.6](#) to choose core completions of the prefixes

$$(g \upharpoonright \alpha) \frown (-1), \quad (g \upharpoonright \alpha) \frown (\alpha + 1),$$

calling them  $L_\alpha$  and  $U_\alpha$ , respectively. A fixed global well-order on the set support codes makes these choices uniform. The appended letters are fresh. For  $\alpha < \beta$ , comparison at coordinate  $\alpha$  gives  $L_\alpha < L_\beta$  and  $U_\beta < U_\alpha$ . Every lower word is below every upper word, by comparison at the smaller divergence coordinate.

Suppose a global enumeration  $E$  lay between all these bounds. If  $E(\delta) \neq \delta$  for some ordinal, take the least such  $\delta$ . If  $E(\delta) < \delta$ , the lower word  $L_{\delta+1}$  agrees with  $g$  through coordinate  $\delta$  and therefore lies above  $E$ , a contradiction. If  $E(\delta) > \delta$ , the upper word  $U_{\delta+1}$  lies below  $E$ , also a contradiction. Hence  $E(\delta) = \delta$  for every ordinal  $\delta$ , making  $E = g$ . But  $g$  omits, for example,  $-1$ , and is not surjective onto  $\mathbf{No}$ .  $\square$

Here the notation  $(\text{Ord}, \text{Ord})$  describes an increasing lower and a decreasing upper cofinal presentation, not a pair of set cardinal cofinalities. More explicitly, compare every global enumeration to the nonexhaustive word  $g$ . Every enumeration differs from  $g$  at a set ordinal and lies on exactly one side. The lower family in the theorem is cofinal on the lower side, and the upper family is coinital on the upper side. Neither side has an endpoint. The missing point would have to be the nonexhaustive branch  $g$  itself.

Every set subfamily of these constraints has an interpolant by [note 19.12](#). The failure is therefore genuinely at the proper-class level, not a missed set-sized limit. In particular, the space of all global enumerations is not a class-cut completion of its surreal core.

*Remark 19.44* (A general missing-branch mechanism). The same proof works for any injective class word  $g : \text{Ord} \rightarrow \mathbf{No}$  which is not surjective. At each set stage choose fresh values below and above  $g(\alpha)$  outside the earlier range, and complete the two prefixes. Any interpolant would agree with  $g$  at every coordinate and would therefore fail surjectivity. The surreal set-cut property guarantees the required fresh values.

**Example 19.45** (Two omitted points produce adjacent raw orders). Let  $r < s$  and choose  $F : \text{Ord} \rightarrow \mathbf{No} \setminus \{r, s\}$  bijectively. The approximants to  $F$  have exactly two raw interpolants: append  $r, s$  in that order, or append  $s, r$ . Both raw orders have type  $\text{Ord} + 2$ , and the first is lexicographically smaller. They are adjacent in  $\mathfrak{W}_{\text{all}}$ . Indeed, a raw order between them cannot have a different core, since an ordinal first difference would put it on the same side of both. With core  $F$  fixed, its residual order is a well-order of a two-element set, and these are exactly the two displayed possibilities. Thus the density theorem for  $\mathfrak{W}_{\text{sl}}$  does not extend to all raw well-orders.

**Corollary 19.46** (Exactly which raw set cuts admit bounded completions). *Let  $(A_i)_{i \in I} <_{\text{lex}} (B_j)_{j \in J}$  be a uniformly set-indexed strict cut in  $\mathfrak{W}_{\text{all}}$ . A member of  $\mathcal{P}_{\text{bd}}$  lies between the two sides if and only if*

$$F_{A_i} \neq F_{B_j} \quad (i \in I, j \in J),$$

where  $F_R$  is the canonical ordinal enumeration of the set-like initial part of a raw well-order  $R$ . The condition is vacuous when a side is empty.

*Proof.* If the cross cores are different, their comparisons are decided at ordinal first differences and have the same direction as the given raw comparisons. Apply Theorem 19.10 to these uniform families in  $\mathfrak{J}$ . Every comparison of the resulting completion with a raw input is already decided within its core, giving the required raw inequalities.

Conversely, suppose a cross pair shares a core  $F$ . This core cannot be surjective: a surjective core determines the entire raw order, contradicting the strict comparison of the pair. Any  $E \in \mathfrak{W}_{\text{sl}}$  therefore differs from  $F$  at an ordinal coordinate. That first difference places  $E$  on the same side of both raw orders, so  $E$  cannot lie between them. This excludes a bounded-support completion in particular.  $\square$

The criterion isolates the obstruction without appealing merely to size. Distinct ordinal cores can be separated by one bounded change of the baseline, even for a whole set-indexed cut. Two opposite sides with the same core require information in the residual non-set-like order, beyond every ordinal coordinate available to a global set-like enumeration.

## Part V

# Foundations, models and formalization

## 20 Formalizing the subject without changing its meaning

### 20.1 A bounded development in ordinary set theory

For any ordinal  $\theta$ , use the set  $X = \mathbf{No}_{<\theta}$ . The well-order relations on  $X$  form a subset of  $\mathcal{P}(X \times X)$ . Their lexicographic comparison can be defined either by unique ordinal enumeration or by the predecessor formula. This is ordinary ZFC mathematics. No inaccessible cardinal, class theory, or new logical sort is required.

This approach is particularly good for proving the general alphabet theorem, investigating cardinal spectra, and checking how a proposed construction changes birthdays. One should distinguish  $\mathcal{W}(X)$ , which permits every possible ordinal type of cardinality  $|X|$ , from its minimal-length stratum. Their cardinalities agree, but their jumps and finer order structure need not.

A family of results for every  $\theta$  does not automatically give a coherent global map. To take a union, the maps must agree on overlaps. The repository's bounded-surreal nonembedding example makes this restriction concrete.

### 20.2 Second-order class theory

In GB or GBC, the formula

$$\text{ClassWO}(R) \wedge \text{ClassWO}(S) \implies R = S \vee \text{Lex}(R, S) \vee \text{Lex}(S, R)$$

is meaningful with class variables. One can prove trichotomy, transitivity, existence theorems, and uniform-family embedding theorems in this language. It is unnecessary to form a class whose members are  $R, S$ .

When a family is indexed by a class  $I$  of sets, one class relation  $T \subseteq I \times \mathbf{No} \times \mathbf{No}$  supplies its rows. If the rows are pairwise distinct, substituting them into the elementary predecessor formula produces a class linear order on  $I$ . With repeated rows, one instead has the corresponding comparison on codes modulo equal evaluations. This is the correct format for most class-sized examples and applications.

In contrast, an expression such as

$$\{R : R \text{ is a class well-order of } \mathbf{No}\}$$

does not define an ordinary GB class of members. Our fraktur notation abbreviates a domain of class quantification. The diagonal theorem shows why a single uniform set-code replacement cannot recover the full domain either.

### 20.3 Why KM does not erase the extra level

KM strengthens comprehension by allowing class quantifiers, but its classes still have *sets* as members. It therefore does not turn the totality of class well-orders into an ordinary class. A genuine object containing arbitrary classes as members requires another sort, or a containing universe in which those classes become sets.

This distinction matters when one wants an arbitrary topology of higher-order open collections, a measure on all global well-orders, or a power object of their totality. Such notions require an explicit ambient theory. Hyperclass forcing provides one example of higher-level foundational practice [28]; it is not a reason to silently ignore the level distinction in bare KM.

There is also a separate recursion issue. Extracting the canonical initial Ord-part of one raw well-order is an elementary class construction. Iteratively deleting proper-class tails through an arbitrary transfinite sequence would have class-valued stages and needs its own analysis. General comparability of abstract class well-orders by initial-segment isomorphisms is another stronger topic; ETR implies it [27]. None of that machinery is needed for the labeled comparison proved in this article.

### 20.4 An explicit containing-universe model

A useful concrete model assumes a strongly inaccessible cardinal  $\kappa$  in an ambient universe and takes

$$U = V_\kappa, \quad \mathcal{C} = \mathcal{P}(V_\kappa).$$

This is a sufficient setting for interpreting a full class universe. The internal surreal class becomes the ambient set

$$\mathbf{No}^U = \mathbf{No}_{<\kappa}, \quad |\mathbf{No}^U| = \kappa.$$

All its ambient well-orders form a set of cardinality  $2^\kappa$ . Those that are internally set-like have ambient order type  $\kappa$ ; unrestricted well-orders may have any ambient ordinal type of cardinality  $\kappa$ .

To see the set-like assertion, every initial segment of a  $\kappa$ -enumeration has fewer than  $\kappa$  members, with ranks bounded below  $\kappa$ ; regularity puts it in  $U$ . Conversely, an ordinal type strictly exceeding  $\kappa$  has an initial segment of cardinality  $\kappa$ , which cannot be a set of  $U$ . A smaller type cannot enumerate the entire carrier.

The bounded-support class becomes an ambient order of cardinality  $\kappa$ , while the full  $\kappa$ -permutation order has cardinality  $2^\kappa$ . Thus a  $\kappa$ -sized dense suborder can coexist with a larger order of all enumerations. The exact ambient ordinal cutoff remains  $\kappa^+$ .

Every ordinal of  $U$  is below  $\kappa$ . There is no contradiction between internally embedding all ordinals and having an ambient successor-cardinal barrier. Inaccessibility is an additional assumption for this full universe example; it is not required for an individual birthday fragment.

## 20.5 A strict nonembedding result

The containing-universe interpretation makes a further comparison decidable by ordinary set-order invariants.

**Theorem 20.1** (Nonembedding in a full universe). *In the preceding full interpretation  $U = V_\kappa$ ,  $\mathcal{C} = \mathcal{P}(V_\kappa)$ , with ambient ZFC and  $\kappa$  strongly inaccessible,*

$$\mathfrak{W}_{\text{sl}}(\mathbf{No}^U) \hookrightarrow \mathfrak{W}_{\text{all}}(\mathbf{No}^U), \quad \mathfrak{W}_{\text{all}}(\mathbf{No}^U) \not\hookrightarrow \mathfrak{W}_{\text{sl}}(\mathbf{No}^U).$$

*These are assertions about the actual ambient sets of internal class well-orders and arbitrary ambient order embeddings.*

*Proof.* The first embedding is inclusion. Put  $X = \mathbf{No}^U$ . The target of the proposed reverse embedding is the dense order of all bijections  $\kappa \rightarrow X$ . Its bounded-support suborder  $D = \mathcal{P}_{\text{bd}}^U$  is dense and has ambient cardinality  $\kappa$ . For the upper bound, codes with domain  $\lambda < \kappa$  are subsets of  $\lambda \times \lambda$ ; strong inaccessibility bounds their number below  $\kappa$ , and there are  $\kappa$  possible domains. Transpositions give the matching lower bound.

Fix labels  $a < b$  in  $X$ . There are  $2^\kappa$  bijections  $F : \kappa \rightarrow X \setminus \{a, b\}$ , by the fixed-alphabet cardinality theorem. Each determines a convex adjacent pair

$$R_F = F + (a, b) <_{\text{lex}} S_F = F + (b, a)$$

in the unrestricted order. Distinct  $F$ 's determine distinct, disjoint convex fibers; one entire pair precedes the other.

If  $\Phi : \mathfrak{W}_{\text{all}}(X) \hookrightarrow \mathfrak{W}_{\text{sl}}(X)$  existed, the intervals

$$(\Phi(R_F), \Phi(S_F))$$

would be  $2^\kappa$  pairwise disjoint nonempty open intervals in the target. Each contains a point of  $D$ . Choosing the least such point under a fixed well-order of  $D$  would inject  $2^\kappa$  into  $\kappa$ , a contradiction.  $\square$

Thus equal cardinality  $2^\kappa$  and equal ordinal embedding cutoff  $\kappa^+$  do not imply equimorphism. The useful invariant here is the size of a family of disjoint open intervals relative to a dense suborder. The repository already uses related separability and cellularity arguments for the real alphabet [1, Remark `lwo:sp:rem:conditional`]; the argument above supplies the precise surreal-universe version.

There is also a direct class-theoretic obstruction, provided the inverse evaluation relation can be formed by impredicative comprehension.

**Theorem 20.2** (No definable uniform embedding in  $\text{KM} + \text{GC}$ ). *For every fixed formula, with fixed set and class parameters, that defines a total transformation  $R \mapsto \Phi(R)$  from  $\mathfrak{W}_{\text{all}}(\mathbf{No})$  to  $\mathfrak{W}_{\text{sl}}(\mathbf{No})$ , the theory  $\text{KM} + \text{GC}$  proves that this transformation is not an order embedding. The transformation is specified relationally: the defining formula assigns a unique output class graph to each input class well-order. This is a schema for fixed formulas, not quantification over a third sort of arbitrary transformations.*

*Proof.* Suppose such an order embedding were defined. Fix  $a < b$  and a global well-order of the set codes in  $\mathcal{P}_{\text{bd}}$ . For each class bijection  $F : \text{Ord} \rightarrow \mathbf{No} \setminus \{a, b\}$ , form the adjacent raw pair  $R_F, S_F$  from the preceding proof. Density of  $\mathcal{P}_{\text{bd}}$  in  $\mathfrak{W}_{\text{sl}}$  supplies codes strictly between  $\Phi(R_F)$  and  $\Phi(S_F)$ . Let  $q_F$  be the globally least such code. Comprehension in KM makes this a legitimate least-element definition, even if the formula specifying  $\Phi$  contains class quantifiers. Disjointness of the image intervals implies

$$q_F = q_G \implies F = G.$$

Now use KM comprehension to form the ordinary class relation

$$\text{Eval}(q, \alpha, x) \iff \exists \text{ class } F [F : \text{Ord} \xrightarrow{\sim} \mathbf{No} \setminus \{a, b\} \wedge q = q_F \wedge F(\alpha) = x].$$

Its rows are empty or the graphs of unique such bijections, and every such bijection occurs. Compose all rows with one fixed class bijection  $\mathbf{No} \setminus \{a, b\} \rightarrow \mathbf{No}$ . The resulting single class evaluator, with the ordinary set codes  $q \in \mathcal{P}_{\text{bd}}$ , contains every global enumeration of  $\mathbf{No}$ . This contradicts Theorem 19.37.  $\square$

The inverse evaluator is the decisive extra comprehension step: its definition quantifies over an arbitrary class  $F$ . The preceding proof does not claim that elementary GB comprehension suffices. Nor does it exclude arbitrary external maps between the available-class collections of a nonfull model. In particular, for an externally countable model these collections can both be countable, and its externally dense set-like order can admit an external copy of its unrestricted order. Such a map need not be representable by any uniform definition in the model. This is why the stated interpretation of an embedding matters.

## 20.6 Internal and external well-foundedness

For a model  $(M, \mathcal{X})$ , an internally well-founded class relation need not be externally well-founded. An external descending sequence might not be represented by a set in  $M$ . Thus comparing the internal theory with an external collection of all relations requires care.

Over GBC, well-foundedness of a class relation can be characterized by the absence of a set-coded descending  $\omega$ -sequence [27, Section 3]. Keeping the sets and an existing relation fixed while changing only the available classes does not arbitrarily change that relation's internal well-foundedness in suitable models. What can change is which class relations are available at all. External correctness can be ensured by an appropriate well-founded full universe interpretation, as above.

## 20.7 A practical Lean architecture

The repository already has a universe-indexed sign carrier [7]. Its type structure can be displayed schematically as:

```
structure SignSequence : Type (u + 1) where
  birthday : Ordinal.{u}
  signAt : Ordinal.{u} -> SignType
  signAt_ne_zero_iff : forall i, signAt i != 0 <-> i < birthday
```

This is mathematical pseudocode using ASCII logical notation, not a new executable Lean declaration. The key point is the level separation: the full carrier is one universe above the types indexing its small sign lengths.

The following existing declarations were inspected:

| Module or declaration                                                   | Role in the proposed development                            |
|-------------------------------------------------------------------------|-------------------------------------------------------------|
| <code>SignSequence.ordinalOrderEmbedding</code>                         | The all-plus ordinal embedding                              |
| <code>birthdays_bounded</code> , <code>small_bounded</code>             | Control of small parameter families and bounded fragments   |
| <code>SignSequence.not_small</code>                                     | The carrier cannot be treated as small at its ordinal level |
| <code>SignSequenceCutOperation.cut</code> and <code>cut_realizes</code> | Actual separators for small cut data                        |
| <code>SizeObstructions.noUnrestrictedCuts</code>                        | The obstruction to unrestricted cut filling                 |

These are source-level observations, not results of a fresh build. The current repository contains later arithmetic modules as well; historical proposal notes should not be mistaken for the present implementation status.

A sensible formalization proceeds in four parts.

1. **Set carriers.** For  $X : \text{Type } u$ , represent well-orders as relations on  $X$  together with their laws. Prove the predecessor-based comparison and its equivalence with ordinal enumeration. This avoids transporting across ordinal representatives at every comparison.
2. **Ordinal words.** Define words with small ordinal domains, an injective subtype, ordinal concatenation, and the sign code. Formalize prefix-freeness and first disagreement before proving the cardinal spectrum.
3. **Relative set-likeness.** If  $X$  lives in  $\text{Type } (u+1)$ , express the condition that each predecessor subtype is `Small.{u}`. A well-order of this larger  $X$  has its unrestricted order type at the larger ordinal universe. A same-level enumeration must not be inferred without the relative smallness hypothesis.
4. **Uniform families.** Keep an explicit index type and an evaluation relation. The bounded-support codes are sets of ordinal pairs at the selected level. Formulate the interpolation theorem only for small index families and the no-code theorem at its correct larger level.

Lean universes and Mathlib ordinals provide precisely the needed separation [29, 30]. Universe polymorphism is a schema of well-typed constructions, not a term denoting the union of all universes. This article supplies no new Lean file and makes no machine-verification claim.

[merge] Source 12's Section 11 identifies both global orders in the full-class model  $(V_\kappa, \mathcal{P}(V_\kappa))$  of [theorem 20.1](#). Its clause (iv) gives a second proof of that theorem's non-embedding: the full order  $\mathcal{W}(\mathbf{No}_{<\kappa})$  has binary coding length  $\kappa^+$  ([theorem 6.8](#)), whereas the set-like order  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$  has coding length  $\kappa$  ([theorem 8.3](#), regular case), and coding length cannot decrease under embeddings ([lemma 6.4](#)). Source 11's proof counts  $2^\kappa$  disjoint intervals against a dense suborder of size  $\kappa$ .

## 21 A full-class model that connects the two size levels (source 12)

Assume in an ambient ZFC universe that  $\kappa$  is strongly inaccessible. Consider the two-sorted structure

$$\mathcal{M} = (V_\kappa, \mathcal{P}(V_\kappa)),$$

with all external subclasses of  $V_\kappa$  available as its classes. This is a familiar full-class interpretation of strong class set theory: regularity and the strong-limit property ensure the required closure of set operations and class Replacement. It satisfies KM and global choice. We use this as an explicit relative model, not as a claim that inaccessible cardinals are necessary for the earlier GBC theorems.

**Theorem 21.1** (Exact external identification). *For the full-class interpretation above:*

- (i) *the internal surreal carrier is externally  $\mathbf{No}_{<\kappa}$ , and its internal ordinals are the external ordinals below  $\kappa$ ;*
- (ii) *the internal set-like global surreal well-orders, viewed as an external set order, are exactly  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$ ;*
- (iii) *all internal global surreal well-orders, viewed externally, form exactly  $\mathcal{W}(\mathbf{No}_{<\kappa})$ ;*
- (iv) *both external orders have cardinality  $2^\kappa$  and ordinal spectrum  $\beta < \kappa^+$ , but their binary coding ranks are respectively  $\kappa$  and  $\kappa^+$ . Therefore the full order does not embed into the set-like order.*

*Proof.* A sign sequence belongs to  $V_\kappa$  precisely when its ordinal domain has length less than  $\kappa$ . Inaccessibility gives  $|\mathbf{No}_{<\kappa}| = \kappa$ .

Every external relation on  $\mathbf{No}_{<\kappa}$  is a permitted internal class: each ordered pair of its labels is an element of  $V_\kappa$ . External well-foundedness implies internal well-foundedness. Conversely, if a relation is externally ill-founded, ambient choice supplies a descending  $\omega$ -sequence. Its countably many labels have ranks bounded below  $\kappa$  by regularity, so the sequence is an element of  $V_\kappa$  and witnesses internal ill-foundedness. Thus the well-orders agree.

An internal set has external cardinality less than  $\kappa$ . Conversely, a subset of  $\mathbf{No}_{<\kappa}$  of cardinality less than  $\kappa$  has bounded ranks and is an element of  $V_\kappa$ . Therefore internal set-likeness means that every proper predecessor segment has cardinality less than  $\kappa$ . An external well-order of  $\kappa$  labels has that property exactly when its order type is  $\kappa$ , proving (ii). Arbitrary external well-orders on those labels have types exactly the ordinals of cardinality  $\kappa$ , proving (iii). Comparisons agree by [theorem 14.7](#). Finally apply [theorems 6.8](#) and [8.3](#) and the monotonicity of coding rank under embeddings.  $\square$

## 21.1 Why this does not contradict surreal universality

Internally, each class linear order has elements that are sets of  $V_\kappa$  and hence externally at most  $\kappa$  elements. The external collection of all class well-orders has  $2^\kappa$  elements and is not an internal class carrier. Thus it is outside the scope of the internal class-universality theorem.

If  $\lambda > \kappa$  is another inaccessible cardinal, the entire external set  $\mathcal{W}(\mathbf{No}_{<\kappa})$  can be studied as an ordinary set in  $V_\lambda$ . It then embeds into the larger surreal carrier there by set-order universality. Its labels have moved up one foundational level; no same-level universal object has been created.

The singular cutoff  $\beth_\omega$  in [section 8](#) must not be used as though  $V_{\beth_\omega}$  were this model. That rank lacks the regularity used in Replacement and in the well-foundedness argument. The singular theorem is an ordinary ZFC theorem about a bounded set, not a full-class model construction at a singular height.

## 21.2 Henkin classes, countable models, and relativity

If the class collection is some  $\mathcal{X} \subsetneq \mathcal{P}(M)$ , only those well-orders whose relations lie in  $\mathcal{X}$  are admitted. External cardinality and saturation can then differ from the full-class calculation. A countable model may have an externally countable collection of admitted classes and external countable cofinal families, while internally having no *coded set-indexed* cofinal family. The missing external families are simply not internal objects.

For nonstandard or non- $\beta$  class models, one must additionally separate internal and external well-foundedness. Our exact identification in [theorem 21.1](#) used transitivity, full classes, and regularity; it was not asserted for arbitrary models. The general subtleties of class well-foundedness are discussed in [\[27, §3\]](#).

[merge] Clause (ii) of [theorem 21.1](#) is source 11’s statement that the internally set-like well-orders have ambient type  $\kappa$ , and clause (iii) its statement that unrestricted ones have every ambient type of cardinality  $\kappa$  ([section 20](#)). Source 12’s remark that the singular cutoff  $\beth_\omega$  must not be used as though  $V_{\beth_\omega}$  were such a model is the counterpart of source 11’s remark that inaccessibility is needed for the full universe example but not for an individual birthday fragment.

[merge] (3 October 2026, batch 89.) Source 31 (Part XV) extends this model from inaccessible  $\kappa$  to the full-class rank structures  $\mathcal{M}_\lambda = (V_\lambda, \mathcal{P}(V_\lambda))$  at every limit height  $\lambda > \omega$ , with the sign carrier  $S_\lambda = \bigcup_{\alpha < \lambda} {}^\alpha 2$  (so  $S_\kappa = \mathbf{No}_{<\kappa}$  as a set of sign sequences; no field operations are asserted at other cutoffs). Global choice and birthday-monotone set-like class well-orders of  $S_\lambda$  exist at every such height ([propositions XV.6.1](#) and [XV.6.2](#)); an Ord-enumeration of  $S_\lambda$  exists exactly when  $\lambda = \kappa$  is a cardinal with  $2^{<\kappa} = \kappa$  ([theorem XV.7.2](#)), a birthday-monotone one exactly when  $\lambda$  is a strong-limit cardinal ([theorem XV.7.4](#)), universal set coding and ordinal abstraction exactly when  $\lambda = \kappa = \beth_\kappa$  ([theorems XV.8.2](#) and [XV.8.4](#)); Class Replacement on a set  $a$  holds exactly when  $|a| < \text{cf } \lambda$ , so full Class Replacement exactly when  $\lambda$  is strongly inaccessible ([lemma XV.9.2](#) and [theorem XV.9.3](#)). The inaccessibility assumed above is therefore exactly what full Class Replacement needs in this family, and the warning that  $V_{\beth_\omega}$  is not such a model is made exact: there Class Replacement fails already on the domain  $\omega$ , although  $S_{\beth_\omega}$  has an ordinal birthday enumeration ([section XV.11](#)). Source 31 does not identify the external orders of clauses (ii)–(iv) at other heights; the external types of the set-like well-orders of  $S_\lambda$  are its [research question 113.241](#).

[merge] Source 09’s inaccessible model is the same setting. Its clause (ii) is the bounded form of [corollary 19.15](#), its clause (iii) of [theorem 19.10](#), and its clause (iv) the bounded form of [theorem 19.43](#); its  $\mathcal{E}_\kappa$  is  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$ , the set-like order of [theorem 21.1\(ii\)](#).

## 22 A concrete universe enlargement: all objects become sets (source 09)

A useful consistency-safe visualization of the size jump is available in ordinary set theory with a strongly inaccessible cardinal. This assumption is for the illustration, not for the earlier ZFC or GBC results.

Fix a strongly inaccessible cardinal  $\kappa$ , put  $X = \mathbf{No}_{<\kappa}$ , and choose a bijection  $b : \kappa \rightarrow X$ . Externally,  $X$  is a set of cardinality  $\kappa$ . In the smaller universe  $V_\kappa$ , it plays the role of the entire surreal class. Every element of  $X$  and every set-length prefix of length below  $\kappa$  belong to  $V_\kappa$ .

Define the external set

$$\mathcal{E}_\kappa = \text{Bij}(\kappa, X)$$

and let  $\mathcal{P}_s^{<\kappa}(b)$  contain its enumerations eventually equal to  $b$  below  $\kappa$ , equivalently the permutations of  $\kappa$  with bounded support. Regularity makes bounded support equivalent here to support of cardinality less than  $\kappa$ .

**Theorem 22.1** (Inaccessible set-sized model). *In this setting:*

- (i)  $|\mathcal{P}_s^{<\kappa}(b)| = \kappa$  and  $|\mathcal{E}_\kappa| = 2^\kappa$ .
- (ii)  $\mathcal{P}_s^{<\kappa}(b) \cong X$ , as linear orders, and the core is order-dense in  $\mathcal{E}_\kappa$ .
- (iii) Every separated pair of families in  $\mathcal{E}_\kappa$  of combined size less than  $\kappa$  has an interpolant in the core.
- (iv) There is a separated  $(\kappa, \kappa)$ -configuration in the core with no interpolant even in  $\mathcal{E}_\kappa$ .

*Proof.* By [proposition 7.3](#),  $|X| = 2^{<\kappa} = \kappa$ . There are fewer than  $\kappa$  permutations on any fixed  $\alpha < \kappa$ ,

because  $\kappa$  is strong limit. Their union over  $\kappa$  stages has size at most  $\kappa$ , and the swaps of position zero with other positions give the reverse bound. The cardinality of  $\mathcal{E}_\kappa$  is  $2^\kappa$  by [note 6.12](#).

For fewer than  $\kappa$  lower and upper constraints, regularity bounds all cross first-disagreement coordinates below  $\kappa$ . The forced-prefix construction in [note 19.12](#) therefore has length below  $\kappa$ . Its chosen separators remain in  $X$ : the option families and previously used values have size below  $\kappa$ , their birthdays are bounded below  $\kappa$ , and (1) supplies a separator of birthday below  $\kappa$ . Prefix completion can be carried out at a larger cardinal still below  $\kappa$ . This proves (iii), and in particular density and the  $< \kappa$ -cut property of the core.

The same birthday argument gives the  $< \kappa$ -cut property of  $X$ . A back-and-forth of length  $\kappa$ , with partial maps of size less than  $\kappa$  at every stage, gives the isomorphism in (ii). Finally repeat [theorem 19.43](#) for  $\alpha < \kappa$  and the nonexhaustive word  $\alpha \mapsto \alpha$  into  $X$ . Both  $-1$  and each required successor ordinal belong to  $X$ , and the same comparison argument proves (iv).  $\square$

This model explains the apparently conflicting assertions that every class-coded portion embeds into the surreal line and yet all enumerations are larger. A class of set codes over  $V_\kappa$  has external size at most  $\kappa$ ; the set  $\mathcal{E}_\kappa$  has external size  $2^\kappa$ . It is an object of the larger universe, not such a class of codes in the smaller universe. External arbitrary families of  $\kappa$  or more class objects are not automatically small-universe sets.

Even externally,  $\mathcal{E}_\kappa$  only represents well-orders of length  $\kappa$ . All well-orders on the external set  $X$  also include lengths  $\alpha$  with  $\kappa < \alpha < \kappa^+$ . Thus a universe jump must record not just the carrier but which ordinal lengths are admitted.

[merge] Source 08's Section 15 discusses the same frameworks and the same full-class model; its (S08.13) is [theorem 21.1\(ii\)](#).

## 23 Universes, class models, and paradox avoidance (source 08)

The preceding proofs can be studied in several foundations, provided the meaning of “all” is kept explicit.

### 23.1 ZFC with definable classes

In ordinary ZFC, **No** is given by a formula defining sign sequences. Statements about a specified finite list of definable class functions can be translated into statements about their formulas. Set-sized cutoffs and all theorems about  $\mathcal{W}(X)$  are ordinary set theorems. Global conclusions can be formulated as schemes relative to specified definable enumerations or in a theory supplying a definable global well-order.

However, “take the set of formulas defining class well-orders and interpret them all in  $V$ ” is not a free replacement for a class collection. Formula codes are sets, but uniform unrestricted truth for all formulas of the universe is a separate issue. One cannot silently insert a full satisfaction predicate for  $V$  into the base theory. Uniformity and definability claims must state their truth resources.

### 23.2 Two-sorted GBC and stronger class theories

In a model  $(M, \mathcal{C})$  of GBC, the virtual collection  $\mathfrak{W}_{\text{sl}}$  means the bijections whose graphs belong to  $\mathcal{C}$ . The cut families in [note 19.13](#) are represented by one relation in  $\mathcal{C}$ , indexed by an  $M$ -set. The skeleton consists of the  $M$ -set support codes, interpreted relative to  $b \in \mathcal{C}$ . All class unions and selections asserted by the proofs are made inside this model.

Passing from GBC to KM strengthens class comprehension, but it still does not make proper classes eligible as members of ordinary classes. Stronger comprehension is not an additional membership sort. A literal object containing every class enumeration belongs to an explicitly higher-order theory or to an external metatheory.

The literature on class recursion gives useful warnings here: even natural uniform truth or forcing relations may require principles stronger than GBC [23, 25]. Our elementary lexicographic operators do not themselves supply such truth relations.

### 23.3 A concrete full-class model at an inaccessible cardinal

Let  $\kappa$  be strongly inaccessible in an external set universe, and consider the full-class model

$$(V_\kappa, \mathcal{P}(V_\kappa)). \quad (\text{S08.12})$$

The second occurrence of  $\mathcal{P}_s$  here is the ordinary power-set notation, not the permutation-code class. Internally,  $\text{Ord}^{V_\kappa}$  is a proper class; externally it is the set  $\kappa$ . Likewise the internal surreal class is externally  $\mathbf{No}_{<\kappa}$  and has cardinality  $\kappa$ .

The full collection of internal global enumerations is, externally,

$$\{e : \kappa \longrightarrow \mathbf{No}_{<\kappa} : e \text{ is a bijection}\}, \quad (\text{S08.13})$$

a set of cardinality  $2^\kappa$ . An internal set-supported perturbation has support of size below  $\kappa$ , equivalently bounded support in  $\kappa$ . There are exactly  $\kappa$  canonical codes: at each bound there are fewer than  $\kappa$  possibilities by strong inaccessibility, and there are  $\kappa$  bounds; the first-entry embedding gives the matching lower bound. Thus externally the skeleton has size  $\kappa$  and the full enumeration order size  $2^\kappa$ .

This is a direct set-theoretic model of the size distinction. The internal isomorphism  $\mathcal{P}_s(b) \cong \mathbf{No}$  becomes an external isomorphism between two  $\kappa$ -sized  $\eta_\kappa$ -orders. Internally “every set cut” means externally every cut specified by fewer than  $\kappa$  elements, not every external set cut.

Also, (S08.13) is the *fixed-length* order  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$ . It is not the external order of all well-orderings of the set  $\mathbf{No}_{<\kappa}$ , which also allows lengths  $\kappa + 1$ ,  $\kappa + \omega$ , and all other ordinals of cardinality  $\kappa$ . Those longer enumerations may have internally proper-class initial segments and are not internal set-like well-orders. This is an important bridge between section 7.2 and the global theory.

Strong inaccessibility is used here to obtain a convenient full model and its size calculation. It is not an additional hypothesis of the GBC theorems: it describes one external way to realize their set/class distinction.

### 23.4 Restricted classes and external viewpoints

For a general class model, enlarging  $\mathcal{C}$  may add new global enumerations and new binary class words while leaving the sets of  $M$  unchanged. Thus the virtual ambient orders depend on the chosen class collection. The explicit formulas for pair coding, prefix extension, and diagonalization still work with their stated parameters in each model, but one must not identify an internal “all” with an external one.

Similarly, an internal well-foundedness assertion in a nonstandard or nontransitive model need not mean external well-foundedness. Concrete full-class models such as (S08.12) avoid some of these ambiguities; unrestricted absoluteness claims do not follow from our proofs.

### 23.5 What prevents the paradoxes

The safeguards are structural. A surreal is a set sign sequence, not a sequence of length  $\text{Ord}$ . Its birthday is a set ordinal. A support code is a set, while its identity extension is a class function. A uniform family is one class relation with set-valued indices, not a set containing proper classes. The full collection of class enumerations is virtual or lives at a higher type. Finally, “every set cut is realized” never means that a separator is required between two arbitrary proper classes.

For instance, a surreal above every ordinal would contradict [proposition 5.4](#); the left options in that purported cut are a proper class, so [theorem 5.6](#) does not apply. Likewise a list of every set-supported code could be a class enumeration, but an exhaustive class-uniform list of all global enumerations is ruled out by [note 19.41](#). Neither obstruction is bypassed by changing notation.

[merge] The three remaining sections are the other sources’ formalization proposals. The modules they name are proposals and do not exist; every existing declaration they cite exists at the current revision, and none of them states a result of this report ([section 1.5](#)).

## 24 A formalization architecture with explicit size boundaries (source 12)

### 24.1 Start with a universe-polymorphic set theorem

The most efficient verified starting point is independent of surreal arithmetic. For a type  $X$  with a linear order, represent a well-order on  $X$  by its binary relation and a proof of well-foundedness and linearity. Define the common prefix by equality of predecessor sets and equality of the restricted relations, exactly as in [section 14.1](#). Prove maximality, distinct next labels, and transitivity of comparison. This gives a generic theorem reusable for reals, surreal cutoffs, and other ordered alphabets.

For a fixed ordinal domain, represent an enumeration as an equivalence between an ordinal’s carrier and  $X$ . For all well-orders of a small  $X$ , using relations on  $X$  often avoids unnecessarily quantifying over every ordinal in a larger universe. The ordinal enumeration can be recovered later from the well-order type. This is a representation choice, not an identification of all ordinals with a small type.

### 24.2 Use the existing sign-sequence foundations selectively

The inspected repository file

`Algebra/SurrealNumbers/Surreal/Foundations/SignSequenceSimplicity.lean`

contains, among others,

```
isPrefix_of_minimum_birthday
existsUnique_prefix_of_ordConnected
existsUnique_minimum_birthday_of_ordConnected
existsUnique_simplest_separator
```

[10]. Its comments explicitly distinguish uniqueness of a simplest separator from existence of separators for arbitrary small cuts. The last theorem assumes a separator exists. It must not be imported as though it independently established all cut-filling instances.

A suitable interface for the order-theoretic development needs a birthday map, a numerical linear order, sign concatenation and truncation, the first-difference comparison, and small-cut existence with a birthday bound. Field operations can be omitted except in illustrative examples.

### 24.3 Suggested proof modules

| Module                         | Principal obligations                                                                                                |
|--------------------------------|----------------------------------------------------------------------------------------------------------------------|
| <code>CommonPrefix</code>      | The elementary definition; initiality; maximality; next-label inequality; generic full lexical linearity.            |
| <code>ExhaustiveLex</code>     | Prefix-freeness; equivalence with ordinal first-difference comparison; transport between relations and enumerations. |
| <code>BinaryCubes</code>       | Cylinder fusion; strict hierarchy; characteristic-cut embeddings; precise ordinal concatenation.                     |
| <code>PermutationCoding</code> | Pair orientation, product scheduler, transpositions, and exhaustive output.                                          |
| <code>BirthdayCutoffs</code>   | Size of $\mathbf{No}_{<\kappa}$ ; prefix-free numerical code; cone partition; regular and singular sums.             |
| <code>ClassFamilies</code>     | A formal set/class model, sections of class relations, baseline enumeration, and diagonal non-enumerability.         |
| <code>UniverseModels</code>    | A chosen inaccessible-rank interpretation; internal/external well-foundedness and identification of the two orders.  |

The finite common-prefix theorem should be proved directly for relations, not by first developing all of ordinal arithmetic. The scheduler proof should record both surjectivity and the first-row-appearance invariant; a bare cardinal pairing equivalence is insufficient. The singular theorem must use ordinal sums, never a cardinal cast that silently loses order.

### 24.4 Universe accounting

Schematically, a sign-sequence type built from small ordinal lengths has one universe level for its ordinal index and potentially a higher level for the total carrier. One should retain explicit levels rather than promise a concrete declaration before checking the chosen ordinal API. A bounded carrier with a specified small birthday bound is the cleanest first implementation.

Three operations must remain visibly different: taking a subtype of one fixed surreal carrier; lifting an existing carrier to a larger universe; and constructing all surreals of the larger universe. The third adds new birthdays and is not merely a type lift. Likewise, a type of relations on a fixed carrier can exist at a higher level without becoming a same-level class of all class relations.

For global theorems, two safe routes are available. One may formalize GB or GBC models and express theorems about their class predicates. Or one may formalize the bounded analogue inside a hierarchy of explicit universes and separately prove its interpretation in a set/class model. Neither route requires an inconsistent type of all types.

### 24.5 Axioms, kernels, and honest validation

A full formalization should record the uses of classical logic, set choice, global choice, and any ambient model-existence assumptions. The common-prefix comparison should not acquire an ETR assumption merely because abstract class order comparison sometimes uses one. The inaccessible-rank example is conditional on that ambient cardinal, whereas the bounded singular theorem needs no inaccessible cardinal.

The present package includes exact executable tests of finite shadows: sign coding, pair coding, the scheduler, the common-prefix formula, and finite adjacency. These are useful implementation

checks and counterexample detectors. They are not kernel-checked proofs of any infinite or class theorem, and no supplied file is advertised as such.

[merge] Source 09's frameworks and Lean dependency plan.

## 25 Formalization strategies and paradox avoidance (source 09)

### 25.1 Four suitable frameworks

**Birthday-bounded ZFC.** For the most immediately formalizable results, fix  $\mathbf{No}_{<\theta}$  and a length bound. Everything is then a set: relations, permutations, words, embeddings, and counterexamples. The exact ordinal spectrum and finite residual adjacency results belong here. No inaccessible cardinal is needed.

**Two-sorted GBC.** Use set variables for surreal numbers, support codes, ordinals, and bounded prefixes; use class variables for global enumerations. Treat  $E <_{\text{lex}} F$  as a formula on class variables. State family theorems with an explicit uniform ternary relation. The core is a genuine class linear order. This framework proves all the global results above without a class-of-classes object.

**A larger universe or explicit higher sorts.** To make the entire collection of smaller-universe global enumerations an object, put it in a larger universe, or use separate sorts for sets, classes, and collections of classes. Membership and comprehension must be stratified. The inaccessible model in [section 22](#) demonstrates one controlled interpretation. A higher-sort theory requires its own axioms; merely writing a new symbol for all classes does not specify one.

**Universe-polymorphic dependent type theory.** A type-theoretic formalization can construct a carrier relative to a universe, then form its function types at an appropriate larger level. It must not infer that those functions are indexed by the original small ordinals or that every large subtype is small. Universe polymorphism handles repeated constructions; it does not identify the universe levels.

### 25.2 Kelley–Morse does not create classes of classes

KM strengthens class comprehension, but its ordinary two-sorted interpretation still has sets as the members of classes. It does not turn proper classes into elements of other classes. Similarly, adding ETR resolves certain class-valued recursion problems but does not invalidate [note 19.40](#). These are separate issues: recursion strength, comprehension strength, and object level.

For non-set-like class well-orders, recursion along predecessors may need class-valued histories. One should therefore not reuse our set-valued recursion justification without checking the new hypotheses. The literature on ETR supplies the appropriate distinctions [\[24, 26\]](#).

### 25.3 Concrete reuse of the ProveIt sign-sequence foundation

At the pinned snapshot, the foundational module declares

```
structure SignSequence : Type (u + 1) where
  birthday : Ordinal.{u}
  signAt : Ordinal.{u} -> SignType
  signAt_ne_zero_iff : ...
```

The ASCII arrow above is only a typographical transcription. The actual module supplies a linear order via zero-extended signs and contains the following relevant named declarations [7]:

| Declaration                        | Role in this project                                   |
|------------------------------------|--------------------------------------------------------|
| <code>lt_iff</code>                | First-disagreement characterization of sign order.     |
| <code>ordinalOrderEmbedding</code> | Increasing embedding of small ordinals.                |
| <code>birthdays_bounded</code>     | Birthday bounds for explicitly small families.         |
| <code>small_bounded</code>         | Smallness of bounded sign fragments.                   |
| <code>not_small</code>             | The entire carrier does not fit in the lower universe. |

The companion cut-operation file contains `cut_realizes` and `birthday_cut_le_iSup`, together with the separator theorem `exists_separator_of_small_sets` [9]. Its documentation explicitly distinguishes this order/cut development from supplying field operations. The present proofs need only the order/cut development.

## 25.4 A proposed Lean dependency plan

A practical implementation should proceed in the following dependency order, keeping the formal claims smaller than the whole manuscript at first.

1. **Fixed-alphabet enumeration order.** Represent an enumeration by its ordinal domain and an equivalence onto a fixed small alphabet. Prove prefix-freeness before defining variable-domain first disagreement. Then prove pair-switch coding, cardinality bounds, and the  $\kappa^+$  stabilization obstruction.
2. **Small injective prefixes.** Prove the extension lemma for a partial injection into a sufficiently large ordinal. Keep the equal cardinality of both complements as an explicit lemma. This part is independent of surreals.
3. **Abstract small-cut alphabets.** Parameterize the avoidance and forced-prefix interpolation lemmas by a linear order with separators for explicitly small option families. Instantiate with the existing sign carrier only afterwards.
4. **Coded support core.** Use a small support, a permutation on it, and a no-fixed-point condition, or use bounded permutations followed by a proved equivalence relation and canonical normalization. Supply a baseline equivalence as an explicit parameter.
5. **Large-family interface.** Represent rows by a single function or relation, retain its universe levels, and prove bounded reflection for small index types. State separately which large index orders possess an ordinal enumeration with small initial segments.
6. **Back-and-forth and the diagonal.** Formalize the set-valued recursion invariant. Only after its smallness obligations are discharged should the abstract core isomorphism and no-coding statements be instantiated.

In a universe-indexed version, a proposed baseline has the shape  $\text{Ordinal}.\{u\} \simeq \text{SignSequence}.\{u\}$ . Its existence is not inferred here merely because both types live in  $\text{Type}(u + 1)$ ; equal universe level does not imply equipotence. Likewise, the type of *all* functions between these carriers can be formed in the ambient type theory without becoming a small-universe class of set codes. This is exactly the distinction exhibited by [theorem 22.1](#).

## 25.5 A checklist of invalid shortcuts

The following shortcuts would change the mathematical problem or introduce an unjustified assumption:

- treating **No** as a set in its original universe, or treating all global enumerations as members of an ordinary class;
- using an arbitrary class option family in the surreal cut constructor, or replacing set-indexed interpolation by class-indexed interpolation;
- assuming every class well-order has type `Ord`, or confusing the well-order represented by an enumeration with the lexicographic order of enumerations;
- completing a partial injection without checking complement cardinalities, or using a set of individually given class witnesses without a uniform family relation;
- transferring a proof of equimorphism to isomorphism, or assuming an order embedding preserves ambient suprema;
- attributing the new global core and diagonal theorems to existing Lean declarations merely because the requisite sign-cut primitives are present.

[merge] Source 08’s Lean plan. The declarations of its table exist; source 08 correctly identifies `exists_cut_separator_of_birthday_lt` as the formal landing point of [theorem 5.6](#) and [corollary 5.7](#) ([section 1.5](#)).

## 26 A Lean formalization plan tied to ProveIt (source 08)

The repository was inspected at commit

ae7c1e6aae3dc58c9c638b35646865ad6c10387d.

The relevant project is `Algebra/SurrealNumbers`. Its README explicitly distinguishes research drafts from machine-checked results and describes an axiom audit [6]. This manuscript uses that distinction rather than treating all repository prose as a formal theorem.

### 26.1 Inspected declarations

The source `Surreal/Foundations/SignSequence.lean` defines a universe-indexed carrier of the form

```
structure SignSequence : Type (u + 1) where
  birthday : Ordinal.{u}
  signAt : Ordinal.{u} -> SignType
  signAt_ne_zero_iff :
    forall i, Iff (Not (signAt i = 0)) (i < birthday)
```

This display is an ASCII rendering of the inspected declaration, not a new compiled file. Its zero extension uses the ordered values minus, termination, and plus. The source gives the numerical linear order via Mathlib’s lexicographic function `order` and proves `lt_iff`, `ordinalOrderEmbedding`, `birthdays_bounded`, `small_strict_upper_bounds`, `not_small`, and `small_bounded` [7].

Two declarations in `SignSequenceCut.lean` are particularly relevant: `exists_cut_separator_of_birthday_lt` and `small_cut_fillers`. The construction uses full-length binary words, uses their complete lexicographic order, and produces a separator of exactly a prescribed birthday above

all option birthdays [8]. This is the formal landing point for [theorem 5.6](#) and [corollary 5.7](#); it is stronger than merely having a dense linear order.

| Inspected ingredient                             | Role in a formalization                                                        |
|--------------------------------------------------|--------------------------------------------------------------------------------|
| <code>SignSequence.lt_iff</code>                 | Express every comparison by its least differing coordinate                     |
| <code>birthdays_bounded</code>                   | Bound options indexed by a lower-universe small type                           |
| <code>not_small</code>                           | Exclude collapsing the whole carrier into the birthday universe                |
| <code>small_bounded</code>                       | Represent a fixed birthday fragment by a genuinely small type                  |
| <code>exists_cut_separator_of_birthday_lt</code> | Choose a separator outside a small forbidden family by increasing its birthday |
| <code>small_cut_fillers</code>                   | Discharge the ordered-cut interface used by the abstract arguments             |

## 26.2 Smallness is not the same as having a type

In Lean, `SignSequence.{u}` and `Ordinal.{u}` live in `Type (u + 1)`. They are not small relative to universe `u`. A `Set SignSequence` is a predicate on the whole larger carrier; it need not be a small family of surreals. Thus a formal cut theorem must carry a condition such as `Small.{u} I` on its index type, not merely declare its options to be a `Set`.

The same applies to permutations. A predicate-defined support in the larger universe is not automatically an admissible set support at the smaller level. The orbit should use explicit small support codes or an equivalent `Small.{u}` hypothesis. Otherwise the crucial prefix bound and the intended distinction between skeleton and full enumeration space are lost.

One safe interface keeps an equivalence

```
b : Equiv Ordinal.{u} SignSequence.{u}
```

as an explicit parameter. The present manuscript does not claim that the repository already constructs this equivalence with all the required relative-smallness properties. An implementation must either prove that baseline theorem in its universe framework or retain the baseline as a stated assumption.

## 26.3 Suggested module boundaries

The following are proposed modules, not existing files or completed formalizations.

1. `WellOrders/Exhaustive.lean`: exhaustive enumerations of a fixed carrier, no-prefix ambiguity, first-disagreement order, and relations versus enumerations.
2. `WellOrders/PairCoding.lean`: binary pair blocks, small-order universality, cardinality, prefix stabilization, and the exact ordinal spectrum.
3. `WellOrders/FiniteTails.lean`: cylinder extrema, adjacency, and finite-condensation blocks.
4. `WellOrders/PrefixExtension.lean`: small partial injections, choice of a larger support bound, complement bijections, and canonical moved-point codes.
5. `WellOrders/SetCuts.lean`: the active-row invariant, the bound on cross-disagreement coordinates, stopping, and strict separation before completion.
6. `WellOrders/BoundedPermutations.lean`: the code carrier, its small-cut interface, and the relative-universe form of the surreal-skeleton theorem.
7. `WellOrders/ClassBinaryCoding.lean`: terminal block codes, ordinal concatenation, and uniform diagonalization in the chosen higher-type representation.

The first three modules can be developed without surreal arithmetic or class metatheory. The next three isolate the delicate smallness and extension arguments. The final module should be delayed until the meaning of a uniform operator on larger function types is fixed.

## 26.4 Two complementary implementation routes

A *cutoff-first* implementation proves theorems for  $\mathbf{No}_{<\kappa}$  and  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$  with explicit regularity and cardinal hypotheses. All carriers are ordinary types and the formal statements closely match [note 7.6](#). This is the simplest route to substantial checked mathematics.

A *universe-relative* implementation abstracts over a large ordered carrier, a lower-universe small-cut operation, and a baseline equivalence. It formalizes the local orbit argument relative to that notion of smallness. Care is needed when proving back-and-forth: an arbitrary well-order of a large type may have initial segments too large for the small-cut operation. One must use an enumeration whose proper initial segments are small, rather than invoke an unrestricted large-type choice order.

A third option is a deep formalization of a two-sorted class theory or of a specified model  $(M, \mathcal{C})$ . This is the best route for comparing axiomatic strengths and internal/external semantics, but is not necessary to certify the set-sized combinatorics.

## 26.5 Trust boundary

The cited repository files were read, not rebuilt in this work. No new Lean module accompanies this manuscript, and no new kernel-checking claim is made. A future implementation should pin the repository and Mathlib revisions, compile in dependency order, reject unfinished proofs, and inspect the resulting axiom dependencies. Finite tests of codes, even exhaustive ones, cannot certify the class interpolation or back-and-forth arguments.

[merge] The four plans agree on a first milestone that is independent of surreal arithmetic: the predecessor or common-prefix comparison of well-orders on a small carrier, prefix-freeness and the successor-cardinal obstruction, then bounded-support prefix completion and small-family interpolation, reusing the existing small-cut interface. This is a proposal recorded for the collection's formalization work; no such module exists.

## Part VI

# Set-sized strata: topology, cut spectra and block types

[merge] (3 October 2026.) This Part opens the batch-81 addition of six further manuscripts, sources 13–18 ([section 1.8](#)); its notation is fixed in [section 1.3.1](#). It prints everything the six sources prove about set-sized enumeration orders: the density and cellularity of every stratum  $\mathcal{W}_\alpha(X)$  of every infinite linear alphabet ([section 27](#)), conditional incompleteness and global characters ([section 28](#)), the cut spectrum of the alphabet  $\mathbf{No}_{<\kappa}$  ([section 29](#)), the characters, fusion theorem, exact gap spectrum and gap multiplicities of the minimal slice  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  ([section 30](#)), the coding lengths, cube spectra and density of the longer strata  $\mathcal{W}_{\mu \cdot \gamma + n}(\mathbf{No}_{<\kappa})$  ([section 31](#)), and the six sources' set-sized baselines and warnings ([section 32](#)). [Section 33](#) records which questions of this report and of the reals report the Part answers.

The bases are chosen by generality, as in Parts I–V: source 16 for density, cellularity and incompleteness (every infinite alphabet, every stratum), source 17 for the alphabet and the minimal slice (every infinite cardinal cutoff, with no hypothesis on  $2^{<\kappa}$ ), source 15 for the longer strata (the only source treating them). Source 18, written before sources 13–17 had arrived and without knowledge of them, proves most of the minimal-slice results a third time; its density, characters and interpolation proofs differ in detail and are printed as routes, its gap-spectrum proof repeats source 17's and is recorded in notes, and its general permutation principle and exact gap multiplicities are new and printed in full. The whole Part is set theory in ZFC; no class is involved.

Throughout the Part,  $\kappa$  is an infinite cardinal used as a birthday cutoff,  $\mu = 2^{<\kappa} = |\mathbf{No}_{<\kappa}|$ ,  $r = \text{cf } \kappa$  and  $q = \text{cf } \mu$ ; a general alphabet  $X$  is an infinite linearly ordered set of cardinality  $\mu$ . Source 16 wrote  $\kappa$  for  $|X|$  and  $\theta$  for the cutoff, and source 18 wrote  $\nu, \tau$  for  $r, q$ ; their text is printed in the convention above (section 1.3.1).

## 27 Density and cellularity at every fixed type (source 16)

[merge] Source 16's Section 5, printed whole. Its  $\kappa$  (the cardinality of  $X$ ) is printed  $\mu$ , its cutoff  $\theta$  is printed  $\kappa$ , and its  $d, c$  are printed  $d, \text{cell}$  (section 1.3.1); its equations keep their numbers as (S16.n). Source 18 proves the same theorem independently, with a different lemma and a different lower-bound family (section 27.1); the reals report proves the case  $X = \mathbb{R}$  (note 27.5).

For a set linear order  $L$  with its *order topology*, let  $d(L)$  be the least cardinality of a dense subset. Let  $\text{cell}(L)$  be the supremum of the cardinalities of families of pairwise disjoint nonempty open sets. Always  $\text{cell}(L) \leq d(L) \leq |L|$ . A prefix cylinder is the collection of enumerations extending one fixed injective prefix. Cylinders are convex, but need not themselves be open. Our lower bounds use actual open intervals lying inside cylinders; our upper bounds use a family that meets every nonempty open set.

**Lemma 27.1** (No jump between distinct short-prefix branches). *If  $e < f$  in  $\mathcal{W}_\alpha(X)$  first differ at a coordinate  $\delta < \mu$ , then they are not adjacent.*

*Proof.* Write  $p = e \restriction \delta = f \restriction \delta$  and  $a = e(\delta) < b = f(\delta)$ . If there is no point between  $e$  and  $f$ , then  $e$  must be the maximum of its  $p \frown a$  cylinder, and  $f$  the minimum of its  $p \frown b$  cylinder. Any ascent in the remaining suffix of  $e$  can be swapped to produce a larger member of its cylinder. Thus that suffix is numerically strictly decreasing. Similarly, the suffix of  $f$  must be strictly increasing. Their common remaining label set is  $X \setminus (\text{ran}(p) \cup \{a, b\})$ , of cardinality  $\mu$ . Its numerical order would be both a well-order and a reverse well-order. An infinite linear order cannot have both properties. This contradiction proves the claim.  $\square$

**Theorem 27.2** (Exact density and cellularity). *Let  $|X| = \mu$  be infinite and  $|\alpha| = \mu$ . Then*

$$d(\mathcal{W}_\alpha(X)) = \text{cell}(\mathcal{W}_\alpha(X)) = \begin{cases} \mu^{<\mu}, & \alpha = \mu, \mu + 1, \text{ or } \mu + 2, \\ 2^\mu, & \text{all other } \alpha. \end{cases} \quad (\text{S16.3})$$

*Moreover  $d(\mathcal{W}(X)) = \text{cell}(\mathcal{W}(X)) = 2^\mu$ . No regularity assumption is needed.*

*Proof.* For any  $\delta < \mu$  there are  $\mu^{|\delta|}$  injective prefixes of length  $\delta$ , and each extends to an admissible enumeration. One way to see the lower count is to choose, for each coordinate, its label in a separate  $\mu$ -sized cell of a partition of  $X$ ; the choices are automatically injective. Every such cylinder contains

at least three points and hence a nonempty ambient open interval. Distinct cylinders at one level are disjoint and convex. Consequently

$$\text{cell}(\mathcal{W}_\alpha(X)) \geq \sup_{\delta < \mu} \mu^{|\delta|} = \mu^{<\mu}.$$

Suppose  $\alpha = \mu + n$ ,  $n \leq 2$ . Group enumerations by their common prefix of length  $\mu$ . A nonempty group has exactly  $n!$  points, coming from the permutations of the omitted  $n$  labels. Thus every group has at most two points. By [Lemma 27.1](#), distinct groups have dense quotient order: if two groups were consecutive, the last point of the first and first point of the second would be adjacent and differ before  $\mu$ .

It follows that every nonempty open set contains a cylinder specified before  $\mu$ , except possibly a singleton consisting of an isolated global endpoint. Indeed, select a group strictly between the relevant boundary groups, choose a member of it, and bound its first disagreement with the boundaries by a coordinate below  $\mu$ . The resulting prefix cylinder lies inside the open set. Select one completion for each injective prefix of length less than  $\mu$  and add any isolated global endpoints. This gives a dense set of size at most

$$\sum_{\delta < \mu} \mu^{|\delta|} = \mu^{<\mu}.$$

Together with the lower bound this proves the first line of [\(S16.3\)](#), including singular  $\mu$ .

If  $\alpha = \mu + n$  for finite  $n \geq 3$ , fix  $F \subseteq X$  of size  $n$ . There are  $2^\mu$  bijections  $p : \mu \rightarrow X \setminus F$ . The completion cylinder for each is a finite convex chain of  $n! \geq 6$  points. An interior point has both immediate neighbors in that chain; the interval between those neighbors is its singleton, an open set in the entire order. Different prefixes give  $2^\mu$  disjoint open singletons.

In every remaining case  $\alpha \geq \mu + \omega$ . Let  $\tau$  be the order type of the interval  $[\mu, \alpha)$ , so  $\alpha = \mu + \tau$  and  $|\tau|$  is infinite. Choose  $Y \subseteq X$  with  $|Y| = |\tau|$  and  $|X \setminus Y| = \mu$ . Each of the  $2^\mu$  bijections  $p : \mu \rightarrow X \setminus Y$  gives a convex cylinder of completions with residual order  $\mathcal{W}_\tau(Y)$ . Every such cylinder has at least three points, so supplies a nonempty ambient open interval. These intervals are pairwise disjoint. The cardinal upper bound  $|\mathcal{W}_\alpha(X)| \leq 2^\mu$  finishes the proof for all strata.

For  $\mathcal{W}(X)$  use the same construction with a fixed residual set of three labels. The resulting six-point cylinders are convex even when all enumeration lengths are admitted. Thus  $\text{cell}(\mathcal{W}(X)) \geq 2^\mu$ , and the cardinality bound gives equality throughout.  $\square$

*Remark 27.3* (Why two terminal labels differ from three). There can be  $2^\mu$  adjacent pairs in  $\mathcal{W}_{\mu+2}(X)$  while its density is only  $\mu^{<\mu}$ . An adjacent pair does not contain an open interval. Three or more terminal labels give a permutation block with an interior point, and that point is isolated. This is why the topological transition occurs at  $\mu + 3$ , rather than  $\mu + 1$  or  $\mu + 2$ . If  $\mu^{<\mu} = 2^\mu$ , the two displayed values coincide; the structural distinction still holds.

**Corollary 27.4** (Birthday-stage topology). *For every infinite cardinal  $\kappa$ , put  $\mu = 2^{<\kappa}$ . Formula [\(S16.3\)](#) applies to  $\mathbf{No}_{<\kappa}$ , whose cardinality is  $\mu$ . If  $\kappa$  is regular and  $2^{<\kappa} = \kappa$ , the first three strata have density and cellularity  $\kappa$ , whereas all later strata and the full order have density and cellularity  $2^\kappa$ .*

*Proof.* Only the last simplification needs comment. Regularity and  $2^{<\kappa} = \kappa$  imply  $\kappa^{<\kappa} = \kappa$ : for  $\lambda < \kappa$ , every function  $\lambda \rightarrow \kappa$  has bounded range, and for  $\rho < \kappa$  one has  $\rho^\lambda \leq 2^{\rho^\lambda} \leq \kappa$ . Taking the union of  $\kappa$  bounds proves the assertion.  $\square$

*Note 27.5* ([merge]; the reals report's case). For  $X = \mathbb{R}$ , the reals report proves  $d(\mathcal{W}_\alpha) = \text{cell}(\mathcal{W}_\alpha) = 2^{<\mathfrak{c}}$  for  $\alpha \in \{\mathfrak{c}, \mathfrak{c} + 1, \mathfrak{c} + 2\}$  and  $2^\mathfrak{c}$  for  $\mathfrak{c} + 3 \leq \alpha < \mathfrak{c}^+$  (lwo:prop:all-strata-density), with the

adjacent pairs at  $\mathfrak{c} + 2$  and the isolated points from  $\mathfrak{c} + 3$  on (`lwo:prop:finite-topology`) and the minimal slice in `lwo:prop:fixed-topology`. Since  $\mathfrak{c}^\lambda = 2^\lambda$  for infinite  $\lambda < \mathfrak{c}$ , one has  $\mathfrak{c}^{<\mathfrak{c}} = 2^{<\mathfrak{c}}$ , and [theorem 27.2](#) with  $X = \mathbb{R}$  is exactly that result, by the same two mechanisms (short-prefix cylinders, and the finite terminal permutation block). Source 16 does not cite these statements; it cites the reals report only for the set baseline ([note 32.1](#)). New in source 16 is the generality: every infinite linear alphabet, of any cardinality including singular ones and  $\aleph_0$ , with no density or saturation assumption on  $X$ .

*Note 27.6* ([`merge`]; the birthday-cutoff instances, and why three formulas agree). For  $X = \mathbf{No}_{<\kappa}$ , [corollary 27.4](#) gives  $d = \text{cell} = \mu^{<\mu}$  on  $\mathcal{W}_\mu$ ,  $\mathcal{W}_{\mu+1}$ ,  $\mathcal{W}_{\mu+2}$  and  $2^\mu$  on every longer stratum. Three other sources compute instances: source 17 for the minimal slice ( $d = w = \text{cell} = \mu^{<\mu}$ , [theorem 30.2](#)), source 18 for every stratum of every alphabet ([theorems 27.8](#) and [27.9](#), printed next), and source 15 for the block types  $\mathcal{W}_{\mu \cdot \gamma + n}$ , with the value  $2^{<\mu}$  when  $\rho_\kappa = \mu$ ,  $\gamma = 1$  and  $n \leq 2$ , and  $2^\mu$  otherwise ([corollary 31.7](#)). The formulas agree. If  $\mu > \kappa$  then  $\mu \leq 2^\kappa$ , so for  $\lambda < \mu$  one has  $\mu^\lambda \leq 2^{\kappa \cdot \lambda} = 2^{\max(\kappa, \lambda)} \leq 2^{<\mu}$ , whence  $\mu^{<\mu} = 2^{<\mu}$ . If  $\mu = \kappa$  is regular then  $2^{<\kappa} = \kappa$  and  $\kappa^{<\kappa} = \kappa$  (proof of [corollary 27.4](#)). If  $\mu = \kappa$  is singular,  $\kappa$  is a strong limit,  $\rho_\kappa = \kappa \cdot \kappa$  falls under source 15's second case, and  $\kappa^{<\kappa} = 2^\kappa$  ([corollary 30.26](#)). In every case the four sources give the same cardinal.

## 27.1 Source 18's route: exact cardinal invariants of bounded enumeration orders

[`merge`] Source 18's Section 4 up to its residual-alphabet subsection, printed whole as a second route to [theorem 27.2](#). Source 18 presents these theorems as advances; within batch 81 source 16 proves them too, and source 18 could not know it (its pin precedes the arrival of sources 13–17). Source 18's status table says that its proof review “corrected the arbitrary-alphabet density construction to include possible isolated global endpoints”; source 16's proof treats the same endpoints (“except possibly a singleton consisting of an isolated global endpoint”). Its remaining subsections are printed in [section 30.8](#), its residual-alphabet lemmas in [notes 29.8](#) and [29.9](#).

Throughout this section,  $X$  is an infinite linearly ordered set of cardinality  $\mu$ , identified with its initial ordinal when it is used as an index. If  $|\alpha| = \mu$ , write

$$\mathcal{W}_\alpha(X) = \{e : \alpha \longrightarrow X : e \text{ is bijective}\},$$

ordered by the first unequal coordinate. A proper-prefix comparison never occurs between two exhaustive enumerations of the same carrier. We use  $d(L)$  for the least cardinality of a topologically dense subset of the order topology, and  $\text{cell}(L)$  for the supremum of the cardinalities of pairwise disjoint families of nonempty open sets. The lower-bound families constructed below attain the asserted cellularities, so no convention concerning whether the supremum is attained affects the answers. All assertions in this section are theorems of ZFC.

### 27.1.1 Prefix cylinders and the minimal enumeration type

For an injective prefix  $p : \delta \rightarrow X$ ,  $\delta \leq \alpha$ , its cylinder is

$$C_p = \{e \in \mathcal{W}_\alpha(X) : e \restriction \delta = p\}.$$

Every cylinder is convex. If  $\delta < \mu$ , the cylinder is nonempty: both the unused alphabet and the remaining index set have cardinality  $\mu$ , so a bijection between them completes the prefix. Such a cylinder has at least three elements, obtained, for example, by permuting three unused labels in a fixed completion. It therefore contains a nonempty open interval of the ambient enumeration order. The entire cylinder need not be open; the proof uses only the open interval it contains.

**Lemma 27.7** (The dense order of cofinite prefixes). *For  $n < \omega$ , let*

$$Q_n(X) = \{p : \mu \rightarrow X : p \text{ is injective and } |X \setminus \text{ran } p| = n\}.$$

*With first-difference comparison,  $Q_n(X)$  is a dense linear order. Consequently  $\mathcal{W}_\mu(X) = Q_0(X)$  is dense.*

*Proof.* Take  $p < p'$  and let  $\delta < \mu$  be their first disagreement. If there are  $\delta < \beta < \gamma < \mu$  with  $p(\beta) < p(\gamma)$ , interchanging these two entries gives  $p < s < p'$ , with  $s \in Q_n(X)$ . Similarly, a descent  $p'(\beta) > p'(\gamma)$  after  $\delta$  gives  $p < s < p'$  by an interchange in  $p'$ . If neither operation is available, the tail of  $p$  after  $\delta$  is strictly decreasing and the tail of  $p'$  after  $\delta$  is strictly increasing. Their ranges have an infinite common subset: they omit from  $X$  only their common prefix, of size less than  $\mu$ , two first-disagreement labels, and two finite sets of omitted labels. On that common subset the numerical order would be both a well-order and a reverse well-order. This is impossible for an infinite set. Indeed, an infinite well-order contains an initial suborder of type  $\omega$ , which has no largest element. Thus one of the interchanges is available.  $\square$

**Theorem 27.8** (Exact density and cellularity at the minimal type). *For every infinite linearly ordered alphabet  $X$  of cardinality  $\mu$ ,*

$$d(\mathcal{W}_\mu(X)) = \text{cell}(\mathcal{W}_\mu(X)) = \mu^{<\mu}.$$

*No regularity assumption on  $\mu$ , and no density assumption on  $X$ , is needed.*

*Proof.* There are  $\mu^{<\mu}$  injective prefixes of length less than  $\mu$ . For the upper bound, choose one completion for each such prefix. Given  $e < f$ , density supplies  $g$  strictly between them. Choose  $\delta < \mu$  larger than both first-disagreement coordinates of  $(e, g)$  and  $(g, f)$ . Then  $C_{g|\delta} \subseteq (e, f)$ , so the selected completions are dense. Since a dense linear order with at least two points has no isolated endpoint, meeting all nonempty open intervals also gives topological density. This proves  $d \leq \mu^{<\mu}$ , and a dense set meets every member of a disjoint nonempty open family, giving  $c \leq d$ .

For the lower bound, choose distinct labels  $a_\delta \in X$  for  $\delta < \mu$ . For each  $\delta$ , take every injective prefix of length  $1 + \delta$  whose first label is  $a_\delta$ . There are  $\mu^{|\delta|}$  such prefixes. To justify this count for infinite  $\delta$ , functions  $\delta \rightarrow \mu$  can be encoded as injective maps  $\delta \rightarrow \delta \times \mu \cong \mu$  by recording the coordinate alongside its value; the reverse inequality is immediate. The finite cases are equally direct. Prefixes in different chosen levels have different first labels, while two distinct prefixes within a level have equal lengths and disagree. Their cylinders are therefore pairwise disjoint. Choose one nonempty open interval in each cylinder. The resulting disjoint family has cardinality

$$\sum_{\delta < \mu} \mu^{|\delta|} = \mu^{<\mu},$$

because  $1 + \delta < \mu$  for every  $\delta < \mu$ . This proves the lower bound and also proves that the stated cellularity is attained.  $\square$

### 27.1.2 A sharp transition at the third terminal coordinate

**Theorem 27.9** (Density and cellularity for every fixed type). *If  $|X| = \mu$  is infinite and  $\mu \leq \alpha < \mu^+$ , then*

$$d(\mathcal{W}_\alpha(X)) = \text{cell}(\mathcal{W}_\alpha(X)) = \begin{cases} \mu^{<\mu}, & \alpha \in \{\mu, \mu + 1, \mu + 2\}, \\ 2^\mu, & \mu + 3 \leq \alpha < \mu^+. \end{cases}$$

*These formulas are valid for arbitrary numerical orders on  $X$ .*

*Proof.* First take  $\alpha = \mu + n$  with  $n \leq 2$ . Restriction to the first  $\mu$  coordinates exhibits  $\mathcal{W}_{\mu+n}(X)$  as a lexicographic sum over  $Q_n(X)$  of finite fibers of size  $n!$ ; the omitted  $n$  labels are the only possible final labels. Each fiber has at most two points. By Lemma 27.7, the quotient  $Q_n(X)$  is dense. Thus every nonempty open interval in  $\mathcal{W}_{\mu+n}(X)$  contains a point whose  $\mu$ -prefix lies strictly between the prefixes of its two bounds: if the bounds had the same prefix, their fiber of at most two points would have empty open interval. A prefix of this intermediate point of length less than  $\mu$ , taken beyond both relevant first disagreements, has its entire cylinder inside the interval. Choose one completion of every prefix of length less than  $\mu$ , and also include the global least and greatest points whenever they exist. The resulting family is topologically dense: it meets every nonempty open interval, while the added endpoints handle a possible isolated endpoint in a two-point terminal fiber. Adding at most two points does not change its cardinality bound  $\mu^{<\mu}$ . The antichain of cylinders from the preceding proof gives the matching lower bound. This argument explicitly deals with the possible jumps when  $n = 2$ ; it does not assume that every cylinder is open, or that every interval contains a point separated from both bounds merely by choosing an arbitrary intermediate point.

Now suppose  $\alpha \geq \mu + 3$ , and write  $\alpha = \mu + \beta$ , where  $\beta$  is the order type of its tail after the first  $\mu$  positions. Choose  $T \subseteq X$  with  $|T| = |\beta|$  and  $|X \setminus T| = \mu$ . If  $|\beta| = \mu$ , use a partition of  $X$  into two  $\mu$ -element sets; otherwise remove a set of size  $|\beta|$ . There are  $2^\mu$  bijections  $p : \mu \rightarrow X \setminus T$ . This standard count follows either from the cardinality theorem for well-order enumerations or directly by orienting  $\mu$  disjoint pairs of labels. For each such  $p$ , the cylinder  $C_p$  consists of all continuations that biject  $\beta$  onto  $T$ . Since  $\beta \geq 3$ , it contains at least three points and hence a nonempty open interval. The cylinders are pairwise disjoint because the prefixes are distinct and have the same length. We obtain  $2^\mu$  disjoint nonempty open intervals. On the other hand,  $|\mathcal{W}_\alpha(X)| \leq \mu^\mu = 2^\mu$ , so no density or cellularity can exceed  $2^\mu$ .  $\square$

*Remark 27.10.* For  $\mu^{<\mu} < 2^\mu$ , the values for  $\mu + 2$  and  $\mu + 3$  differ. Thus merely adding one terminal coordinate can change both density and cellularity. For singular strong-limit  $\mu$ , both expressions are already  $2^\mu$ , so the geometric distinction remains but the cardinal invariants coincide. The formula is a new consequence beyond the baseline's finite-residual adjacency classification; it is not a new claim about the already-established ordinal embedding spectrum.

## 28 Countable incompleteness and global characters (source 16)

[merge] Source 16's Section 6 up to its subsection on regular saturated stages, which is printed in section 30.4.

Conditional Dedekind completeness means that every nonempty bounded-above set has a supremum, equivalently every nonempty bounded-below set has an infimum. It should not be confused with filling all small strict cuts, with order density, or with the completeness of a separately adjoined Dedekind completion.

**Theorem 28.1** (Every infinite stratum is incomplete). *For every infinite linearly ordered set  $X$  and every ordinal  $\alpha$  with  $|\alpha| = |X|$ ,  $\mathcal{W}_\alpha(X)$  is not conditionally Dedekind complete. A countable bounded monotone family witnesses this failure. The same conclusion holds for  $\mathcal{W}(X)$ .*

*Proof.* Every infinite linear order contains an increasing or decreasing  $\omega$ -sequence. For completeness, choose a countable set of distinct points and color each pair of its indices according to the numerical comparison; the infinite Ramsey theorem gives such a sequence. First assume  $a_0 < a_1 < a_2 < \dots$  in  $X$ , and put  $p(n) = a_{2n}$ .

For each  $n \geq 0$  choose  $U_n$  extending the finite prefix

$$(a_0, a_2, \dots, a_{2n-2}, a_{2n+1}),$$

and for  $n \geq 1$  choose  $L_n$  extending

$$(a_0, a_2, \dots, a_{2n-2}, a_{2n-1}).$$

All these prefixes extend to the prescribed type  $\alpha$ . First disagreement gives  $L_n < L_{n+1}$ ,  $U_{n+1} < U_n$ , and  $L_n < U_m$  for all  $n, m$ . Hence  $(U_n)$  is bounded below.

Let  $g$  be any lower bound. If it first differs from the infinite prefix  $p$  at a finite coordinate  $j$ , it must differ downward: an upward difference would give  $g > U_{j+1}$ . Consequently  $g < L_n$  for every  $n > j$ , so it is not the greatest lower bound.

Otherwise  $g$  agrees with all of  $p$ . Its remaining suffix contains all odd labels  $a_{2n+1}$ . That suffix cannot be numerically strictly decreasing: the positions of these increasing labels would form an infinite descending sequence of ordinals. It therefore has an ascent. Swap the two labels of such an ascent. The new enumeration has the same type, is strictly above  $g$ , and still agrees with  $p$  at every finite coordinate. It remains below every  $U_n$ . Again  $g$  is not greatest. If no completion of  $p$  with the specified type exists, this second case simply never occurs.

Thus  $(U_n)$  has no infimum. Reversing the numerical alphabet treats a decreasing  $\omega$ -sequence and yields the dual failure of a supremum. The argument for the full order is identical: swapping an ascent preserves whatever ordinal type the candidate bound happens to have.  $\square$

**Proposition 28.2** (Global characters from the first label). *If  $X$  has no greatest element, then*

$$\text{cf}(\mathcal{W}_\alpha(X)) = \text{cf}(\mathcal{W}(X)) = \text{cf}(X)$$

*for every admissible infinite  $\alpha$ . There is a dual statement for coinitality when  $X$  has no least element. In particular, for every infinite cardinal cutoff  $\kappa$ , all the fixed strata and the full order on  $\mathbf{No}_{<\kappa}$  have global cofinality and coinitality  $\text{cf}(\kappa)$ .*

*Proof.* Complete a cofinal family of possible first labels to enumerations. It is cofinal in the lexicographic order. Conversely, the first labels of a cofinal family of enumerations must be cofinal in  $X$ , or a larger first label would put an enumeration above the entire family. For  $\mathbf{No}_{<\kappa}$ , the ordinals below  $\kappa$  are numerically cofinal and the negatives coinital. Any family with bounded birthdays is bounded numerically, so the least possible size is  $\text{cf}(\kappa)$ .  $\square$

*Note 28.3* ([merge]; global characters in sources 15, 17 and 18). For the minimal slice of  $\mathbf{No}_{<\kappa}$ , the global part of [proposition 28.2](#) ( $\text{cf} = \text{ci} = r$ ) is also proved by source 17 ([theorem 30.2](#), with the same value for every cylinder in [lemma 30.1](#)), by source 15 ([note 30.7](#)) and by source 18 ([theorem 30.24](#), also for  $\mathcal{W}_{\mu+n}$ , and [note 30.13](#) for cylinders), each by the same first-label projection. Source 16's proposition is the general form: it holds for every stratum and for the full order  $\mathcal{W}(X)$  of any alphabet without a greatest element. Source 16's subsection "Regular saturated stages", the last part of its Section 6, is printed in [section 30.4](#) with the other gap spectra.

## 29 The cut spectrum of the alphabet $\mathbf{No}_{<\kappa}$ (source 17)

[merge] Source 17's Section 4, printed whole. Its  $\Sigma(L)$  is printed  $\text{GapChar}(L)$  (the reals report's symbol), and its displayed equations keep their numbers as (S17. $n$ ). At regular uncountable  $\kappa$  its main theorem is already in the repository ([note 29.7](#)). Sources 15 and 18 prove the alphabet lemmas again; their statements follow in [notes 29.8 to 29.10](#).

For the remainder of the set-sized analysis, fix an infinite cardinal  $\kappa$ , regarded as an initial ordinal, and write

$$X = \mathbf{No}_{<\kappa}, \quad \mu = 2^{<\kappa}, \quad r = \text{cf } \kappa, \quad q = \text{cf } \mu. \quad (\text{S17.3})$$

Here  $\mathbf{No}_{<\kappa}$  consists of all sign sequences of ordinal length below  $\kappa$ , ordered by first difference with  $- < \text{termination} < +$ . We write  $\text{Reg}$  for the infinite regular cardinals. No arithmetic closure of  $X$  is assumed. In particular, no field hypothesis is being inferred from the mere fact that  $\kappa$  is a cardinal.

**Definition 29.1** (Characters and genuine gaps). For a point  $x$  of a dense order  $L$  without endpoints, its left and right characters are  $\text{cf}(L_{<x})$  and  $\text{ci}(L_{>x})$ . A *gap* is a partition  $L = A \sqcup B$  into nonempty initial and final parts, with  $A < B$ , such that  $A$  has no greatest element and  $B$  no least element. Its character is  $(\text{cf } A, \text{ci } B)$ ;  $\text{GapChar}(L)$  denotes the set of these pairs. Thus a split immediately before or after an actual point is not a gap. Cofinalities of orders with a greatest element would be 1, but do not occur in  $\text{GapChar}(L)$ .

## 29.1 Size, intervals, and deletion

**Lemma 29.2.** *The order  $X$  has cardinality  $\mu$ . Every nonempty open interval and every nonempty open ray in  $X$  has cardinality  $\mu$ . Consequently, deletion of fewer than  $\mu$  labels leaves an order-dense, cofinal and coinitial suborder, with  $\mu$  labels still in each nonempty interval and ray.*

*Proof.* There are  $2^{|\alpha|}$  sign sequences of length  $\alpha$ , so  $|X| = \sum_{\alpha < \kappa} 2^{|\alpha|} = 2^{<\kappa}$ ; the supremum on the right is at least  $\kappa$  and absorbs the number of summands. Given  $a < b$ , choose a sign sequence  $z$  strictly between them, of length below  $\kappa$ . A sufficiently long extension of  $z$  fixes its comparisons with  $a, b$  before any subsequent signs. Hence an entire sign cone lies inside  $(a, b)$ . If its fixed prefix has length  $\delta < \kappa$ , then all extensions of lengths  $\delta + \gamma$ ,  $\gamma < \kappa$ , remain below  $\kappa$ : an infinite initial ordinal is closed under sums of two smaller ordinals. This cone has  $\mu$  elements. The same construction applies to rays. Removing fewer than  $\mu$  elements cannot empty a set of cardinality  $\mu$  and leaves its cardinality unchanged, even when  $\mu$  is singular.  $\square$

**Lemma 29.3.** *The cofinality and coinitiality of  $X$  are  $r$ , and every point of  $X$  has left and right character  $r$ . The same assertions hold in  $Y = X \setminus Z$  whenever  $|Z| < \mu$ .*

*Proof.* The ordinal surreals below  $\kappa$  are cofinal, and a cofinal sequence of ordinals of length  $r$  gives an upper bound  $r$ . A family of fewer than  $r$  sign sequences has bounded birthdays below  $\kappa$  and is bounded above and below by ordinal surreals, proving the reverse bound.

At  $x$ , the sequences

$$x \frown - \frown +^\gamma \quad \text{and} \quad x \frown + \frown -^\gamma \quad (\gamma < \kappa)$$

are respectively cofinal below and coinitial above  $x$ ; a cofinal choice of  $\gamma$ 's of length  $r$  suffices. Conversely, fewer than  $r$  points have bounded birthdays. A longer sign extension of  $x$  lies between  $x$  and all the points on the appropriate side. Hence the character is not smaller than  $r$ .

For  $Y$ , replace each member of a cofinal or coinitial sequence by a remaining label in an appropriate interval. Such labels exist by Lemma 29.2. Any smaller sequence cofinal in  $Y$  would also be cofinal in the relevant interval or ray of  $X$ , by density.  $\square$

## 29.2 The alphabet's own gaps

The alphabet is not Dedekind complete. Even at a regular uncountable cutoff, its gaps need not have two equal characters. Distinguishing this fact from its uniform *point* characters is essential.

**Theorem 29.4** (Cut spectrum of the birthday alphabet).

$$\text{GapChar}(X) = \{(r, r)\} \cup \{(\theta, r), (r, \theta) : \theta \in \text{Reg}, \theta < \kappa\}.$$

*If  $|Z| < \mu$ , the same formula holds for  $X \setminus Z$ .*

*Proof.* Let  $(A, B)$  be a gap of  $X$ . Define a sign sequence  $s$  of length  $\kappa$  by set recursion: at stage  $\alpha$ , the already defined prefix  $s \upharpoonright \alpha$  is in  $X$ , so put  $s(\alpha) = +$  if that prefix belongs to  $A$ , and  $s(\alpha) = -$  if it belongs to  $B$ . Put

$$I_+ = \{\alpha < \kappa : s(\alpha) = +\}, \quad I_- = \{\alpha < \kappa : s(\alpha) = -\}.$$

The nodes  $s \upharpoonright \alpha$  for  $\alpha \in I_+$  increase and are cofinal in  $A$ ; the nodes for  $\alpha \in I_-$  decrease and are cointial in  $B$ . To verify cofinality, compare any  $x \in A$  with the path  $s$ . If  $x$  is a path prefix it is one of the displayed lower nodes. Otherwise the first disagreement cannot place  $x$  to the right of the chosen path: at a minus choice the corresponding node is in  $B$ . It therefore places  $x$  below a lower node. The dual argument handles  $B$ .

Neither index set has a greatest element, since the cut is a gap. At least one is unbounded in  $\kappa$  and has cofinality  $r$ . An unbounded other side also has cofinality  $r$ ; a bounded other side has an infinite regular cofinality  $\theta < \kappa$ . This proves the upper inclusion. Conversely, the path  $+^\theta \frown -^\kappa$ , with the evident length  $\kappa$  interpretation, has lower and upper index cofinalities  $(\theta, r)$ . Reversing signs gives  $(r, \theta)$ . A path with both signs cofinal in  $\kappa$  gives  $(r, r)$ . In each case the induced partition has no endpoint, as the associated node sequences have no last member.

Now let  $Y = X \setminus Z$  be as stated. Density of  $Y$  implies that a gap of  $Y$  corresponds either to a gap of  $X$  or to a single removed point of  $X$ : there cannot be two  $X$ -points between the two sides, because a  $Y$ -point would lie between them. At an  $X$ -gap, density preserves both cofinalities by choosing intermediate  $Y$ -points. At a removed point both characters are  $r$  by Lemma 29.3. Conversely, every  $X$ -gap survives restriction to  $Y$ , with the same characters. This proves the deletion assertion.  $\square$

**Example 29.5** (A warning about equal-character guesses). For  $\kappa > \omega$ , the path which first has  $\omega$  plus signs and then only minus signs determines an  $(\omega, r)$  gap. It lies at a boundary of a limit sign cone. The cone itself contains many surreal numbers; none is its missing boundary point. Thus uniform point character  $r$  does not mean that every gap has character  $(r, r)$ .

**Lemma 29.6.** *One has  $\mu \geq \kappa$  and  $q \geq r$ .*

*Proof.* The first assertion follows from the count in Lemma 29.2. If the increasing cardinal sequence  $2^\nu$ ,  $\nu < \kappa$ , never reaches its supremum  $\mu$ , a purported cofinal family in  $\mu$  of size below  $r$  is bounded by some  $2^\nu$ : choose an index bound for each of its members and then use  $\text{cf } \kappa = r$  to bound all those indices. Thus  $\text{cf } \mu \geq r$ . If the supremum is attained, the powers are constantly  $\mu$  for all sufficiently large cardinals  $\nu < \kappa$ . König's inequality  $\text{cf}(2^\nu) > \nu$  then gives  $\text{cf } \mu \geq \kappa$ . For completeness, that inequality follows from  $\rho^{\text{cf } \rho} > \rho$  for infinite cardinals  $\rho$ , applied to  $\rho = 2^\nu$ : if  $\text{cf } \rho \leq \nu$ , then  $\rho^{\text{cf } \rho} \leq (2^\nu)^\nu = 2^\nu$ , a contradiction.  $\square$

*Note 29.7* ([merge]; the repository's case of theorem 29.4). At a regular uncountable cutoff  $\kappa$ , theorem 29.4 is the case  $M = N$  of the cutoff gap decomposition of the report `surreal-fields-a-cross-universes` (`univ:gs:lem:boundary`), quoted in `birthday-cutoffs-and-hereditary-sets` (`hset:rem:cutoffgaps`): with no fresh signs, the gap pairs of  $\mathbf{No}_{<\kappa}$  are  $(\theta, \kappa)$  and  $(\kappa, \theta)$  for every infinite regular  $\theta \leq \kappa$ , realized by the same sign paths  $+^\theta \frown -^\kappa$ . Source 17 does not cite these reports. New in source 17 are the singular cutoffs, where the bounded side ranges over the regular  $\theta < \kappa$  while the unbounded side has character  $r = \text{cf } \kappa < \kappa$ ; the countable cutoff  $\kappa = \omega$ , where only  $(\omega, \omega)$  occurs; and the deletion clause.

*Note 29.8* (Source 18, Lemmas 4.5 and 5.3, and source 15, Lemma 9.1). Source 18's Lemma 4.5 ("Large intervals and unchanged cut sides after deletion"): *every nonempty numerical open interval in  $\mathbf{No}_{<\kappa}$  has cardinality  $\mu$ ; if  $U \subseteq \mathbf{No}_{<\kappa}$  has cardinality less than  $\mu$ , then  $\mathbf{No}_{<\kappa} \setminus U$  meets every*

such interval; in particular (1)  $\text{cf}(\mathbf{No}_{<\kappa}) = \text{ci}(\mathbf{No}_{<\kappa}) = r$ , (2) immediately below or above any point the cofinality or coinitality is  $r$ , and (3) every nonprincipal side of a cut retains its cofinality or coinitality after deletion of  $U$ , as do the two open sides at a point, even a deleted one (an endpoint retained in the residual alphabet still gives a principal side of character 1). Its Lemma 5.3 (“Small deletions preserve order density”) repeats this for  $R = X \setminus U$  and adds that *every proper gap of  $R$  has character in  $\text{GapChar}(X) \cup \{(r, r)\}$* . Source 15’s Lemma 9.1 (“Full-size numerical intervals”): *every nonempty open interval of  $\mathbf{No}_{<\kappa}$ , and every nonempty open ray, contains a sign-prefix cone order-isomorphic to  $\mathbf{No}_{<\kappa}$ ; in particular each has cardinality  $\mu$* . These are [lemmas 29.2 and 29.3](#) and the deletion clause of [theorem 29.4](#), by the same sign-cone argument. Source 15 makes the cone explicit in three cases (neither endpoint a prefix of the other: take  $a \frown +$ ;  $a$  a proper prefix of  $b$ : take  $b \frown -$ ;  $b$  a proper prefix of  $a$ : take  $a \frown +$ ), and source 18 obtains the cone from the birthday-controlled separator theorem ([section 5.2](#)) and adds an explicit approach to a point from below by  $x \frown - \frown +^\gamma$ ,  $\gamma$  cofinal in  $\kappa$ , and from above by the sign-reversed words.

*Note 29.9* (Source 15, Lemma 9.3, and source 18, Lemma 4.6). Both sources state more than [lemma 29.6](#):  $q \geq r$ ; if the supremum  $2^{<\kappa}$  is not attained then  $q = r$ , and if it is attained,  $2^\lambda = \mu$  for some cardinal  $\lambda < \kappa$ , then  $q \geq \kappa$ . The proofs are source 17’s: cofinal exponents give  $q \leq r$  in the unattained case, a shorter cofinal family would have bounded exponent witnesses, and in the attained case König’s inequality  $\text{cf}(2^\lambda) > \lambda$  for all  $\lambda$  between the attaining exponent and  $\kappa$  gives  $q \geq \kappa$ .

*Note 29.10* (Source 18, Lemma 5.2, “Alphabet gap spectrum”). For  $X = \mathbf{No}_{<\kappa}$ ,  $\text{GapChar}(X) = \{(r, r)\} \cup \{(\theta, r), (r, \theta) : \theta < \kappa \text{ an infinite regular cardinal}\}$ ; every point has left and right character  $r$ , and the global cofinality and coinitality are also  $r$ . This is [theorem 29.4](#) with [lemma 29.3](#), by the same recursion  $s(\alpha) = +$  if and only if  $s \restriction \alpha \in A$ . Source 18 adds the warning that the lemma “corrects a tempting but false simplification: unfilled alphabet cuts need not all have character  $(r, r)$ ”; at  $\kappa = \omega_1$  the cut below all positive infinite elements, represented by  $+^\omega -^{\omega_1}$ , has character  $(\omega, \omega_1)$ , and “the asymmetric alphabet gaps will, however, already be covered by the longer-prefix construction in  $P$ ”. This is the point of [example 29.5](#).

### 30 The minimal slice $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$ (source 17; routes of sources 15, 16 and 18)

[merge] Source 17’s Sections 5 and 6 are printed in their order, with two insertions: source 18’s general permutation principle ([section 30.3](#)), stated before source 17’s exact gap spectrum because that theorem and source 16’s are instances of it, and source 18’s multiplicities ([section 30.5](#)). The second and third routes to the characters and the saturation threshold (sources 15 and 18) follow source 17’s saturation corollary. Source 17 writes  $[p]$  for the cylinder of an injective prefix  $p$ ; sources 16 and 18 write  $C_p$  for the same set. All three call a cylinder meeting both sides of a cut *straddling*.

#### 30.1 Exact local and topological invariants of the minimal slice (source 17)

Put  $P = \mathcal{W}_\mu(X)$ . For an injective prefix  $p : \alpha \rightarrow X$  with  $\alpha < \mu$ , let

$$[p] = \{f \in P : f \restriction \alpha = p\}, \quad Y_p = X \setminus \text{ran } p.$$

The set  $Y_p$  has cardinality  $\mu$ . Every such prefix has a completion: the remaining ordinal interval  $[\alpha, \mu)$  has order type  $\mu$ , so a bijection from it to  $Y_p$  suffices. This elementary extension fact would be false for arbitrary prescribed prefixes of length  $\mu$ .

**Lemma 30.1** (The cylinder base). *Every  $[p]$  is nonempty, convex, and clopen in the order topology of  $P$ . The cylinders form a base. No cylinder has an endpoint. Moreover,*

$$\text{cf}[p] = \text{ci}[p] = r.$$

*Proof.* Convexity is the first-difference property. Given  $f \in [p]$ , change its entry at coordinate  $\alpha$  to a fresh smaller or larger label and then complete. Lemma 29.2 provides such labels after deletion of  $f[\alpha]$ . This produces bounds on either side of  $f$  within  $[p]$ , proving openness and absence of endpoints. All length- $\alpha$  cylinders partition  $P$ , so the complement is also open. For  $a < f < b$ , a prefix of  $f$  extending beyond its first differences with  $a, b$  has its entire cylinder inside  $(a, b)$ . This proves the base assertion.

The first unused coordinate maps the cylinder onto  $Y_p$  in lexicographic blocks. Choosing one completion for cofinally many first unused labels shows  $\text{cf}[p] \leq \text{cf } Y_p = r$ . Conversely, the first unused entries of a cofinal family in  $[p]$  must be cofinal in  $Y_p$ , since otherwise a larger entry starts a cylinder above the entire family. Cointinality is dual.  $\square$

**Theorem 30.2** (Characters and size invariants). *Every point  $f \in P$  has character  $(q, q)$ , and*

$$\text{cf } P = \text{ci } P = r, \quad \text{d}(P) = \text{w}(P) = \text{cell}(P) = \mu^{<\mu}. \quad (\text{S17.4})$$

Here  $\text{d}$  is density,  $\text{w}$  is topological weight, and  $\text{cell}$  is cellularity as the supremum of cardinalities of pairwise disjoint families of nonempty open sets. In particular,  $P$  is zero-dimensional. The formula for  $\text{cell}$  does not assert that its supremum is always attained by one family.

*Proof.* For each coordinate  $\delta < \mu$ , choose  $f_\delta^- < f < f_\delta^+$  whose first difference from  $f$  is exactly  $\delta$ . Such choices are possible by the preceding lemma. Along a cofinal set of coordinates of order type  $q$ , the lower choices are increasing and cofinal below  $f$ , and the upper choices are decreasing and cointial above it. Conversely, for a family of fewer than  $q$  elements below  $f$ , the first-difference coordinates are bounded below  $\mu$ . A lower approximation differing later lies above them all. Thus neither point character is below  $q$ . The global cofinalities are Lemma 30.1 at the root.

The number of prefixes is at most  $\sum_{\alpha < \mu} \mu^{|\alpha|} = \mu^{<\mu}$ , giving that upper bound for weight, density, and cellularity. At each fixed length  $\alpha$ , the cylinders are disjoint nonempty open sets. For  $1 \leq \lambda < \mu$ , the number of injective  $\lambda$ -words over  $X$  is  $\mu^\lambda$ : a fixed injection  $j : \lambda \times X \rightarrow X$  sends any function  $h$  to the injection  $\xi \mapsto j(\xi, h(\xi))$ . Hence both density and cellularity are at least  $\mu^\lambda$  for every such  $\lambda$ . Taking suprema gives the reverse bound. Finally  $d \leq w$  and  $c \leq w$  complete the equalities. The clopen base gives zero-dimensionality.  $\square$

*Remark 30.3.* The point character is controlled by  $\text{cf } \mu$ , whereas the cofinality of a whole cylinder is controlled by  $\text{cf } \kappa$ . These can differ. Confusing the two would lose the central feature of the cut classification below. Hereditary density also equals  $\mu^{<\mu}$ , since every subspace has weight at most  $\text{w}(P)$  and  $P$  itself attains this density.

*Note 30.4* (Source 17, Proposition 5.4, “Set-alphabet background, with a direct proof”). *The order  $P$  has cardinality  $2^\mu$ . Every linear order of cardinality at most  $\mu$  embeds into every nonempty open interval of  $P$ . An ordinal  $\beta$  embeds in  $P$  if and only if  $\beta < \mu^+$ ; the same bound holds for reverse well-ordered suborders.* Source 17 calls these “already part of the source’s theory”. They are the set baseline (theorem 6.1; reals report `lwo:prop:cardinality`, `lwo:thm:ordinal-spectrum`, `lwo:sp:thm:universality`) applied inside a cylinder, whose residual alphabet has size  $\mu$ , together with lemma 30.1; the proof is the pair-orientation, initial-segment and coordinate-stabilization argument of section 6.

### 30.1.1 Fusion with an exhaustiveness requirement

**Theorem 30.5** (A dense-open fusion theorem). *The intersection of fewer than  $q$  open sets is open. The intersection of at most  $q$  dense open subsets of  $P$  is dense. In particular, when  $q = \omega$ ,  $P$  is a Baire space.*

*Proof.* At a point in fewer than  $q$  open sets, choose a cylinder neighborhood for each. Their prefix lengths have supremum below  $\mu$ , so the longest union prefix gives a cylinder inside the intersection.

Let  $(U_i)_{i < q}$  be dense open sets and start with any nonempty cylinder. Write  $X = \bigcup_{i < q} X_i$ , where the  $X_i$  are increasing and each has cardinality below  $\mu$ . Recursively refine the current prefix to a cylinder contained in  $U_i$ , using density and the cylinder base, and then append every member of  $X_i$  not yet used, in a set well-order of length below  $\mu$ . At stages below  $q$ , the accumulated length is still below  $\mu$ , including at limit stages. At the end the union has length exactly  $\mu$  and range  $X$ : its length is at most  $\mu$ , and it has used  $\mu$  distinct labels. It is therefore an element of  $P$ , belongs to every  $U_i$ , and extends the starting prefix. Fewer dense open sets can be padded by copies of  $P$ .  $\square$

The coverage step is essential. Bare prefix fusion of length  $\mu$  can produce an injective word omitting a label, which is not a point of  $P$ . The theorem does not claim a complete metrizable or a general isomorphism classification.

*Note 30.6* ([merge]; repository analogues and the regular size-matched case). For regular  $\kappa$  with  $2^{<\kappa} = \kappa$  one has  $\mu = r = q = \kappa$ , and the character part of [theorem 30.2](#) is source 11's [proposition 12.1](#) (every local and global character  $\kappa$ , and  $\eta_\kappa$ ). For  $X = \mathbb{R}$  the reals report proves the analogues: point characters  $\text{cf } \mathfrak{c}$  and global characters  $\omega$  (`lwo:prop:fixed-topology`), weight  $2^{<\mathfrak{c}}$  (`lwo:sp:prop:minimalweight`), and that fewer than  $\text{cf } \mathfrak{c}$  open sets have open intersection (`lwo:rk:cor:Pspace`). Sources 15, 17 and 18 do not cite these. New in sources 15, 17 and 18 is the alphabet  $\mathbf{No}_{<\kappa}$  at every infinite cardinal  $\kappa$ , in particular the separation of the point character  $q = \text{cf } \mu$  from the global character  $r = \text{cf } \kappa$ ; new in source 17 is the second half of [theorem 30.5](#), where every fusion sequence must also exhaust the alphabet.

*Note 30.7* (Source 15, Theorem 9.2, “Local and global cofinalities”). Source 15 writes  $L = \mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  for  $P$ , and  $\text{cf}^-(f)$ ,  $\text{ci}^+(f)$  for the cofinality of  $L_{<f}$  and the coinitality of  $L_{>f}$ . For every  $f \in L$ ,  $\text{cf}^-(f) = \text{ci}^+(f) = \text{cf } \mu$ ; the global cofinality and coinitality are  $\text{cf } \kappa$ ; consequently the ordinary local topological character of every point of  $L$  is  $\text{cf } \mu$ . This is the character part of [theorem 30.2](#), by the same argument (a swap of the entry at  $\eta$  with a later occurrence of a fresh smaller or larger label gives  $f_\eta^\mp$  with first difference exactly  $\eta$ ; cofinally many  $\eta$  suffice, fewer than  $\text{cf } \mu$  first differences are bounded). Source 15 adds the local base of size  $\text{cf } \mu$  formed by pairs from the two sides, and the examples: “at the cutoff  $\kappa = \omega_1$  the alphabet cardinal is  $\mu = 2^{\aleph_0}$ . The global cofinality is always  $\omega_1$ , whereas the local character is  $\text{cf}(2^{\aleph_0})$ . Under cardinal arithmetic making these cardinals different, the distinction survives at every point of the permutation order. At the singular strong-limit cutoff  $\kappa = \beth_\omega$ , every point has countable local character, even though the density and cellularity of the minimal slice are  $2^\kappa$ .”

## 30.2 The complete nonprincipal cut spectrum of the minimal slice (source 17)

### 30.2.1 Three ways that a cut can occur

For a gap  $(A, B)$  of  $P$ , say that a cylinder  $[p]$  *straddles* the cut when it meets both  $A$  and  $B$ . There is at most one straddling cylinder at any fixed length, because the cylinders at that length are disjoint convex blocks.

**Lemma 30.8** (Cut trichotomy). *Every gap of  $P$  is of exactly one of the following structural forms, using the first stage at which the construction stops.*

1. **A coordinate cut.** *Some straddling  $[p]$ , of length  $\alpha < \mu$ , has no straddling child. Its children are partitioned by a proper cut of the residual alphabet  $Y_p$ .*
2. **A limit-prefix boundary.** *At a nonzero limit  $\delta < \mu$ , all shorter prefixes on a coherent path straddle, but the union cylinder  $[p]$  lies wholly on one side. The cut is exactly the left or right boundary of  $[p]$ .*
3. **An omitted-range branch.** *A coherent prefix straddles at every length below  $\mu$ . Their union is an injection  $f : \mu \rightarrow X$  which is not surjective, and the gap is comparison with  $f$ .*

*Proof.* Begin at the empty prefix, whose cylinder straddles. At a successor stage, continue into the unique straddling child when it exists; otherwise every child belongs wholly to one side, giving case 1. At a limit  $\delta < \mu$ , the union is an injective prefix and has a nonempty cylinder. If that cylinder does not straddle, it is wholly on one side. Every word strictly below it differs at an earlier coordinate, and is below a lower member of an earlier straddling cylinder, so belongs to  $A$ . The dual argument holds above the cylinder. This proves exactly the boundary assertion in case 2.

If the process continues through all lengths below  $\mu$ , let  $f$  be the union injection. For any  $g \in P$  different from  $f$ , its first difference determines its cut side: a later straddling cylinder gives witnesses which force the orientation. If  $f$  were surjective it would itself belong to  $P$ . Whichever side contains it would then have an endpoint, contrary to the gap hypothesis. Thus  $f$  is not surjective, and all words in  $P$  are classified by their comparison with it. These alternatives cover the set recursion through  $\mu$ , and are disjoint by the first stopping stage.  $\square$

**Lemma 30.9** (Characters in the three cases). *In case 1, the gap character belongs to  $\text{GapChar}(X) \cup \{(r, r)\}$ . In case 2 it is respectively (cf  $\delta, r$ ) or  $(r, \text{cf } \delta)$ . In case 3 it is  $(q, q)$ .*

*Proof.* In case 1 partition the residual alphabet into nonempty parts  $U < V$ , according as a child lies on the lower or upper side. If  $U$  has no largest label, the lower character is  $\text{cf } U$ ; choose one point in cofinally many children. If  $U$  has largest label  $u$ , the last lower child is cofinal on the lower side and has cofinality  $r$ . The upper side has the dual description. When neither side has an endpoint, [Theorem 29.4](#) applies to  $Y_p$ . When one has an endpoint, the other has character  $r$  by [Lemma 29.3](#); the endpoint side is replaced by an entire child of character  $r$ .

At the left boundary of a limit cylinder  $[p]$ , lower approximations obtained by a smaller fresh entry at coordinates cofinal in  $\delta$  are cofinal below the cylinder. No family of fewer than  $\text{cf } \delta$  can be cofinal, since its first disagreements with  $p$  would be bounded below  $\delta$ . The upper side has  $[p]$  as a cointial subset, and the cylinder has cointiality  $r$ . The right boundary is dual.

For an omitted-range branch, approximations from either side at cofinally many coordinates give upper bounds  $q$  for both characters. Fewer than  $q$  disagreements are bounded, so a later approximation is closer to the branch. This proves equality.  $\square$

### 30.3 A general permutation-order principle (source 18)

The tree argument is not specific to surreal numbers. It separates the contribution of the alphabet from the new cuts introduced by long prefixes and omitted branches.

**Theorem 30.10** (Gap spectrum under permutation expansion). *Let  $D$  be a dense linear order without endpoints of infinite cardinality  $\mu$ . Assume that every nonempty open interval has cardinality*

$\mu$ , every point has the same two-sided character  $\nu$ , and both global cofinalities are also  $\nu$ . Let  $\text{Perm}_\mu(D)$  be the lexicographic order on bijections  $\mu \rightarrow D$ , and put  $q = \text{cf } \mu$ . Then

$$\begin{aligned} \text{GapChar}(\text{Perm}_\mu(D)) = & \text{GapChar}(D) \cup \{(\nu, \nu), (q, q)\} \\ & \cup \{(\theta, \nu), (\nu, \theta) : \theta < \mu \text{ is an infinite regular cardinal}\}. \end{aligned}$$

*Proof.* Small deletions leave an order dense in  $D$ , so the residual-cut analysis and the straddling-cylinder trichotomy apply verbatim. These give the upper bound. All the explicitly added pairs are attained by the same prefix-boundary and omitted-branch constructions. Finally, each gap of  $D$  lifts to a gap of the permutation order by placing a permutation on the left or right according to its first digit. With neither digit side principal, the two characters are unchanged. This gives the reverse inclusion.  $\square$

[merge] *The steps the proof leaves to the reader.* Source 18 writes “apply verbatim”; the two facts it uses are written out here. Put  $P = \text{Perm}_\mu(D)$ .

*Small deletions add only  $(\nu, \nu)$ .* Let  $U \subseteq D$  with  $|U| < \mu$  and  $R = D \setminus U$ . Every interval of  $D$  has  $\mu$  points, so  $R$  meets every interval of  $D$ ; in particular  $R$  is dense, has no endpoints, and has global cofinalities  $\nu$  and point characters  $(\nu, \nu)$ , because cofinal and cointial families transfer between  $D$  and  $R$  through points of the other order. Let  $(A, B)$  be a gap of  $R$ . Two points of  $D$  cannot lie between  $A$  and  $B$ , since a point of  $R$  would lie between them. If no point of  $D$  lies between them, the downward closure of  $A$  and the upward closure of  $B$  in  $D$  form a gap of  $D$  with the same characters. If one point  $x$  of  $D$  lies between them, then  $x \in U$ ,  $A$  is cofinal in  $D_{<x}$  and  $B$  cointial in  $D_{>x}$ , and the character is the point character  $(\nu, \nu)$  of  $x$ . Hence  $\text{GapChar}(R) \subseteq \text{GapChar}(D) \cup \{(\nu, \nu)\}$ .

*The three cases.* Let  $(A, B)$  be a gap of  $P$ . The prefixes  $p$  of length below  $\mu$  whose cylinders  $C_p$  meet both sides form a chain under extension, as in lemma 30.8. If there is a longest one,  $p$ , the residual alphabet  $R_p = D \setminus \text{ran } p$  (with  $|\text{ran } p| < \mu$ ) is cut into the digits whose child cylinders lie in  $A$  and those whose child cylinders lie in  $B$ ; both parts are nonempty and,  $R_p$  being dense, they do not both have endpoints. If neither has one, the character of  $(A, B)$  is the character of this gap of  $R_p$ , which lies in  $\text{GapChar}(D) \cup \{(\nu, \nu)\}$  by the first step:  $A \cap C_p$  is cofinal in  $A$  and is the lexicographic sum of the lower child cylinders. If the lower part has a last digit  $u$ ,  $A$  is cofinally the child cylinder  $C_{p \frown u}$ , whose cofinality is that of its residual alphabet,  $\nu$ , while  $B$  approaches  $u$  from above in  $R_p$ , with cointiality  $\nu$ ; the dual case is the same, so the character is  $(\nu, \nu)$ . If the straddling lengths have a limit supremum  $\delta < \mu$ , the union  $p$  has a nonempty cylinder lying on one side, the gap is a boundary of  $C_p$ , and its character is  $(\text{cf } \delta, \nu)$  or  $(\nu, \text{cf } \delta)$ : the approximations with a smaller (larger) unused digit at coordinates cofinal in  $\delta$  exist because rays of  $D$  contain intervals of size  $\mu$ , and  $C_p$  has global characters  $\nu$ . If the lengths are cofinal in  $\mu$ , the union is a nonsurjective injection  $\mu \rightarrow D$  and the character is  $(q, q)$ , exactly as in case 3 of lemma 30.9. This proves the upper bound.

*Attainment.* For a regular  $\theta < \mu$ , the two boundaries of the cylinder of an injective prefix of length  $\theta$  have characters  $(\theta, \nu)$  and  $(\nu, \theta)$ ; the lower boundary of a one-digit cylinder  $C_{\langle x \rangle}$  has character  $(\nu, \nu)$ , since its lower side approaches the digit  $x$  from below and  $C_{\langle x \rangle}$  has cointiality  $\nu$ ; a bijection of  $\mu$  onto  $D \setminus \{x\}$  gives  $(q, q)$ ; and a gap of  $D$  lifts at the first digit, as source 18 says.  $\square$

**Theorem 30.11** (Exact gap spectrum). *For every infinite cardinal  $\kappa$ , with the parameters in (S17.3),*

$$\text{GapChar}(\mathcal{W}_\mu(\mathbf{No}_{<\kappa})) = \{(r, r), (q, q)\} \cup \{(\theta, r), (r, \theta) : \theta \in \text{Reg}, \theta < \mu\}. \quad (\text{S17.5})$$

*Proof.* The upper inclusion follows from the two preceding lemmas and  $\kappa \leq \mu$ : alphabet gap pairs involving a regular cardinal below  $\kappa$  already belong to the displayed set.

For  $(r, r)$ , fix a label  $x \in X$  and place on the lower side every word whose first entry is at most  $x$ , and on the upper side every word whose first entry exceeds  $x$ . The last lower child has cofinality  $r$ , and the upper first-entry ray has coinitality  $r$ . Neither side has an endpoint.

For any infinite regular  $\theta < \mu$ , choose an injective prefix of length  $\theta$ . Its two boundary cuts have characters  $(\theta, r)$  and  $(r, \theta)$  by the limit-boundary calculation. The fresh smaller and larger labels used there exist at every coordinate, so both sides of both cuts are nonempty.

Finally choose a bijection  $f : \mu \rightarrow X \setminus \{x\}$  for some label  $x$ . Each proper prefix is completable in  $P$ , but  $f$  itself is not in  $P$ . Its comparison cut is a gap of character  $(q, q)$ .  $\square$

*Note 30.12* ([merge]; [theorem 30.11](#) as an instance).  $D = \mathbf{No}_{<\kappa}$  satisfies the hypotheses of [theorem 30.10](#) with  $\nu = r$ : [lemmas 29.2](#) and [29.3](#) give the interval size and the uniform point and global characters. With  $\text{GapChar}(\mathbf{No}_{<\kappa})$  from [theorem 29.4](#), whose asymmetric pairs  $(\theta < \kappa)$  are among those with  $\theta < \mu$ , the principle returns exactly ([S17.5](#)). Source 17's proof above is the direct one.

*Note 30.13* (Source 18, Theorem 5.1, “Exact gap spectrum”, and Lemma 5.4). Source 18's Section 5 “settles the cut-spectrum question for the minimal-length permutation order at every infinite cardinal birthday cutoff”. It writes  $P$  for the bijections  $\mu \rightarrow \mathbf{No}_{<\kappa}$ , defines a *proper Dedekind gap* as a partition  $P = A \sqcup B$  into nonempty sets with  $A < B$ ,  $A$  without greatest and  $B$  without least element, of character (cf  $A$ , ci  $B$ ), and writes  $\text{GapChar}(P)$  for the set of characters (“this convention excludes principal cuts and the two external ends”). Its Theorem 5.1 is ([S17.5](#)) together with: *every displayed pair is attained; (1) every point of  $P$  has left and right character  $q$ ; (2) the global cofinality and coinitality are  $r$ ; (3) the principal cuts have character  $(1, q)$  or  $(q, 1)$ ; (4) if empty sides are assigned cofinality 0, the external ends have character  $(0, r)$  and  $(r, 0)$* . Its Lemma 5.4: *every cylinder  $C_p$  has cofinality and coinitality  $r$  and no endpoints; if  $p$  has nonzero limit length  $\delta < \mu$ , the lower boundary of  $C_p$  is a proper gap of character (cf  $\delta, r$ ) and the upper boundary one of character  $(r, \text{cf } \delta)$* . These are [lemma 30.1](#), case 2 of [lemma 30.9](#) and [theorems 30.2](#) and [30.11](#), and source 18's proof is source 17's: the straddling prefixes form a chain under extension, and its three cases (a longest straddling prefix, a limit supremum  $\delta < \mu$ , lengths cofinal in  $\mu$ ) are the three cases of [lemma 30.8](#), in the same order, with the same character computations. Source 18 attains  $(r, r)$  by the boundary of a successor-length cylinder  $C_{\langle x \rangle}$  (the exterior side approaches the digit  $x$ ) rather than by source 17's first-entry split; “every infinite regular  $\theta < \mu$  can be used as  $\delta$ ” in Lemma 5.4, so the asymmetric pairs are attained “independently of which of them already occur as gaps in the alphabet”.

### 30.4 Source 16's route: regular saturated stages over any saturated alphabet

[merge] The last subsection of source 16's Section 6. It is printed here, after source 17's spectrum, because it computes the same spectrum for the regular size-matched case and generalizes it to every regular saturated alphabet of the same size ([note 30.15](#)).

Suppose  $\mu$  is regular infinite and  $X$  is an  $\eta_\mu$  order of size  $\mu$ . The earlier report proves that  $\mathcal{W}_\mu(X)$  is itself  $\eta_\mu$ , with every local and global cofinality and coinitality  $\mu$  ([proposition 12.1](#)). Here is the mechanism. If one side is empty, choose a fresh first label beyond all first labels on the other side and complete it. For two nonempty families of fewer than  $\mu$  lower and upper enumerations, bound their cross first disagreements below  $\mu$ . Follow their forced common coordinates until the active next labels have strictly separated lower and upper sets. Choose a fresh interpolating label using saturation, and complete the resulting prefix. Fewer than  $\mu$  used labels can be avoided by a further small cut. The procedure must stop before the bound is passed. Small cut filling gives the lower character bound; [Note 32.1](#) gives the upper bound.

**Theorem 30.14** (Complete gap-character spectrum). *Under the preceding hypotheses, the cofinality pairs of proper unfilled Dedekind cuts in  $\mathcal{W}_\mu(X)$  are exactly*

$$(\mu, \lambda) \quad \text{and} \quad (\lambda, \mu), \quad \omega \leq \lambda \leq \mu, \quad \lambda \text{ regular.} \quad (\text{S16.4})$$

*Both sides of a cut here are nonempty, and neither has an endpoint.*

*Proof.* The two characters are infinite regular cardinals. Neither exceeds  $\mu$ , because a larger character would produce a monotone sequence of type  $\mu^+$ , contrary to [Note 32.1](#). They cannot both be below  $\mu$ : cofinal and coinital sets of those sizes would form a strict small cut, and saturation would insert a point in the supposed unfilled cut. This proves necessity.

For an infinite regular  $\lambda < \mu$ , fix an injective prefix  $p$  of length  $\lambda$ . Its completion cylinder  $C_p$  is convex and has no endpoints; its cofinality and coinitality are  $\mu$ , by the same saturation argument. The cut just above the entire cylinder has lower character  $\mu$ . Enumerations above the cylinder first differ upward from  $p$  at some coordinate below  $\lambda$ . Choose such upward deviations at a cofinal sequence of coordinates in  $\lambda$ ; their completions form a coinital family of size  $\lambda$  on that upper side. Fewer than  $\lambda$  deviation coordinates are bounded, and a later upward deviation lies below all of them. Thus the upper character is exactly  $\lambda$ . The cylinder has no maximum and the upper side has no minimum, so this cut is unfilled. The lower edge gives  $(\lambda, \mu)$ .

For  $(\mu, \mu)$  fix  $a \in X$  and split the order according to first label  $\leq a$  or  $> a$ . The lower side is cofinally the cylinder with first label  $a$ , of character  $\mu$ . The upper side has coinitality  $\mu$ , inherited from the native segment above  $a$ . Both sides have no endpoint. This realizes the final case.  $\square$

For regular  $\kappa$  satisfying  $2^{<\kappa} = \kappa$ , these conclusions apply to  $\mathbf{No}_{<\kappa}$ . They answer the earlier report's regular-stage density, cellularity, and cut-character questions under precisely those hypotheses. Singular stages and regular stages of larger cardinality require separate analysis; the theorem does not erase the singular coding phenomenon in [\(S16.2\)](#).

*Note 30.15* ([merge]; source 16's theorem as an instance). An  $\eta_\mu$  order  $X$  of regular cardinality  $\mu$  satisfies the hypotheses of [theorem 30.10](#) with  $\nu = \text{cf } \mu = \mu$ : it is dense without endpoints, its intervals have size  $\mu$ , and every point and both ends have character  $\mu$ , by saturation and  $|X| = \mu$ . An  $\eta_\mu$  order has no gap with both characters below  $\mu$ , so the principle gives the pairs  $(\mu, \theta)$ ,  $(\theta, \mu)$  with  $\theta \leq \mu$  regular, which is [\(S16.4\)](#). For  $X = \mathbf{No}_{<\kappa}$  with  $\kappa$  regular and  $2^{<\kappa} = \kappa$ , [theorem 30.14](#) and [example 30.20](#) coincide. Source 17 is more general in the cutoff (any  $\kappa$ , no hypothesis on  $2^{<\kappa}$ ), source 16 in the alphabet (any regular saturated alphabet). For  $X = \mathbb{R}$  the reals report's `two:rk:thm:Pgaps` is the corresponding spectrum,  $\{(\omega, \theta), (\theta, \omega) : \theta < \mathfrak{c} \text{ regular}\} \cup \{(\text{cf } \mathfrak{c}, \text{cf } \mathfrak{c})\}$ ; it is source 17's formula with  $r = \omega$ ,  $q = \text{cf } \mathfrak{c}$ ,  $\mu = \mathfrak{c}$  and the alphabet spectrum  $\text{GapChar}(\mathbb{R}) = \emptyset$  (the formula's  $(r, r)$  comes from a principal digit split, and  $(\omega, \omega)$  is the case  $\theta = \omega$ ). Neither source 16 nor source 17 cites it.

### 30.5 How many gaps have each character? (source 18)

[merge] “The same classification” and “the three cases” below are the straddling-cylinder classification of the gaps of  $P$ : a longest straddling prefix, a limit supremum of straddling lengths below  $\mu$ , and lengths cofinal in  $\mu$ , which are cases 1, 2 and 3 of [lemma 30.8](#) ([note 30.13](#)). Source 18's  $d_*$  is the density  $\mu^{<\mu}$  of  $P$  ([theorem 30.2](#)); its prefix variable  $q$  is printed  $p'$ , since  $q = \text{cf } \mu$  here. The theorem is the minimal-slice analogue of the reals report's count of  $2^{\mathfrak{c}}$  gaps of  $\mathcal{W}$  (`two:sp:thm:gapcount`), which source 18 does not cite.

The same classification gives exact multiplicities, not just a list of the possible character pairs. Write

$$d_* = \mu^{<\mu} = \sup_{\lambda < \mu} \mu^{|\lambda|}.$$

This is also the cardinality of the tree of injective prefixes of length less than  $\mu$ .

**Theorem 30.16** (Exact multiplicities). *The minimal permutation order  $P$  has exactly  $2^\mu$  proper Dedekind gaps. For a pair  $(a, b)$  in the spectrum of [Note 30.13](#), let  $G_{a,b}$  be the set of proper gaps of that character. Then*

$$|G_{a,b}| = \begin{cases} 2^\mu, & (a, b) = (q, q), \\ d_*, & (a, b) \neq (q, q). \end{cases}$$

*In particular, the Dedekind completion of  $P$ , with or without its two external ends, has cardinality  $2^\mu$ .*

*Proof.* First, every full nonsurjective injection  $f : \mu \rightarrow X$  gives a proper gap of character  $(q, q)$ . Fix  $x_* \in X$  and consider injections into  $X \setminus \{x_*\}$ . There are  $2^\mu$  such injections: for a lower bound partition this set into  $\mu$  disjoint pairs and choose one entry of each pair according to a binary word; the upper bound is  $\mu^\mu = 2^\mu$ .

Distinct injections give distinct gaps. If  $f < g$  first differ at  $\alpha$ , choose an unused digit strictly between  $f(\alpha)$  and  $g(\alpha)$  and extend the common prefix followed by that digit to a bijection. This is possible because the intervening interval has cardinality  $\mu$ , while fewer than  $\mu$  digits have been used. The resulting member of  $P$  lies strictly between  $f$  and  $g$ . There are therefore at least  $2^\mu$  gaps of character  $(q, q)$ .

For an upper bound on all gaps, the tree of short prefixes has cardinality  $d_* \leq 2^\mu$ , an alphabet of size  $\mu$  has at most  $2^\mu$  cuts, and there are at most  $\mu^\mu = 2^\mu$  full injections. The three cases of the straddling-cylinder classification therefore give at most  $2^\mu$  gaps altogether. This proves both the total number and the multiplicity of  $(q, q)$ .

Next fix an infinite regular  $\theta < \mu$ . There are exactly  $d_*$  prefixes whose lengths have cofinality  $\theta$ . For the nontrivial lower bound, take any infinite cardinal  $\lambda$  with  $\theta \leq \lambda < \mu$  and put

$$\delta = \lambda \cdot \theta.$$

Then  $\delta < \mu$ ,  $|\delta| = \lambda$ , and  $\text{cf } \delta = \theta$ . There are  $\mu^\lambda$  injective words of this length. One way to see the lower bound is to partition  $X$  into  $\lambda$  disjoint sets, each of cardinality  $\mu$ , and choose the digit at each coordinate from its assigned set. Taking the supremum over  $\lambda$  gives  $d_*$ . The opposite bound is the cardinality of the whole prefix tree.

Distinct prefixes give distinct lower-boundary cuts. For incomparable prefixes, an unused digit strictly between their first disagreeing digits yields a permutation between their cylinders; the interval has size  $\mu$  and fewer than  $\mu$  digits have been used. If  $p'$  properly extends  $p$ , choose at the first additional coordinate an unused digit smaller than the corresponding digit of  $p'$ . This gives a point of  $C_p$  below all of  $C_{p'}$ ; a larger choice gives a point above all of  $C_{p'}$ . Thus the lower boundaries, and also the upper boundaries, are distinct in this case as well. Consequently there are at least  $d_*$  gaps of each character  $(\theta, r)$  and  $(r, \theta)$ .

It remains to bound the number of gaps of any character other than  $(q, q)$ . Full-length omitted branches contribute none of these. Limit-cylinder boundaries contribute at most  $d_*$  gaps. For the maximal-prefix case distinguish two possibilities.

If  $q = r$ , the character being counted is not  $(r, r)$ . In the alphabet sign-path description, a gap not of character  $(r, r)$  has one sign set bounded below  $\kappa$ , so its path is eventually constant. There are at most  $\sum_{\delta < \kappa} 2^{|\delta|} = \mu$  such paths. Deleting a small set only adds  $(r, r)$  gaps, and a principal digit cut likewise lifts to that character. Thus each maximal prefix contributes at most  $\mu$  gaps of the character under consideration, and all short prefixes together contribute at most  $d_* \cdot \mu = d_*$ .

If  $q \neq r$ , then  $\mu > \kappa$ : equality would give  $\text{cf } \mu = \text{cf } \kappa$ . Every alphabet cut is represented by a length- $\kappa$  sign word, so there are at most  $2^\kappa$  of them. Cuts created by deletions and retained points add at most  $\mu$ . Since  $\kappa < \mu$ ,

$$2^\kappa \leq \mu^\kappa \leq d_*.$$

Again all maximal prefixes together contribute at most  $d_*$  gaps.

Every allowed character other than  $(q, q)$  has the form  $(\theta, r)$  or  $(r, \theta)$  for a regular  $\theta < \mu$ . The only apparent exception would be  $(r, r)$  with  $r = \mu$ , but then  $\kappa = \mu$  is regular and  $q = r$ , so that pair is precisely the already excluded  $(q, q)$ . The prefix-boundary lower bound therefore applies to every remaining character, completing the multiplicity calculation.

Finally  $|P| = 2^\mu$ , and its completion adds one point for each proper gap (and optionally its two ends). The completion cardinality is consequently  $2^\mu$ .  $\square$

### 30.5.1 Consequences and distinctions

The exact formula makes several distinctions transparent.

1. If  $\mu = \kappa$  is regular, then  $r = q = \kappa$  and the spectrum is

$$\{(\kappa, \kappa)\} \cup \{(\theta, \kappa), (\kappa, \theta) : \theta < \kappa \text{ infinite regular}\}.$$

In particular, the order's  $\eta_\kappa$  property does not prohibit asymmetric gaps with one small side.

2. At a singular strong-limit cutoff,  $\mu = \kappa$  and  $r = q = \text{cf } \kappa$ . The asymmetric pairs range over every infinite regular  $\theta < \kappa$ , including regular cardinals much larger than  $\text{cf } \kappa$ .
3. If  $\kappa = \omega_1$  and  $2^{\aleph_0} = \aleph_2$ , the proper gap spectrum consists exactly of

$$(\omega, \omega_1), \quad (\omega_1, \omega), \quad (\omega_1, \omega_1), \quad (\omega_2, \omega_2).$$

Every point has character  $(\omega_2, \omega_2)$ , while both global cofinalities are  $\omega_1$ . Thus local character, global character, and gap character cannot be conflated.

4. If  $\kappa = \omega$ , then  $\mu = r = q = \omega$  and every proper gap has character  $(\omega, \omega)$ .

The set of possible character pairs depends only on  $\mu$ ,  $r$ , and  $q$ ; its proof retains substantially more information. Every gap has a precise structural cause: a split between next digits, a boundary of a limit-length cylinder, or a nonsurjective branch of full length. Coinciding character pairs need not have the same structural cause. Nor does equality of these spectra by itself establish order isomorphism.

Natural further problems include classifying the order of the gaps of each character, studying which of the three mechanisms can be recognized intrinsically from the pure linear order, and extending the analysis to strata of nonminimal enumeration length. In the last problem a prefix can leave a small residual alphabet near the end of the domain, so the uniform large-interval argument used here no longer applies without a separate analysis of the ordinal tail.

## 30.6 Saturation and illustrative cases (source 17)

**Definition 30.17.** For an infinite regular cardinal  $\tau$ , an order is an  $\eta_\tau$  order when every pair of separated sets  $A < B$ , each of size below  $\tau$ , has a strict interpolant. Empty sides are allowed.

**Corollary 30.18** (Exact saturation threshold). *The order  $P$  is an  $\eta_r$  order, and is not an  $\eta_{r+}$  order.*

*Proof.* Suppose  $A < B$  have sizes below  $r$  and no strict interpolant. If one side is empty, the other would be cofinal or coinital in  $P$ , contradicting (S17.4). If both are nonempty, let

$$D = \{x : \exists a \in A (x \leq a)\}, \quad U = \{x : \exists b \in B (b \leq x)\}.$$

They are disjoint, and no strict interpolant means that they cover  $P$ . If  $D$  has a greatest element  $x$ , then  $B$  is coinital immediately above  $x$ , contradicting right point character  $q \geq r$ . If  $U$  has a least element, the dual contradiction uses  $A$ . If neither has an endpoint,  $(D, U)$  is a gap with both characters below  $r$ , forbidden by (S17.5). An  $(r, r)$  gap exists; cofinal and coinital witnesses of size  $r$  show failure of  $\eta_{r+}$ .  $\square$

**Example 30.19** (The countable birthday cutoff). At  $\kappa = \omega$ ,  $X$  is the order of finite sign sequences,  $\mu = r = q = \omega$ , and  $P$  has countable weight and density, character  $(\omega, \omega)$  at every point, and only  $(\omega, \omega)$  gaps. It is a Baire, zero-dimensional order. These facts do not identify it with the real line, whose order topology has a completely different connectedness structure.

**Example 30.20** (Regular size-matched cutoffs). If  $\kappa$  is regular and  $2^{<\kappa} = \kappa$ , then  $\mu = r = q = \kappa$ . The gap spectrum is

$$\{(\kappa, \kappa)\} \cup \{(\theta, \kappa), (\kappa, \theta) : \theta \in \text{Reg}, \theta < \kappa\}.$$

The order is  $\eta_\kappa$  but not  $\eta_{\kappa+}$ . The small character on one side of a limit-prefix boundary does not violate  $\eta_\kappa$ , because the other side requires  $\kappa$  witnesses.

**Example 30.21** (A singular strong-limit cutoff). At  $\kappa = \beth_\omega$ , one has  $\mu = \kappa$  and  $r = q = \omega$ . Every point has countable character, but for every infinite regular  $\theta < \kappa$  there are gaps of character  $(\theta, \omega)$  and  $(\omega, \theta)$ . Weight, density and cellularity are  $\kappa^{<\kappa} = 2^\kappa$ . This complements rather than replaces the source's  $\kappa \cdot \kappa$  binary-coding-length theorem (theorem 8.3).

[merge] (3 October 2026.) Source 17 wrote “are  $\kappa^{<\kappa}$ , with no extra cardinal-arithmetic simplification asserted”. At a singular strong limit  $\kappa$  one has  $2^\kappa \leq \kappa^{\text{cf } \kappa} \leq \kappa^{<\kappa} \leq 2^\kappa$ , so the value is  $2^\kappa$ ; source 18 proves this identity in corollary 30.26, and source 15 obtains the same value  $2^\kappa$  from its block-type theorem (corollary 31.7).

*Remark 30.22* (What has not been classified). The preceding formulas concern the minimal type  $\mu$ . They do not extend by replacing  $\mu$  with an arbitrary ordinal  $\alpha$  of cardinality  $\mu$ : a prefix of length below  $\alpha$  can already use  $\mu$  labels, leaving a radically smaller residual alphabet. Nor do equal values of these invariants imply order-isomorphism. Both issues remain in the research program at the end of this article.

### 30.7 Source 15’s route to the saturation threshold

[merge] Source 15’s Section 9, “Exact local characters at every cardinal cutoff”. Its Lemma 9.1 is recorded in note 29.8, its Theorem 9.2 in note 30.7 and its Lemma 9.3 in note 29.9; its saturation theorem is proved directly, by a prefix search, not from the gap spectrum as in corollary 30.18, and is printed in full. Its  $\delta = \text{cf } \kappa$  is printed  $r$ . Its first sentence describes this report at source 15’s pin; the point characters it mentions are now theorem 30.2.

The repository leaves the point characters of  $\mathcal{W}_{2^{<\kappa}}(\mathbf{No}_{<\kappa})$  open when  $2^{<\kappa}$  need not equal  $\kappa$ . They can be computed exactly. The local invariant is controlled by the enumeration length, whereas the global invariant is controlled by the numerical alphabet.

Throughout this section let

$$X = \mathbf{No}_{<\kappa}, \quad \mu = 2^{<\kappa}, \quad r = \text{cf } \kappa, \quad L = \mathcal{W}_\mu(X),$$

where  $\kappa$  is an infinite initial cardinal. For  $f \in L$ , write  $\text{cf}^-(f)$  for the cofinality of the open initial segment  $L_{<f}$ , and  $\text{ci}^+(f)$  for the coinitality of the open final segment  $L_{>f}$ .

We use the convention that an order is  $\eta_\nu$  if every cut  $A < B$  with  $|A| + |B| < \nu$  has a strict interpolant, including the cases where one side is empty. This does not assert that an arbitrary cut with larger sides is filled.

**Theorem 30.23** (Exact saturation threshold for the minimal slice). *The order  $L = \mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  is  $\eta_{\text{cf } \kappa}$ . For every infinite cardinal  $\nu > \text{cf } \kappa$ , it is not  $\eta_\nu$ . Equivalently, among infinite cardinal cut-size parameters,*

$$L \text{ is } \eta_\nu \iff \nu \leq \text{cf } \kappa.$$

*In particular, at every regular  $\kappa$ , the minimal slice is  $\eta_\kappa$  without the additional assumption  $2^{<\kappa} = \kappa$ .*

*Proof.* Let  $A < B$  be subsets of  $L$  with  $|A| + |B| < r$ . Any family of fewer than  $r$  surreal labels has birthdays bounded below  $\kappa$ . Consequently, for any strict numerical cut formed by such labels, there are two points  $u < v$  of  $X$  strictly between its sides. This follows from the usual surreal cut construction applied twice; all resulting birthdays stay below  $\kappa$ . The same statement holds with an empty side. By [Note 29.8](#), the interval  $(u, v)$  has cardinality  $\mu$ . Thus a numerical cut of this size admits a separator outside any prescribed set of fewer than  $\mu$  labels.

If one of  $A, B$  is empty, choose the first entry strictly above all first entries on the left or below all first entries on the right, and complete to a permutation. Suppose both are nonempty. For each  $(a, b) \in A \times B$ , let  $d(a, b) < \mu$  be its first-difference coordinate. By [Note 29.9](#),

$$\beta = \sup\{d(a, b) + 1 : a \in A, b \in B\} < \mu.$$

Build an injective prefix  $p$ , keeping as active those rows of  $A$  and  $B$  that still agree with  $p$ . At a stage  $\eta$ , every active left value at coordinate  $\eta$  is at most every active right value. If a value occurs on both sides, it is unique; append that value to  $p$  and keep the rows taking it. Every discarded left row is already below all extensions of the new prefix, and every discarded right row is already above them. The appended value is fresh because it belongs to active injective rows.

If the active value sets have no common value, they form a strict numerical cut. Choose a separator outside the range of  $p$  using the preceding full-size-interval argument, append it, and stop. If an active side becomes empty, use the same argument for the resulting one-sided cut. At a limit stage take the union of the prefixes and retain the rows that extend it. The search cannot still have active rows on both sides at stage  $\beta$ : such a pair would agree at every coordinate below  $\beta$ , contradicting the definition of  $\beta$ . Therefore it stops with a prefix of length less than  $\mu$ .

That prefix has used fewer than  $\mu$  labels. Its remaining labels and remaining positions both have cardinality  $\mu$ , and an exhaustive completion has order type  $\mu$ . Every such completion lies strictly above  $A$  and below  $B$ , proving  $\eta_r$ .

Finally, [Note 30.7](#) gives a global cofinal subset of size  $r$ . Together with an empty right side it is a cut of total size below every cardinal  $\nu > r$ , but it has no upper interpolant. Hence no such  $\eta_\nu$  property holds.  $\square$

These results settle the point-character part, and the maximal uniform cut-size threshold, of the earlier minimal-slice question. They do not compute its full two-sided unrealized-cut spectrum. In particular, saturation below  $\text{cf } \kappa$  and failure above that threshold do not specify which individual larger pairs of regular cofinalities occur as gaps.

[merge] (3 October 2026.) The “full two-sided unrealized-cut spectrum” that source 15 leaves open is source 17’s [theorem 30.11](#) (and source 18’s [note 30.13](#)); its multiplicities are [theorem 30.16](#).

### 30.8 Source 18's route and extension: characters, interpolation and two regimes

[merge] The rest of source 18's Section 4, printed whole. Its point characters and interpolation theorem are source 17's [theorem 30.2](#) and [corollary 30.18](#) and source 15's [theorem 30.23](#), proved again with a different interpolation argument (bounded dropout coordinates); it extends both to the types  $\mu + n$  and to the finite-cofinite prefix orders  $Q_n$  ([lemma 27.7](#)), and it exhibits a bounded  $(r, r)$  obstruction explicitly. Its corollary on two regimes merges with source 17's examples [examples 30.20](#) and [30.21](#); its second part supplies the value  $\kappa^{<\kappa} = 2^\kappa$  used in [example 30.21](#).

#### 30.8.1 Exact point characters and global cofinalities

For a point  $e$  in a linear order, its left character means the cofinality of  $(-\infty, e)$ , and its right character means the coinitality of  $(e, \infty)$ . An immediate predecessor or successor therefore gives character 1 on the respective side.

**Theorem 30.24** (Complete local and global characters at the minimal type). *Every point of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$  has left and right character  $q = \text{cf}(\mu)$ , whereas*

$$\text{cf}(\mathcal{W}_\mu(\mathbf{No}_{<\kappa})) = \text{ci}(\mathcal{W}_\mu(\mathbf{No}_{<\kappa})) = r.$$

*More generally,  $Q_n(\mathbf{No}_{<\kappa})$  has point characters  $(q, q)$  for every finite  $n$ . Accordingly, in  $\mathcal{W}_{\mu+n}(\mathbf{No}_{<\kappa})$ :*

- *if  $n = 0$  or 1, every point has characters  $(q, q)$ ;*
- *if  $n \geq 2$ , the first and last points of each finite  $n!$ -point fiber have characters  $(q, 1)$  and  $(1, q)$  respectively;*
- *all interior points of a finite fiber have characters  $(1, 1)$ .*

*Interior points exist exactly when  $n \geq 3$ . The global cofinality and coinitality remain  $r$  for every finite  $n$ .*

*Proof.* Fix  $p \in Q_n(\mathbf{No}_{<\kappa})$  and  $\delta < \mu$ . There are  $\mu$  labels numerically below  $p(\delta)$ , and equally many above it. The labels used before  $\delta$ , together with the finitely many labels omitted from  $p$ , exclude fewer than  $\mu$  labels. Choose a smaller available label which therefore occurs later in the  $\mu$ -prefix, and transpose its occurrence with position  $\delta$ . This gives  $p_\delta^- < p$  with first difference exactly  $\delta$ . An analogous transposition gives  $p_\delta^+ > p$ .

As  $\delta$  runs along an increasing cofinal sequence in  $\mu$ , the points  $p_\delta^-$  increase cofinally toward  $p$ , while  $p_\delta^+$  decrease coinitially toward it. This proves both upper bounds  $q$ . Conversely, fewer than  $q$  points below  $p$  have first-disagreement coordinates bounded below  $\mu$ . Changing  $p$  at a later coordinate gives a point above all of them and below  $p$ . They cannot be cofinal. The dual argument gives the right lower bound. This proves the character statement for  $Q_n$ .

The map  $e \mapsto e(0)$  is onto  $\mathbf{No}_{<\kappa}$  and respects comparisons whenever the first coordinates differ. A family cofinal in the enumeration order must therefore have first coordinates cofinal in  $\mathbf{No}_{<\kappa}$ ; conversely, choose one enumeration over every member of a numerical cofinal sequence. This proves the global cofinality formula, and the coinitality formula is dual. Finally,  $\mathcal{W}_{\mu+n}(\mathbf{No}_{<\kappa})$  is the lexicographic sum over  $Q_n$  of finite ordered fibers of size  $n!$ . Immediate neighbors inside a fiber give character 1, while approach to the outside of a fiber is controlled by the character  $q$  of the quotient point.  $\square$

### 30.8.2 Sharp interpolation at every infinite cardinal cutoff

We say that  $L$  is  $\eta_r$  if for all sets  $A, B \subseteq L$  with  $|A \cup B| < r$  and  $a < b$  for every  $a \in A, b \in B$ , there is  $z \in L$  satisfying  $A < z < B$ . Empty sides are allowed. The sharpness result below also uses a bounded cut with both sides nonempty, so it does not depend on the empty-side convention.

**Theorem 30.25** (Exact guaranteed interpolation). *For every infinite initial cardinal  $\kappa$ , with notation as above,*

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \text{ is } \eta_r, \quad r = \text{cf}(\kappa).$$

*It has a bounded unfilled cut of character  $(r, r)$ , so it is not  $\eta_{r+}$ . The same interpolation and sharpness assertions hold for  $\mathcal{W}_{\mu+1}(\mathbf{No}_{<\kappa})$ . For  $n \geq 2$ , adjacent points in the terminal fibers already preclude  $\eta_\omega$ .*

*Proof of interpolation.* First  $\mathbf{No}_{<\kappa}$  is  $\eta_r$ . A family of fewer than  $r$  numerical options has birthdays bounded below  $\kappa$ , so the set-cut theorem supplies a separator with birthday less than  $\kappa$ . Applying it twice supplies a nonempty interval of possible separators, still between the prescribed options. By [Note 29.8](#), such an interval has  $\mu$  labels.

Let  $A < B$  be sets of input enumerations with  $|A \cup B| < r$ . We construct an injective common prefix  $p$  until a completion separating the inputs becomes possible. At a prefix of length  $\delta < \mu$ , the active inputs are

$$A_p = \{a \in A : a \restriction \delta = p\}, \quad B_p = \{b \in B : b \restriction \delta = p\}.$$

The invariant is that all discarded lower inputs lie below every completion of  $p$ , while all discarded upper inputs lie above every completion of  $p$ . Let  $L$  and  $U$  be the sets of next entries of the active lower and upper inputs. Then every  $l \in L$  is at most every  $u \in U$ .

If  $L \cap U = \emptyset$ , the two next-entry sets are strictly separated (with empty sides permitted). Choose an interval of numerical separators between them. It has  $\mu$  labels, whereas  $\text{ran } p$  has size less than  $\mu$ . Choose an unused separator  $z$  in it. Every completion of  $p \frown (z)$  lies strictly between all inputs, and an exhaustive completion of the required type exists by cardinality. The construction stops.

Otherwise,  $L \cap U$  consists of exactly one label  $z$ : two different common labels would contradict  $L \leq U$ . This label is unused, since an active input is injective. Append it to  $p$ . Inputs with a smaller lower entry or a larger upper entry are discarded in the correct direction, maintaining the invariant. At limits take the union of the prefixes.

Suppose the construction never stopped before  $\mu$ . The union is an injective word  $p$  of length  $\mu$ . Every input whose  $\mu$ -prefix differs from  $p$  drops out at its first disagreement. There are fewer than  $r \leq q = \text{cf}(\mu)$  inputs, so these dropout coordinates are bounded below  $\mu$ . At most one input can have  $\mu$ -prefix exactly  $p$ : for type  $\mu$  the whole enumeration is determined, and for type  $\mu + 1$  its single omitted label determines the last entry. Since  $A < B$ , that one input cannot lie on both sides. Beyond the bound on the dropout coordinates, at least one active side is therefore empty, forcing the stopping case. This contradiction proves that the construction stops at a coordinate below  $\mu$ .  $\square$

*Proof of the bounded obstruction.* Choose a sign word  $s$  of length exactly  $\kappa$  such that both its plus positions and minus positions are cofinal in  $\kappa$ , and whose first two signs are  $+, -$ . For example, use the parity of the finite tail of each ordinal coordinate. Then  $0 < s < 1$ , while  $s \notin \mathbf{No}_{<\kappa}$ . Prefixes  $s \restriction \gamma$  at cofinally many positions with  $s(\gamma) = +$  lie below  $s$  and are cofinal below its cut in  $\mathbf{No}_{<\kappa}$ ; prefixes at cofinally many minus positions are coinital above it. Choose such two cofinal collections indexed by  $r$ .

Every  $x \in \mathbf{No}_{<\kappa}$  has its comparison with  $s$  decided before  $\kappa$ . A sufficiently long chosen prefix therefore passes  $x$  on the appropriate side. No element of  $\mathbf{No}_{<\kappa}$  separates the two prefix families. Neither side can have a smaller cofinal family: fewer than  $r$  birthdays are bounded below  $\kappa$ , and a longer appropriate prefix passes every label in that family. Thus this is a bounded numerical gap of character  $(r, r)$ .

Pull the cut back under the first-coordinate map  $e \mapsto e(0)$ . Choose arbitrary completions for the two numerical cofinal families. A hypothetical separating enumeration would need its first entry to lie in the missing numerical cut, which is impossible. Conversely those completions are cofinal and cointial on their respective sides, and the first-coordinate projection proves the matching lower bounds. Enumerations starting with 0 and 1 bound the whole configuration. This supplies the claimed bounded  $(r, r)$  obstruction.  $\square$

### 30.8.3 Regular and singular consequences

**Corollary 30.26** (Two especially transparent regimes). *1. If  $\kappa$  is regular and  $2^{<\kappa} = \kappa$ , then*

$$|\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})| = 2^\kappa, \quad \text{d} = \text{cell} = \kappa,$$

*and every local character and global cofinality or cointiality is  $\kappa$ . The order is  $\eta_\kappa$  and has a bounded unfilled  $(\kappa, \kappa)$ -cut.*

*2. If  $\kappa$  is a singular strong-limit cardinal, then*

$$|\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})| = 2^\kappa, \quad \text{d} = \text{cell} = 2^\kappa,$$

*while every point character and both global cofinalities are  $\text{cf}(\kappa)$ . Its sharp interpolation threshold is  $\eta_{\text{cf}(\kappa)}$ .*

*Proof.* In the regular case,  $\kappa^{<\kappa} = \kappa$ . For a fixed  $\lambda < \kappa$ , every function  $\lambda \rightarrow \kappa$  has bounded range, and the possibilities for each range bound are at most  $2^{<\kappa} = \kappa$ ; summing over  $\kappa$  range bounds gives  $\kappa^\lambda = \kappa$  for nonzero  $\lambda < \kappa$ .

In the singular strong-limit case,  $2^{<\kappa} = \kappa$ . Let  $r = \text{cf}(\kappa)$  and take a cofinal sequence  $(\kappa_\xi)_{\xi < r}$  below  $\kappa$ . A subset of  $\kappa$  is determined by its intersections with the  $\kappa_\xi$ . Each intersection has fewer than  $\kappa$  possibilities by the strong-limit hypothesis, so

$$2^\kappa \leq \kappa^r \leq \kappa^{<\kappa} \leq \kappa^\kappa = 2^\kappa.$$

Thus  $\kappa^{<\kappa} = 2^\kappa$ . The other conclusions now follow from the preceding theorems and the baseline cardinality theorem.  $\square$

**What these results settle, and what they do not.** The baseline explicitly left density, cellularity and much of the singular-cutoff interpolation analysis as continuation questions. The preceding theorems determine density and cellularity for every fixed enumeration type and every infinite alphabet, and give exact local/global characters and sharp guaranteed interpolation at every infinite initial birthday cutoff for the minimal slice. They do not identify the order up to isomorphism. In particular, equality of these invariants is not an isomorphism theorem, and the old exact ordinal spectrum remains logically separate from the new topological information. The full spectrum of unfilled cut characters requires an additional analysis of boundaries of transfinite prefix cylinders.

### 31 Longer strata: every cardinal-block type (source 15)

[merge] Source 15's Section 8, printed whole: the only batch-81 treatment of strata longer than the minimal one. Its  $r_\kappa$  is printed  $\rho_\kappa$  (by [theorem 8.3](#),  $\rho_\kappa = \ell_2(\mathcal{W}_\mu(\mathbf{No}_{<\kappa}))$ ), so that  $r$  keeps the meaning of  $\kappa$ ; its  $D_{\sigma,m}$  is printed  $\mathbb{B}_\sigma \times_{\text{lex}} m$ , so that no letter clashes with its core  $\mathcal{D}$  ([section 1.3.1](#)). The section extends source 12's [theorem 8.3](#) ( $\gamma = 1$ ,  $n = 0$ ) along the targets of [research question 113.11](#). Its entry code ([lemma 31.1](#)) is source 12's [lemma 19.33](#) and source 16's mechanism in (S16.2); its cube clause is [lemma 6.4](#) (reals report `two:thm:cube-strict`); its row scheduler ([lemma 31.3](#)) is source 12's [lemma 8.1](#) run blockwise along  $\gamma$ ; its finite-deletion lemma ([lemma 31.4](#)) is [lemma 8.2](#) with a finite set removed; its finite-capacity lemma is, by its own account, the finite-fiber fusion argument of the reals report. Source 15 states its finite-deletion lemma for singular strong-limit  $\kappa$ ; the hypothesis is not used in its proof.

The earlier minimal-slice theorem ([section 8](#)) extends to all enumeration types whose remainder on division by the alphabet cardinal is finite. This includes the explicitly proposed next cases  $\mu \cdot 2$  and  $\mu \cdot \gamma + n$ . It does not classify an additional infinite remainder smaller than  $\mu$ . All products and sums of ordinals in this section are ordinal operations.

Let  $\kappa$  be an infinite initial cardinal, and put

$$X = \mathbf{No}_{<\kappa}, \quad \mu = |X| = 2^{<\kappa}, \quad \rho_\kappa = \begin{cases} \kappa \cdot \kappa, & \kappa \text{ is a singular strong-limit cardinal,} \\ \mu, & \text{otherwise.} \end{cases}$$

For an ordinal  $\alpha$  with  $|\alpha| = \mu$ , write  $\mathcal{W}_\alpha(X)$  for the bijections  $\alpha \rightarrow X$ , compared by their first unequal entry in the numerical order of  $X$ . For a positive integer  $m$ , write

$$\mathbb{B}_\sigma \times_{\text{lex}} m = \mathbb{B}_\sigma \times_{\text{lex}} \{0, \dots, m-1\}, \quad \mathbb{B}_\sigma = (2^\sigma, <_{\text{lex}}),$$

the finite chain  $m = \{0, \dots, m-1\}$  being the last coordinate.

**Lemma 31.1** (An explicit entry code and the strict cube hierarchy). *Replace each minus sign by 00, each plus by 11, and terminate with 01. The resulting code  $c(s)$  is prefix-free and preserves numerical surreal order. Its length is  $2 \cdot \text{bd}(s) + 2$ , less than  $\kappa$  for  $s \in \mathbf{No}_{<\kappa}$ . Furthermore,*

$$\mathbb{B}_\alpha \hookrightarrow \mathbb{B}_\beta \iff \alpha \leq \beta.$$

*Proof.* The three blocks  $00 < 01 < 11$  encode precisely minus, termination, and plus. Distinct completed codes cannot be proper prefixes: at the first termination of one of them the other either terminates too or has a different block. Padding a completed entry therefore does not alter its comparison with another entry.

For the cube assertion, extension by zeros gives the embedding when  $\alpha \leq \beta$ . Suppose  $\alpha > \beta$  and an embedding in the other direction exists. Successively read target bits, retaining at each step a full source child cylinder whose image lies on one side of the next target-bit split. Such a child exists: if the lower child does not lie wholly below the split, every point of the upper child lies above it. At limits take unions of the chosen prefixes. After  $\beta$  steps, all points extending one source prefix of length  $\beta$  have the same whole target word. There are at least two source extensions since  $\beta < \alpha$ , contradicting injectivity. This is the same cylinder fusion mechanism used in the prior binary-length calculations.  $\square$

When  $\mu = \kappa$  is singular,  $\kappa$  is a strong limit. Otherwise  $2^\rho = \kappa$  for some  $\rho < \kappa$  would also give  $2^\lambda = \kappa$  at  $\lambda = \max(\rho, \text{cf } \kappa) < \kappa$ , contradicting König's inequality  $\text{cf}(2^\lambda) > \lambda$ . Thus the three cases used below are exhaustive.

**Theorem 31.2** (Cardinal blocks and a finite terminal permutation). *For every  $0 < \gamma < \mu^+$  and every  $n < \omega$ ,*

$$\mathcal{W}_{\mu \cdot \gamma + n}(\mathbf{No}_{<\kappa}) \simeq_e (\mathbb{B}_{\rho_\kappa \cdot \gamma} \times_{\text{lex}} n!).$$

*In particular, if  $\kappa$  is a singular strong limit, then*

$$\mathcal{W}_{\kappa \cdot \gamma + n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\kappa \cdot \kappa \cdot \gamma} \times_{\text{lex}} \{0, \dots, n! - 1\}.$$

*The statement concerns equimorphism; it does not identify these permutation orders with the generally nondense binary products.*

We give the scheduler detail before proving the theorem, since a cardinality-preserving reindexing alone would not preserve lexicographic order.

**Lemma 31.3** (Blockwise row scheduling). *Let  $Y$  be a linearly ordered set of infinite cardinality  $\kappa$ , let  $0 < \gamma < \kappa^+$ , and put  $\lambda = \kappa \cdot \gamma$ . Suppose that  $Y$  contains pairwise disjoint subsets  $(Y_i)_{i < \lambda}$ , each of cardinality  $\kappa$ , with an order embedding  $\phi_i : X \rightarrow Y_i$ , and that  $Z = Y \setminus \bigcup_{i < \lambda} Y_i$  is either empty or has cardinality  $\kappa$ . Then*

$$X_{\text{lex}}^\lambda \hookrightarrow \mathcal{W}_\lambda(Y).$$

*Proof.* For each  $i < \lambda$ , fix a bijection  $b_i : \kappa \rightarrow Y_i$ . For  $x \in X$ , transpose  $\phi_i(x)$  with  $b_i(0)$  in that enumeration; denote the result by  $b_{i,x}$ . Its first value is  $\phi_i(x)$ , and for equal  $x$  the whole row is the same.

Split the variable rows into the consecutive blocks  $\{\kappa \cdot \beta + \xi : \xi < \kappa\}$ ,  $\beta < \gamma$ . Within one block schedule row–column pairs  $(\xi, j) \in \kappa^2$  first by  $\max(\xi, j)$  and then lexicographically inside each level. Every pair has fewer than  $\kappa$  predecessors: all earlier pairs lie in a square bounded below  $\kappa$ , and such a square has cardinality less than  $\kappa$ , even when  $\kappa$  is singular. The schedule therefore has order type  $\kappa$ . The first occurrence of row  $\xi$  is  $(\xi, 0)$ , and these first occurrences have increasing row indices.

If  $Z \neq \emptyset$ , include its fixed  $\kappa$ -long enumeration as a filler row before the variable rows in the first block. The row-index order is  $1 + \kappa = \kappa$ , so the same construction applies. The filler row has no input parameter. Every later block uses only its  $\kappa$  variable rows.

For  $x = (x_i)_{i < \lambda}$ , output the entries of  $b_{i,x_i}$  by these successive block schedules. Each block has length  $\kappa$  and there are  $\gamma$  blocks, so the output has length exactly  $\lambda$ . The disjoint rows and the filler exhaust  $Y$  exactly once.

If inputs  $x <_{\text{lex}} x'$  first differ at row  $i = \kappa \cdot \beta + \xi$ , earlier blocks agree completely. In block  $\beta$ , every output before the first entry of row  $i$  comes from a lower row or from the fixed filler. Those outputs agree. The first unequal output is therefore  $\phi_i(x_i) < \phi_i(x'_i)$  at the first entry of row  $i$ . This proves both injectivity and order preservation. No regularity of  $\gamma$  or  $\kappa$  was used.  $\square$

**Lemma 31.4** (Finite deletion does not obstruct the singular scheduler). *If  $\kappa$  is a singular strong limit,  $X = \mathbf{No}_{<\kappa}$ ,  $F \subseteq X$  is finite, and  $\lambda = \kappa \cdot \gamma$  for  $0 < \gamma < \kappa^+$ , then*

$$X_{\text{lex}}^\lambda \hookrightarrow \mathcal{W}_\lambda(X \setminus F).$$

*Proof.* For  $\xi < \kappa$ , let  $C_\xi$  be the sign-sequence cone with prefix  $+\xi \frown -$ . The cones are disjoint, and prefixing gives an order isomorphism  $X \rightarrow C_\xi$ . Indeed,  $\xi + 1 + \eta < \kappa$  for  $\xi, \eta < \kappa$ , because  $\kappa$  is an initial cardinal; deletion of the prefix gives the inverse. Each cone has cardinality  $\kappa$ . At most finitely many cones meet  $F$ . Select  $\kappa$  unaffected cones and index them by  $\lambda$ , which has cardinality  $\kappa$ .

The complement of those selected cones in  $X \setminus F$  has cardinality  $\kappa$ : it contains all but finitely many of the all-plus sequences, one for each length below  $\kappa$ , and is a subset of  $X$ . The preceding lemma now applies, with that complement as the filler. In particular, no unexplained bijection of a grid with  $\lambda$  is being used in place of a lexicographic scheduler.  $\square$

*Proof of Theorem 31.2.* Write  $\lambda = \mu \cdot \gamma$  and  $\sigma = \rho_\kappa \cdot \gamma$ . We first construct the upper embedding. Use the repository's prefix-free, numerical-order-preserving binary code  $c(s)$  for each  $s \in X$ , with positive length less than  $\kappa$ .

If  $\mu > \kappa$ , pad each individual entry code to length  $\kappa$ . Prefix-freeness ensures that this preserves all entry comparisons. A block of  $\mu$  entries then consumes ordinal length  $\kappa \cdot \mu = \mu$ . Applying this separately to the  $\gamma$  successive blocks gives a prefix code of length  $\mu \cdot \gamma = \sigma$ .

If  $\mu = \kappa$  and  $\kappa$  is regular, concatenate the unpadded codes in each  $\kappa$ -entry block. Each proper partial sum of their lengths is below  $\kappa$  by regularity, while the full sum is  $\kappa$  because all code lengths are positive. Each block therefore consumes exactly  $\kappa$ , again giving length  $\sigma$ .

In the remaining case  $\mu = \kappa$  is singular, it is a strong limit. Pad each entry code to length  $\kappa$ . Each block now consumes  $\kappa \cdot \kappa$ , and the complete  $\lambda$ -entry prefix has code length  $\kappa \cdot \kappa \cdot \gamma = \sigma$ .

In all cases, a prefix of length  $\lambda$  from a bijection  $\lambda + n \rightarrow X$  has a binary code of length exactly  $\sigma$ . The remaining  $n$  labels form a finite set determined by that prefix. Append the rank of their terminal permutation in its increasing lexicographic list of  $n!$  permutations. Different prefixes compare inside the binary code; equal prefixes have the same remaining labels and compare by the finite rank. This gives  $\mathcal{W}_{\lambda+n}(X) \hookrightarrow (\mathbb{B}_\sigma \times_{\text{lex}} n!)$ .

For the reverse embedding in either nonexceptional case, reserve a fixed  $n$ -element set  $F \subseteq X$  and partition  $X \setminus F$  into pairs indexed by  $\lambda$ . Such a partition exists because  $|\lambda| = \mu$ . List each pair in its increasing or decreasing orientation according to the corresponding bit of a member of  $\mathbb{B}_\lambda$ . Since  $\lambda$  is a nonzero limit ordinal,  $2 \cdot \lambda = \lambda$ . Append the requested one of the  $n!$  permutations of  $F$ . Here  $\sigma = \lambda$ , giving the required embedding.

It remains to obtain the longer cube in the singular strong-limit case. Let  $\delta = \text{cf } \kappa < \kappa$ , and choose nonzero ordinals  $(\tau_j)_{j < \delta}$  cofinal in  $\kappa$ , with  $\sum_{j < \delta} \tau_j = \kappa$ . The identities

$$\delta \cdot \kappa = \kappa, \quad \delta \cdot \lambda = \delta \cdot (\kappa \cdot \gamma) = \lambda$$

allow the  $\lambda$  input coordinates of  $X^\lambda$  to be grouped into  $\lambda$  consecutive blocks of  $\delta$  coordinates. In each block, restrict its  $j$ th coordinate to surreals whose sign sequences have length exactly  $\tau_j$ . That coordinate is a copy of  $\mathbb{B}_{\tau_j}$ , so the entire restricted product is

$$\mathbb{B}_{\sum_{i < \lambda} \sum_{j < \delta} \tau_j} = \mathbb{B}_{\kappa \cdot \lambda} = \mathbb{B}_{\kappa \cdot \kappa \cdot \gamma} = \mathbb{B}_\sigma.$$

By Lemma 31.4, this product embeds into  $\mathcal{W}_\lambda(X \setminus F)$ . Append any of the  $n!$  permutations of  $F$ , obtaining  $(\mathbb{B}_\sigma \times_{\text{lex}} n!) \hookrightarrow \mathcal{W}_{\lambda+n}(X)$ .  $\square$

### 31.1 Exact coding lengths, embedded cubes, and comparisons

The next capacity argument is the finite-fiber fusion argument already used in the real-alphabet report. It is included to make the numerical consequences of the extension explicit.

**Lemma 31.5** (Finite fibers over a binary cube). *Let  $\sigma, \tau$  be nonzero limit ordinals and let  $m, n$  be positive integers. Then*

$$(\mathbb{B}_\sigma \times_{\text{lex}} m) \hookrightarrow (\mathbb{B}_\tau \times_{\text{lex}} n) \iff \sigma < \tau \text{ or } (\sigma = \tau \text{ and } m \leq n).$$

Moreover,

$$\ell_2(\mathbb{B}_\sigma \times_{\text{lex}} m) = \sigma + \lceil \log_2 m \rceil, \quad \mathbb{B}_\theta \hookrightarrow (\mathbb{B}_\sigma \times_{\text{lex}} m) \iff \theta \leq \sigma + \lceil \log_2 m \rceil.$$

*Proof.* For equal binary lengths, suppose  $f : (\mathbb{B}_\sigma \times_{\text{lex}} m) \hookrightarrow (\mathbb{B}_\sigma \times_{\text{lex}} n)$ . Recursively choose a source binary prefix  $s_\xi$  and target binary prefix  $t_\xi$ , both of length  $\xi$ , such that

$$f(C_{s_\xi} \times \{0, \dots, m-1\}) \subseteq C_{t_\xi} \times \{0, \dots, n-1\}.$$

At a successor stage the target's next bit cuts the image into two ordered parts. Of the source cylinder's two full children, at least one lies wholly on one side of that cut: if its lower child is not wholly on the lower side, its upper child is wholly on the upper side. Keep that child and the corresponding target bit. At a limit stage take unions of prefixes. The invariant persists, and the source cylinder remains nonempty. At stage  $\sigma$ , all  $m$  points over one source binary sequence lie in one target fiber of size  $n$ . Thus  $m \leq n$ . The converse is immediate.

Coding the finite chain of size  $m$  by  $\lceil \log_2 m \rceil$  bits gives  $(\mathbb{B}_\sigma \times_{\text{lex}} m) \hookrightarrow \mathbb{B}_{\sigma + \lceil \log_2 m \rceil}$ . No cube shorter than  $\sigma$  can contain  $(\mathbb{B}_\sigma \times_{\text{lex}} m)$ , since it already contains  $\mathbb{B}_\sigma$  and the binary cube hierarchy is strict. A target  $\mathbb{B}_{\sigma+j} = (\mathbb{B}_\sigma \times_{\text{lex}} 2^j)$  with  $j < \omega$  can contain it only if  $m \leq 2^j$ , by the same fusion argument. This proves the coding-length formula.

Likewise,  $\mathbb{B}_{\sigma+j}$  embeds into  $(\mathbb{B}_\sigma \times_{\text{lex}} m)$  exactly when  $2^j \leq m$ . Once the first forbidden finite extension has been excluded, every larger cube is excluded because it contains that extension. This proves the complete cube spectrum.

Finally, if  $\sigma < \tau$ , then  $\sigma + \lceil \log_2 m \rceil < \tau$  because  $\tau$  is a limit. Code into that shorter cube and then into the target. If  $\tau < \sigma$ , the target codes into a cube of length  $\tau + \lceil \log_2 n \rceil < \sigma$ , whereas the source contains  $\mathbb{B}_\sigma$ ; strictness excludes an embedding. This proves the comparison criterion.  $\square$

**Corollary 31.6** (The complete invariant on these block types). *Under the hypotheses of Theorem 31.2, put  $\sigma = \rho_\kappa \cdot \gamma$ . Then*

$$\ell_2(\mathcal{W}_{\mu \cdot \gamma + n}(\mathbf{No}_{<\kappa})) = \sigma + \lceil \log_2(n!) \rceil,$$

and

$$\mathbb{B}_\theta \hookrightarrow \mathcal{W}_{\mu \cdot \gamma + n}(\mathbf{No}_{<\kappa}) \iff \theta \leq \sigma + \lceil \log_2(n!) \rceil.$$

For  $0 < \gamma, \eta < \mu^+$  and  $m, n < \omega$ ,

$$\mathcal{W}_{\mu \cdot \gamma + n}(\mathbf{No}_{<\kappa}) \hookrightarrow \mathcal{W}_{\mu \cdot \eta + m}(\mathbf{No}_{<\kappa}) \iff \gamma < \eta \text{ or } (\gamma = \eta \text{ and } n! \leq m!).$$

*Proof.* Apply the finite-capacity lemma and use strict monotonicity in the right argument of  $\gamma \mapsto \rho_\kappa \cdot \gamma$  for a fixed nonzero left factor. Here each  $\rho_\kappa \cdot \gamma$  is a nonzero limit ordinal.  $\square$

For an unconditional singular example, take  $\kappa = \beth_\omega$ . The types  $\kappa \cdot 2$ ,  $\kappa \cdot 2 + 3$ , and  $\kappa^2$  have binary coding lengths respectively

$$\kappa^2 \cdot 2, \quad \kappa^2 \cdot 2 + 3, \quad \kappa^3.$$

The type  $\kappa \cdot 2 + 3$  contains the cube of length  $\kappa^2 \cdot 2 + 2$  but not the cube of its own coding length. These distinctions are invisible to cardinality and to the ordinal embedding spectrum, which remain  $2^\kappa$  and  $\{\beta : \beta < \kappa^+\}$  throughout.

### 31.2 Density and cellularity, including the singular minimal slice

Write  $d(L)$  for the least cardinality of a dense subset in the order topology, and  $\text{cell}(L)$  for the supremum of cardinalities of families of pairwise disjoint nonempty open sets. An additional consequence of the coding theorem is an exact answer for these two invariants on the same block types. In particular, the singular minimal slice has the largest possible cellularity, a fact not visible from its unchanged ordinal embedding spectrum.

**Corollary 31.7** (Density and cellularity of the block types). *For  $L = \mathcal{W}_{\mu \cdot \gamma + n}(\mathbf{No}_{<\kappa})$  as above,*

$$d(L) = \text{cell}(L) = \begin{cases} 2^{<\mu}, & \rho_\kappa = \mu, \gamma = 1, n \leq 2, \\ 2^\mu, & \text{otherwise.} \end{cases}$$

*Consequently*

$$d(\mathcal{W}_\mu(\mathbf{No}_{<\kappa})) = c(\mathcal{W}_\mu(\mathbf{No}_{<\kappa})) = \begin{cases} 2^\kappa, & \kappa \text{ is a singular strong limit,} \\ 2^{<\mu}, & \text{otherwise.} \end{cases}$$

*Proof.* First consider  $\rho_\kappa = \mu$ ,  $\gamma = 1$ , and  $n \leq 2$ . The finite factor  $n!$  has size at most two. There is an embedding  $f : L \rightarrow (\mathbb{B}_\mu \times_{\text{lex}} n!)$ . No point of  $L$  is isolated. Indeed,  $L$  has no endpoints because the native surreal alphabet has neither a least nor a greatest element; swapping the first entry with a smaller or larger label moves either way without changing the enumeration type. The adjacency criterion for exhaustive permutations applies inside a fixed type: if the unused remainder at a first difference is infinite, an ascent in the lower tail or a descent in the upper tail gives an intermediate permutation of the same type. Adjacency is therefore confined to the finite terminal permutation component. For  $n \leq 2$  each such component has at most two points, so no point has both an immediate predecessor and an immediate successor. Thus no point is isolated, and every nonempty open set contains at least five points.

For every binary prefix  $s$  of length less than  $\mu$  whose cylinder meets the first-coordinate projection of  $f[L]$ , choose one element  $x_s \in L$  whose image has that prefix. There are at most  $\sum_{\xi < \mu} 2^{|\xi|} = 2^{<\mu}$  such choices. These choices are dense. To see this, take five increasingly ordered points  $x_0 < \dots < x_4$  in any given nonempty open interval. Each binary fiber has at most two points, so the binary first coordinate of  $f(x_2)$  is strictly between those of  $f(x_0)$  and  $f(x_4)$ . Choose a prefix long enough to distinguish it from both outer coordinates. Its whole binary cylinder lies strictly between them, and the chosen  $x_s$  lies in the original open interval. Hence  $d(L) \leq 2^{<\mu}$ .

Conversely  $L$  contains  $\mathbb{B}_\mu$ . For each  $\xi < \mu$ , its  $2^{|\xi|}$  cylinders of length  $\xi$  each contain three ordered points. The ambient open intervals in  $L$  between the images of the outer two points are nonempty, since they contain the image of the middle point, and they are pairwise disjoint. Therefore  $\text{cell}(L) \geq 2^{<\mu}$ , proving equality in the first case since always  $\text{cell}(L) \leq d(L)$ .

In every remaining case, put  $\sigma = \rho_\kappa \cdot \gamma$ . If  $\sigma > \mu$ , the embedded cube  $\mathbb{B}_\sigma$  has  $2^\mu$  distinct cylinders of prefix length  $\mu$ , each with at least three points because  $\sigma$  is a limit ordinal greater than  $\mu$ . The preceding interval construction gives  $\text{cell}(L) \geq 2^\mu$ . If  $\sigma = \mu$  but  $n \geq 3$ , the embedded order  $(\mathbb{B}_\mu \times_{\text{lex}} n!)$  has a fiber with at least three points over each of its  $2^\mu$  binary sequences. The intervals between the images of its first and last fiber points are again pairwise disjoint and nonempty. Thus  $\text{cell}(L) \geq 2^\mu$  here as well. Finally  $d(L) \leq |L| = 2^\mu$ , giving the claimed equalities.  $\square$

### 31.3 The boundary of the result

Write a general admissible type as  $\alpha = \mu \cdot \gamma + \zeta$ ,  $\zeta < \mu$ . The theorem settles the case that  $\zeta$  is finite. When  $\zeta$  is infinite, the preceding long prefix leaves a residual numerical suborder of cardinality  $|\zeta|$ ; that residual order varies with the prefix. Neither the size nor the coding behavior of this smaller alphabet can simply be replaced by those of  $\mathbf{No}_{<\kappa}$ . An exact treatment must control the possible residual suborders and the code lengths available uniformly for their permutations. Thus the result gives a precise affirmative continuation of the proposed cardinal-block program while leaving the smaller infinite-tail classification explicitly open.

*Remark 31.8* ([merge]; the reals report's display at  $X = \mathbf{No}_{<\kappa}$ ). The reals report asks under which hypotheses on  $X$  the display  $\mathcal{W}_{\lambda+n}(X) \simeq_e \mathbb{B}_\lambda \times_{\text{lex}} n!$  still holds (its question ‘‘Other ground

orders”, `two:sec:research`); its batch-80 note records that [theorem 8.3](#) gives the case  $n = 0$ ,  $\lambda = \mu$  for  $X = \mathbf{No}_{<\kappa}$ , except at a singular strong limit. For  $\lambda = \mu \cdot \gamma$ ,  $0 < \gamma < \mu^+$ , and every  $n < \omega$ , [theorem 31.2](#) gives  $\mathcal{W}_{\lambda+n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\rho_\kappa \cdot \gamma} \times_{\text{lex}} n!$ , and by [lemma 31.5](#) two such products with nonzero limit lengths are equimorphic only when the lengths are equal. So the display holds whenever  $\kappa$  is not a singular strong limit ( $\rho_\kappa = \mu$ ). At a singular strong limit ( $\mu = \kappa$ ,  $\rho_\kappa = \kappa \cdot \kappa$ ) it holds exactly when  $\kappa \cdot \kappa \cdot \gamma = \kappa \cdot \gamma$ , that is, when  $\gamma = \kappa^\omega \cdot \delta$  for some ordinal  $\delta$  (then  $\kappa \cdot \gamma = \gamma$ , by Cantor normal form to base  $\kappa$ ); it fails for  $\gamma = 1, 2, \kappa, \dots$ . The display is therefore not simply false at singular strong limits. Strata  $\lambda$  that are not multiples of  $\mu$  (the first is  $\mu + \omega$ ), cutoffs that are not cardinals, and other alphabets remain open, as source 15 says in [section 31.3](#).

## 32 Set-sized baselines and warnings in sources 13–18

[merge] Every batch-81 source restates the set-sized baseline of the reals report and of Part I ([section 6](#) and [theorem 6.1](#)): cardinality  $2^\mu$ , universality for orders of size at most  $\mu$ , and the exact ordinal spectrum  $\beta < \mu^+$ . They are recorded here once, with the sources’ own provenance statements, followed by the set-level warnings of sources 13, 14 and 17. None of these statements is new.

*Note 32.1* (Source 16, Theorem 4.1, “Basic set-alphabet results”). Source 16’s Section 4 fixes “an infinite linearly ordered set  $X$  of cardinality  $\mu$ ” and records that exhaustive enumerations are prefix-incomparable and that an injective prefix of length less than  $\mu$  extends to a bijection of every ordinal type  $\alpha$  with  $|\alpha| = \mu$ . *The orders  $\mathcal{W}(X)$  and  $\mathcal{W}_\mu(X)$  have cardinality  $2^\mu$ . Every linear order of cardinality at most  $\mu$  embeds into  $\mathcal{W}_\mu(X)$ . For every ordinal  $\beta$ ,  $\beta \hookrightarrow \mathcal{W}(X)$  if and only if  $\beta < \mu^+$ , and the same statement holds with  $\mathcal{W}_\mu(X)$  in place of  $\mathcal{W}(X)$ , and for the reverse of  $\beta$ .* Its proof is the pair-orientation, initial-segment and coordinate-stabilization proof of [section 6](#). Source 16’s status line: “Theorem 4.1 is background from the ProveIt reals and surreal reports; it is reproved here to make the later arguments self-contained. In particular, ‘all ordinals embed’ is false at every fixed set stage.”

*Birthday cutoffs and a singular distinction* (source 16’s Subsection 4.1). For  $\mathbf{No}_{<\kappa}$ ,  $\kappa$  an infinite cardinal, substitute  $\mu = 2^{<\kappa}$  for the alphabet cardinal in [Note 32.1](#). The ordinal embedding cutoff is  $\mu^+$ , not automatically  $\kappa^+$ . The earlier report also proves a sharper binary-coding distinction:

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \simeq_e \begin{cases} 2_{\text{lex}}^{\kappa \cdot \kappa}, & \kappa \text{ is a singular strong-limit cardinal,} \\ 2_{\text{lex}}^\mu, & \text{otherwise.} \end{cases} \quad (\text{S16.2})$$

Here  $\kappa \cdot \kappa$  is ordinal multiplication. This statement is equimorphism, meaning embeddings in both directions, not isomorphism.

The upper coding mechanism replaces a negative sign by 00, a positive sign by 11, and termination by 01. These codes are prefix-free and preserve numerical comparison. At a regular stage, a sum of fewer than  $\kappa$  code lengths remains below  $\kappa$ . At a singular strong-limit stage it can already reach  $\kappa$  before all  $\kappa$  coordinates have been processed; padding every entry to length  $\kappa$  gives total length  $\kappa \cdot \kappa$ . The matching lower bound in the report uses a cofinal sequence of sign lengths and an order-preserving row scheduler ([theorem 8.3](#)). We do not reclassify the binary coding ranks of all longer strata here. The topological classification below, by contrast, covers every admissible enumeration length and every infinite alphabet.

*Note 32.2* (Source 18, Theorem 3.1, “Set-sized universality and the exact ordinal spectrum”). Source 18’s Section 3 defines  $\mathcal{W}(X)$  and  $\mathcal{W}_\alpha(X)$  as here, notes that two exhaustive enumerations are never proper prefixes of one another, so that no termination convention is needed, and that “labels are

essential: two two-point well-orders can be isomorphic as abstract orders and still have different first numerical labels”. *Let  $X$  be an infinite linear order of cardinality  $\mu$ . Then  $|\mathcal{W}(X)| = |\mathcal{W}_\mu(X)| = 2^\mu$ . Every linear order of cardinality at most  $\mu$  embeds into  $\mathcal{W}_\mu(X)$ . An ordinal  $\beta$  embeds into  $\mathcal{W}(X)$  if and only if  $\beta < \mu^+$ . The same exact spectrum holds for reverse ordinals and for every nonempty stratum  $\mathcal{W}_\alpha(X)$ .* The proof is that of [section 6](#); source 18 adds that the stabilization argument “uses the regularity of the successor cardinal  $\mu^+$ , not regularity of  $\mu$ ”, and that cardinality  $2^\mu$  is a poor guide, since such an order contains no increasing sequence of type  $\mu^+$ . Its subsection “What the existing binary-rank result adds” restates [theorem 8.3](#) (binary coding length  $\kappa \cdot \kappa$  at a singular strong-limit cutoff,  $\mu$  otherwise), calls it “background rather than a dependency of our new cut-spectrum proof”, and adds: “Replacing these ordinal sums by cardinalities would erase a genuine distinction. Our results below add topological information not determined by this coding length.”

*Note 32.3* (Source 15, Lemma 3.2 and Theorem 3.3, “Set-sized baseline, from the prior reports”). Source 15’s Lemma 3.2 (“Exhaustiveness removes prefix ambiguity”): *distinct exhaustive bijective enumerations of the same set have a first unequal coordinate in both domains; neither is a proper prefix of the other.* Its Theorem 3.3 is the baseline of [note 32.1](#) for every nonempty fixed-type slice, proved as in [section 6](#), with the fixed type  $\alpha = \lambda + n$  handled by reserving  $n$  final labels and orienting pairs indexed by  $\lambda$ . Source 15 says: “This proof uses no special property of real or surreal arithmetic. It is reproduced to fix the dependence of the later theorems; its content is already in the audited reports. If  $X$  is finite of size  $n$ , the whole order is the finite chain of its  $n!$  permutations. The empty carrier has one empty well-order.” Its subsections on birthday cutoffs and on set-length words, which close its Section 3, follow. Its Lemma 3.1 (fresh separators) belongs to the class layer and is printed with the other batch-81 restatements of [lemma 5.2](#) ([lemma 51.2](#)).

### 32.1 Source 15’s birthday cutoffs and set-length words

[merge] The last two subsections of source 15’s Section 3; its  $X_\kappa$  is printed  $\mathbf{No}_{<\kappa}$ , and its forward reference to its Section 8 points to [section 31](#).

#### 32.1.1 Birthday cutoffs

For an infinite initial cardinal  $\kappa$ , let

$$X_\kappa = \mathbf{No}_{<\kappa}, \quad \mu = |X_\kappa| = 2^{<\kappa}.$$

Counting sign levels proves the cardinality formula: the supremum of their cardinalities is at least  $\kappa$ , and the union of  $\kappa$  levels does not exceed it. The preceding theorem gives

$$|\mathcal{W}(X_\kappa)| = 2^{2^{<\kappa}}, \quad \beta \hookrightarrow \mathcal{W}(X_\kappa) \iff \beta < (2^{<\kappa})^+.$$

At regular  $\kappa$ , a cut using fewer than  $\kappa$  labels has birthdays bounded below  $\kappa$ , and the usual cut construction stays in the cutoff. Singular  $\kappa$  need not have this property. The fixed-type calculation in [Section 31](#) makes the distinction visible even when the cardinalities and ordinal spectra coincide.

#### 32.1.2 Why all set-length words are a different order

If  $X$  varies, the class of all pairs  $(X, R)$  with  $X$  a set of surreals and  $R$  a well-order is a legitimate class of sets. Its ordinal enumerations are injective set-length words. Proper prefixes now occur. For example  $(0)$  is a prefix of  $(0, 1)$ . One may put shorter words first, shorter words last, or use a

termination symbol placed inside the alphabet. These comparisons agree on exhaustive enumerations of a fixed carrier but need not agree on variable carriers.

The prior report gives an explicit self-delimiting sign code embedding all set-length surreal words, with shorter-first order, into **No**. Its code also exhibits why this order need not be isomorphic to **No**: a word of nonzero limit length is the supremum of its shorter prefixes, whereas a surreal point has no set-sized cofinal family below it. Restricting to successor-length words removes that particular obstruction and yields a class order isomorphic to **No** in GBC (this report’s [part II](#), source 11’s Sections 9–11 there). An embedding theorem therefore must not be strengthened to an isomorphism theorem merely because both carriers are proper classes.

### 32.2 Source 13’s fixed-set section

[merge] Source 13’s Section 4, “The fixed-set theory and birthday fragments”, printed whole; its theorem, a restatement credited by source 13 itself, is printed as a note, and its  $X_\kappa$  is printed **No**<sub><κ</sub>.

The set-sized layer is important both in its own right and as a safe formalization starting point. We record its already-established results with their provenance rather than repeating the earlier report in full.

*Note 32.4* (Source 13, Theorem 4.1, “Fixed-alphabet results from the repository”). Let  $X$  be an infinite linearly ordered set,  $|X| = \mu$ , and compare exhaustive enumerations using its label order. Then

$$|\mathcal{W}(X)| = 2^\mu, \quad \beta \hookrightarrow \mathcal{W}(X) \iff \beta < \mu^+,$$

and the same spectrum holds for reversed ordinals. Every linear order of cardinality at most  $\mu$  embeds in  $\mathcal{W}(X)$ .

*Provenance and proof mechanisms* (source 13). These are the general-alphabet results of the repository’s real well-ordering report, carried into Section 6 of the surreal report ([1]; [section 6](#)). The cardinal lower bound codes independent binary choices by pair reversals in an enumeration; the upper bound counts well-order relations on  $X$ . Universality uses binary codes for initial segments of a small order. The ordinal upper bound is a prefix-stabilization obstruction, stronger than a cardinality bound. We invoke that established written theorem here; this paragraph is not a replacement proof of its stabilization argument.

For an infinite cardinal  $\kappa$ , let

$$\mathbf{No}_{<\kappa}, \quad \mu = 2^{<\kappa}.$$

Counting signs gives  $|\mathbf{No}_{<\kappa}| = \mu$ : there are  $2^{|\alpha|}$  sign sequences of length  $\alpha$ , and the union over  $\alpha < \kappa$  has that supremum cardinality. Thus the ordinal spectrum of  $\mathcal{W}(\mathbf{No}_{<\kappa})$  is exactly the ordinals below  $(2^{<\kappa})^+$ . This does not say that only ordinals below the birthday cutoff embed.

#### 32.2.1 A warning about the minimal-length layer

Write  $\mathbb{B}_\theta = (\{0, 1\}^\theta, <_{\text{lex}})$ , and write  $L \simeq_e M$  for mutual order embeddability. The merged surreal report proves the following sharper distinction ([theorem 8.3](#), Theorem 8.3 of the report at its pin):

$$\mathcal{W}_\mu(X_\kappa) \simeq_e \begin{cases} \mathbb{B}_{\kappa \cdot \kappa}, & \kappa \text{ singular strong limit,} \\ \mathbb{B}_\mu, & \text{otherwise,} \end{cases} \quad \mu = 2^{<\kappa}.$$

The multiplication in  $\kappa \cdot \kappa$  is *ordinal* multiplication. At a singular strong limit,  $\mu = \kappa$ , but the lengths  $\kappa$  and  $\kappa \cdot \kappa$  need not have the same lexicographic effect. This is an existing result, not an advance of the present manuscript.

There is no automatic passage from equimorphism to isomorphism, from a minimal-length stratum to all strata, or from independently chosen cutoff embeddings to a coherent global map. The last passage requires agreement on overlaps. These distinctions become especially visible in the product obstruction below.

### 32.2.2 Set-sized approximations to the new cut theorem

For an arbitrary set alphabet, prefix cylinders can terminate by exhaustion and can have extrema. The crossing arguments of source 13’s Section 8 (its reconstruction of cuts from prefix cylinders) still provide a useful tree description, but its clean all-ordinal formulation depends on two genuinely global facts: every set prefix has a completion, and after deleting its range there are fresh labels on both sides of any remaining set cut. A bounded alphabet need not have either property at its boundary. Therefore the new global theorem is not asserted by simply replacing **No** by every birthday fragment in its statement.

*Note 32.5* (Source 14, Theorem 2.1, “Set-carrier baseline, inherited”). *In ZFC, if  $|X| = \mu$  is infinite, then  $|\mathcal{W}(X)| = 2^\mu$  and  $\beta \hookrightarrow \mathcal{W}(X)$  if and only if  $\beta < \mu^+$ , for ordinals  $\beta$ . Every linear order of cardinality at most  $\mu$  embeds in  $\mathcal{W}(X)$ . Adjacent pairs are exactly the consecutive permutations of a finite residual alphabet after a common prefix.* This is [section 6](#) with source 11’s adjacency theorem (reals report `two:thm:adjacency`). Source 14 prints it as “inherited from the repository, not a new result of this continuation” and gives no proof: “The complete proof is in the predecessor report; we do not substitute counting for that argument.” Its set-level remark follows.

[merge] The rest of source 14’s Subsection 2.2, “Fixed carriers and the inherited spectra”.

The size assertion is plausible for two different reasons: a relation on  $X$  has at most  $2^\mu$  possibilities, while independently choosing the orientation of  $\mu$  disjoint pairs gives  $2^\mu$  distinct well-orders. The ordinal upper bound is a lexicographic obstruction, not a cardinality bound:  $2^\mu$  can be much larger than  $\mu^+$ . The complete proof is in the predecessor report; we do not substitute counting for that argument.

For an infinite cardinal  $\kappa$ , sign sequences give

$$|\mathbf{No}_{<\kappa}| = 2^{<\kappa}.$$

Thus [Note 32.5](#) applies with  $\mu = 2^{<\kappa}$ . The repository also proves a more refined minimal-slice dichotomy: with  $\mathbb{B}_\delta = (\{0, 1\}^\delta, <_{\text{lex}})$ ,

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \simeq_e \begin{cases} \mathbb{B}_{\kappa \cdot \kappa}, & \kappa \text{ is singular strong limit,} \\ \mathbb{B}_\mu, & \text{otherwise.} \end{cases}$$

Here  $\cdot$  is *ordinal* multiplication and  $\simeq_e$  means mutual order embeddability, not isomorphism. This inherited result should not be confused with the support-cardinal theorem proved below: birthday bounds restrict the alphabet, whereas support bounds restrict how much of a fixed global enumeration is changed.

### 32.3 Source 17’s labelled well-orders of a fixed set

[merge] Source 17’s Subsection 2.1, from its map of interpretations. Let  $(X, <)$  be a set with a specified linear order. A well-ordering  $R$  of  $X$  has a unique exhaustive enumeration  $e_R : \alpha_R \rightarrow X$ , where  $\alpha_R$  is its ordinal type. For two distinct well-orders, neither exhaustive enumeration is a proper

prefix of the other: after listing every label once there is no fresh label to append. Therefore a first unequal coordinate exists, and we define

$$R <_{\text{lex}} S \iff e_R(\delta) < e_S(\delta), \quad \delta = \min\{\xi : e_R(\xi) \neq e_S(\xi)\}.$$

Write  $\mathcal{W}(X)$  for all such well-orders, and  $\mathcal{W}_\alpha(X)$  for the suborder with enumeration type exactly  $\alpha$ . Equivalently,  $\mathcal{W}_\alpha(X)$  consists of bijections  $\alpha \rightarrow X$ . The notation  $\mathcal{W}_\mu(X)$  below always uses the initial ordinal of the cardinal  $\mu = |X|$ .

The source establishes, for infinite  $|X| = \mu$ ,

$$|\mathcal{W}(X)| = 2^\mu, \quad \beta \text{ embeds in } \mathcal{W}(X) \iff \beta < \mu^+,$$

and universality for linear orders of cardinality at most  $\mu$  ([theorem 6.1](#); [1]). These are labelled-order results. Quotienting well-orders by abstract order-isomorphism removes exactly the labels on which the comparison depends.

### 33 What this Part answers

[merge] Dated notes, 3 October 2026. Each item names the question, where it is asked, and the result that answers it. Where the question index of [section 113](#) (dated 2 October 2026) says otherwise, these notes supersede it.

- (a) *Source 11's question on the cut spectrum and point characters of the minimal slice without  $2^{<\kappa} = \kappa$*  ([research question 113.7](#)): **answered**. Point characters  $(q, q)$ , global characters  $r$ , density, weight and cellularity  $\mu^{<\mu}$  ([theorem 30.2](#)), the exact gap spectrum ([theorem 30.11](#)), its multiplicities ([theorem 30.16](#)), and the saturation threshold  $\eta_r$  ([corollary 30.18](#) and [theorems 30.23](#) and [30.25](#)).
- (b) *Source 12's question on the invariants of  $\mathcal{W}_\mu(\mathbf{No}_{<\kappa})$*  ([research question 113.13](#)): answered except for the isomorphism type and homogeneity, which no source determines (source 17's [remark 30.22](#); source 18 says “equality of these invariants is not an isomorphism theorem”).
- (c) *Source 08's question 2, invariants at regular cutoffs* ([section 113.4](#)): **answered**. Density and cellularity of every stratum ([theorem 27.2](#) and [corollary 27.4](#)), point characters and cut cofinalities ([theorem 30.14](#) and [example 30.20](#)). This completes item (d) of [section 1.7](#).
- (d) *Source 08's question 3, which small cuts fail at singular cutoffs*: answered in character terms by [theorems 29.4](#) and [30.11](#) (source 17 does not claim this question); its coding half was already answered by [theorem 8.3](#) (item (c) of [section 1.7](#)).
- (e) *Source 12's question on all fixed enumeration types* ([research question 113.11](#)) and *source 08's question 4*: answered for  $\alpha = \mu \cdot \gamma + n$ ,  $0 < \gamma < \mu^+$ ,  $n < \omega$ , the first targets the question suggests ([theorem 31.2](#) and [corollary 31.6](#)); open for an infinite remainder  $\zeta < \mu$  ([section 31.3](#)). The density of every stratum is [theorem 27.2](#).
- (f) *Source 09's direction 7, what survives away from inaccessible truncations* ([section 113.3](#)): answered for the minimal slice; it is  $\eta_r$  and not  $\eta_{r+}$ ,  $r = \text{cf } \kappa$  ([corollary 30.18](#) and [theorem 30.23](#)).
- (g) *The reals report's question “Other ground orders”* (`lwo:sec:research`; item (e) of [section 1.7](#)): answered further for  $X = \mathbf{No}_{<\kappa}$ , every stratum  $\lambda = \mu \cdot \gamma$  and every  $n$  ([remark 31.8](#)); open for strata that are not of this form, for noncardinal cutoffs and for other alphabets.
- (h) *The reals report's questions on other alphabets* (`lwo:rk:q:alphabets`, `lwo:sp:q:alphabets`): the density and cellularity of every stratum and the incompleteness of every stratum are settled for every infinite linear alphabet ([theorems 27.2](#) and [28.1](#)); the gap spectrum is settled

for the minimal slice of every alphabet satisfying the hypotheses of [theorem 30.10](#), which bears on the “general cut-spine transfer theorem” that `lwo:sp:q:alphabets` asks for; the gap spectrum of the full order  $\mathcal{W}(X)$  stays open.

Source 16 also says that its regular-stage results “answer the earlier report’s regular-stage density, cellularity, and cut-character questions under precisely those hypotheses” (end of [section 30.4](#)), and source 15 that its block theorem gives “a precise affirmative continuation of the proposed cardinal-block program” ([section 31.3](#)); items (c) and (e) record the same.

[merge] Dated note, 3 October 2026 (batch 83). Items (b), (e), (f) and (g) are answered further by Parts X and XI: the cube spectrum of every fixed type, with its infinite remainders (so the open case of [section 31.3](#) is covered), the topology of the minimal slice, and noncardinal cutoffs ([sections 72 and 79](#); [section 113.25](#) (a)–(c)).

## Part VII

# Words, termination conventions and other comparison orders

[merge] (3 October 2026.) The second Part of the batch-81 addition ([section 1.8](#); notation in [section 1.3.1](#)). Part II ([part II](#)) compared set-length words with proper prefixes first; the six batch-81 sources ask what changes when the comparison convention changes. This Part prints the six sources’ maps of the possible interpretations ([section 34](#)); the isomorphism of the unrestricted, injective and numerically increasing shorter-first word orders ([section 35](#)); the criterion for every placement of a formal terminator and the list of all isomorphism types it produces ([section 36](#)); the exact cut classification of centered increasing words and of the conventions for the entry zero ([section 37](#)); and comparison orders other than numerical enumeration lexicography: inverse ranks, relation tables, restrictions and normal forms ([section 38](#)). [Section 39](#) records which questions the Part answers.

The bases are chosen by generality, as in Part VI: source 16 for the word isomorphism and the termination classification (every placement of a terminator, unrestricted and injective words), source 18 for centered increasing words and the zero conventions (the only source treating them), source 15 for the other comparison orders (the only source proving theorems about them). Source 13’s central termination theorem and source 18’s centered theorem are the same special case of source 16’s criterion, proved independently, with the same letter code; they are printed as routes. Source 18 was written before sources 13–17 arrived. Re-proofs of Part II are printed as notes. Source 16 uses the macro names of this report for other objects (its `\Words` is the class of *all* words, its `\I` the class injections); here they are printed  $\mathcal{T}$  and  $\mathfrak{J}$ , and  $\mathcal{I}$  keeps its meaning of injective words ([section 1.3.1](#)). Labels written for the merge in this Part begin `swo:vii:`.

## 34 The six sources’ maps of interpretations

[merge] Each batch-81 source opens with a map of what “all well-orders of the surreal numbers” can mean, as sources 12, 09 and 08 did ([section 4](#)). The six maps are printed here, each whole, because their rows on varying carriers, termination, increasing subsets, relation codes and abstract types are the subject of this Part; the subsections on a fixed set carrier that sources 14 and 17 put inside their maps are printed in Part VI ([note 32.5](#) and [section 32.3](#)). The six agree with one another and with the batch-80 sources; [note 34.2](#) lists what they share.

### 34.1 Source 13: the interpretations that must be separated

#### 34.1.1 A taxonomy by carrier and representation

The following table fixes the principal meanings. In every row, numerical comparison of surreal labels is distinct from the auxiliary well-order being represented.

| Interpretation                      | Representation                                                                                       | Logical size and caveat                                                                               |
|-------------------------------------|------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------|
| Fixed set $X \subseteq \mathbf{No}$ | Well-order relations on $X$ ,<br>equivalently bijections $\alpha \rightarrow X$ from<br>set ordinals | A set; every possible well-order<br>type on $X$ is permitted.                                         |
| Fixed length on $X$                 | Bijections $\lambda \rightarrow X$                                                                   | A single stratum; $ \lambda  =  X $ is<br>necessary.                                                  |
| Arbitrary set subsets               | Injective words $p : \alpha \rightarrow \mathbf{No}$                                                 | An ordinary class of sets;<br>termination must be specified.                                          |
| Words with<br>repetitions           | Arbitrary $p : \alpha \rightarrow \mathbf{No}$                                                       | An ordinary class, but not a<br>class of well-orderings of the<br>ranges.                             |
| Inherited numerical<br>order        | Subsets on which the restriction of $<$<br>is a well-order                                           | Not arbitrary relabelings;<br>increasing enumerations only.                                           |
| Set-like whole-class<br>orders      | Class bijections $E : \text{Ord} \rightarrow \mathbf{No}$                                            | The virtual domain $\mathfrak{W}_{\text{sl}}$ ; its<br>elements are classes.                          |
| Unrestricted<br>whole-class orders  | Class well-order relations on $\mathbf{No}$                                                          | The virtual domain $\mathfrak{W}_{\text{all}}$ ;<br>proper-class predecessor<br>segments are allowed. |
| Unlabeled order types               | Quotients by order-isomorphism                                                                       | Label-sensitive lexicographic<br>comparison does not descend.                                         |
| Relation-code order                 | Characteristic bits of a relation, read<br>in a chosen order of pairs                                | A different, coding-dependent<br>lexicographic order.                                                 |

This covers the standard semantic axes, not every artificial encoding one could invent. Birthday-first comparison, a fixed global well-order of the labels in place of their numerical order, or comparison of unquotiented Conway expressions each changes the problem again.

#### 34.1.2 Fixed carriers have no end-marker ambiguity

For a set  $X$ , put

$$\mathcal{W}(X) = \{e : \alpha \xrightarrow{\sim} X : \alpha \text{ an ordinal}\}, \quad \mathcal{W}_\lambda(X) = \{e \in \mathcal{W}(X) : \text{dom}(e) = \lambda\}.$$

These are sets: if  $|X| = \mu$  is infinite, the possible domains are among the ordinals below  $\mu^+$  of cardinality  $\mu$ .

**Lemma 34.1** (Prefix-freeness of exhaustive enumerations). *Distinct members of  $\mathcal{W}(X)$  are never proper prefixes of one another. Their lexicographic comparison is determined at a least common coordinate where their values differ.*

*Proof.* A prefix that already enumerates all of  $X$  cannot be extended injectively by another member of  $X$ . If two different enumerations agreed on their common domain, the shorter would be such a prefix. Otherwise their set of disagreement coordinates has a least member.  $\square$

An auxiliary well-order  $R$  on  $X$  has one ordinal type and one increasing enumeration in that order. This is a bijection between relation representations and the displayed exhaustive words. Lexicographic comparison uses the *numerical* order of their values, not the order  $R$  itself.

### 34.1.3 Varying the range introduces a genuine convention

An injective word  $p : \alpha \rightarrow \mathbf{No}$  enumerates a well-order of its range. Once ranges may differ,  $p$  can be a proper prefix of another word. Under *end-first* dictionary comparison,  $p < p \frown x$  for every fresh  $x$ . Under end-last comparison the inequality is reversed. A terminal symbol placed inside an enlarged alphabet gives a third possibility.

Deleting repeated letters from arbitrary words is not a harmless change of representation. For example, with  $a < b$ , the two words  $(a, a, b)$  and  $(a, b)$  have different dictionary positions but the same first-occurrence enumeration. No quotient order is supplied merely by performing this deletion.

### 34.1.4 Inherited well-orders and unlabeled quotients

The numerical order of all surreals is not a well-order: it contains, for example, the descending sequence  $0, -1, -2, \dots$ . Its ordinal subclass, represented by all-plus signs, is a proper-class increasing well-order. Every set ordinal is likewise realized as a numerically well-ordered subset of  $\mathbf{No}$ .

The class of *set-sized* numerically increasing words is an ordinary class of set codes. Under end-first comparison it has an empty minimum and the limit-prefix phenomenon proved in [Section 35.2](#). It therefore differs from the surreal line despite containing a copy of  $\mathbf{No}$  through singleton words. The general class-universality argument below embeds it back into  $\mathbf{No}$ : equimorphism is not isomorphism.

If labels are forgotten altogether, lexicographic comparison is usually lost. On a two-element labeled carrier the two enumerations have the same ordinal type but opposite lexicographic positions. More dramatically, every individual set-like global well-order of  $\mathbf{No}$  has type  $\text{Ord}$ ; its quotient by abstract order-isomorphism has just one element, although  $\mathfrak{W}_{\text{sl}}$  itself is extremely rich.

### 34.1.5 The Kanovei–Shelah comparison is related, not identical

Kanovei and Shelah’s definable hyperreal construction uses a linearly ordered family of maps from the continuum into  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters. The maps are compared lexicographically; injectivity is not the defining requirement [16]. This is an important motivation for ordered collections of enumeration codes. It should not be identified without argument with the exhaustive well-orderings of one fixed labeled carrier. In particular, replacing its index by “all surreal well-orders” would change both the coding and the logical size level.

## 34.2 Source 14: which interpretation is intended?

### 34.2.1 A map of the natural meanings

In the table below, “ordinary class” means a collection of sets defined by a class predicate. “Virtual” means that each candidate is itself a class and the theory quantifies over candidates without forming their collection as another class.

| Interpretation                      | Objects and comparison                                                                                                   | Size and main warning                                                                              |
|-------------------------------------|--------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------|
| Fixed set $X \subseteq \mathbf{No}$ | All well-order relations on $X$ , compared by their exhaustive labelled ordinal enumerations.                            | A set; arbitrary well-order type of cardinality $ X $ is allowed.                                  |
| Fixed length $\alpha$               | Bijections $\alpha \rightarrow X$ , numerical first-disagreement comparison.                                             | A set; one slice of the preceding order.                                                           |
| Birthday fragment                   | $X = \mathbf{No}_{<\theta}$ , with either of the preceding choices.                                                      | A set; the ordinal cutoff and cardinality play different roles.                                    |
| Variable set domain                 | Pairs $(A, R)$ with $A \subseteq \mathbf{No}$ a set and $R$ a well-order of $A$ , or injective set-length surreal words. | An ordinary proper class; a termination convention is indispensable.                               |
| Unrestricted words                  | All functions $\alpha \rightarrow \mathbf{No}$ for set ordinals $\alpha$ , allowing repeated values.                     | An ordinary proper class; these are not enumerations of well-ordered labelled subsets.             |
| Increasing subsets                  | Subsets or subclasses well-ordered by the <i>numerical</i> order inherited from $\mathbf{No}$ .                          | A restriction on labels, not an arbitrary imposed well-order.                                      |
| Set-like global order               | Class bijections $\text{Ord} \rightarrow \mathbf{No}$ .                                                                  | Virtual order $\mathfrak{W}_{\text{sl}}$ ; each proper initial segment is a set.                   |
| Arbitrary global order              | Class well-order relations on all of $\mathbf{No}$ , including non-set-like ones.                                        | Virtual order $\mathfrak{W}_{\text{all}}$ ; direct labelled common-prefix comparison is available. |
| Relation-code lex                   | Characteristic functions of relations, using a fixed well-ordered schedule of ordered pairs.                             | A different order; depends on the schedule and on the bit convention.                              |
| Order types only                    | Isomorphism classes after forgetting surreal labels.                                                                     | Enumeration lex does not descend. Set-like proper class orders all have type $\text{Ord}$ .        |

This list covers the main structural ambiguities, rather than pretending that arbitrary encodings cannot create additional variants. Every subsequent theorem names the interpretation to which it applies.

[merge] Source 14’s Subsection 2.2 (“Fixed carriers and the inherited spectra”) is printed in Part VI (note 32.5); its Subsections 2.3–2.5 follow.

### 34.2.2 Variable domains and the terminal symbol

An imposed well-order on a set  $A \subseteq \mathbf{No}$  is represented uniquely by an injective word  $p : \lambda \rightarrow \mathbf{No}$ . For varying  $A$ , a word may be a proper prefix of another. Three reasonable choices are: *prefix first*, using  $\text{end} < x$  for every numerical letter; *prefix last*, using  $x < \text{end}$ ; and a marker inserted at a specified cut in the numerical alphabet. A fourth order is length-first lexicography. They do not agree, and none becomes a well-order simply because the word domains are ordinals: the one-letter words already contain the numerical order of  $\mathbf{No}$ .

The familiar sign-sequence order of the surreals uses  $- < \mathbf{end} < +$ . It is not prefix-first dictionary order. A useful self-delimiting numerical code replaces  $-$  by 00,  $+$  by 11, and appends 01. Comparisons are preserved because

$$00 < 01 < 11.$$

The terminal block makes distinct numerical codewords prefix-incomparable. Concatenating such codes is useful for embeddings, but does not turn arbitrary repeated-letter words into exhaustive enumerations. The predecessor report treats the resulting compression and the special cuts at limit word lengths (sections 9 to 11; Sections 9–11 of this report at the pin).

### 34.2.3 Numerically increasing well-orders

The numerical order of **No** is not a well-order; for example,  $0 > -1 > -2 > \dots$ . Hence no numerical order-preserving enumeration can well-order all of **No**. This is different from imposing another well-order on the same carrier.

Proper subclasses can nevertheless be numerically well-ordered and non-set-like. For instance,

$$\left\{ -\frac{1}{\alpha + 1} : \alpha \in \text{Ord} \right\} \cup \{0\}$$

together with numerical order has type  $\text{Ord} + 1$ . The ordinal arithmetic in the denominator is interpreted by the corresponding surreal ordinal followed by surreal addition; the displayed values are strictly increasing and all precede 0. Thus a numerically bounded subclass can have a point with a proper class of predecessors. Set-likeness is not a consequence of numerical boundedness.

### 34.2.4 Forgetting labels changes the problem

For a fixed infinite set of cardinality  $\mu$ , its possible abstract well-order types are the ordinals  $\alpha$  satisfying  $\mu \leq \alpha < \mu^+$ . Ordering these types by ordinal size gives a well-order of type  $\mu^+$ , which cannot embed in  $\mathcal{W}(X)$  by Note 32.5. Therefore the order on abstract types is not the induced quotient of enumeration lexicography.

More directly, different enumerations of the same type need not occupy a convex subset: choose first labels  $x < y < z$  and complete the first and third to type  $\mu$ , the middle to type  $\mu + 1$ . All three completions exist, and their lexical positions are decided by those first labels. For a proper class carrier every set-like well-order has abstract type  $\text{Ord}$ , so quotienting that fragment by abstract type collapses it to a single type. Almost all of the lexicographic information was in the labels, not in the abstract order type.

## 34.3 Source 15: a map of the interpretations

Every concrete version is determined by six choices: the carrier; whether orders are labelled or identified up to isomorphism; how an order is coded; which order compares the code entries; which well-order scans the entries; and the universe in which all codes are collected. Prefix conventions add a seventh choice when the coded sequences have variable domains and need not exhaust a common carrier.

| Interpretation                | Objects and comparison                                                                      | Main distinction                                                                   |
|-------------------------------|---------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------|
| Fixed carrier, all types      | All ordinal bijections $e : \alpha \rightarrow X$ , compared at first unequal labels in $X$ | A set in ZFC; exhaustive codes are prefix-free.                                    |
| Fixed enumeration type        | Only $e : \alpha \rightarrow X$ for one prescribed $\alpha$                                 | Same possible ordinal suborders need not mean the same binary coding length.       |
| Variable set carrier          | Injective set-length words, or all well-ordered sets of surreal labels                      | Proper prefixes occur; termination must be ordered explicitly.                     |
| Natural well-ordered subsets  | Subsets $A \subseteq \mathbf{No}$ with the inherited numerical order well-founded           | No arbitrary rearrangement is part of the data.                                    |
| Set-like class orders         | Bijections $\text{Ord} \rightarrow \mathbf{No}$ ; first ordinal difference                  | All predecessors are sets; a predicate on class functions.                         |
| All labelled class orders     | Arbitrary class well-orders on $\mathbf{No}$ ; common labelled prefix                       | May differ only after a proper class of identical earlier labels.                  |
| Fixed class index type        | Bijections $J \rightarrow \mathbf{No}$ for one given class well-order $J$                   | A chosen type such as $\text{Ord} + \text{Ord}$ restricts the domain.              |
| Inverse-rank lexicography     | Rank values of labels scanned in a fixed baseline well-order                                | Uses ordinal values rather than numerical surreal labels; has different endpoints. |
| Relation-table lexicography   | Characteristic bits of $R \subseteq \mathbf{No}^2$ in a fixed well-ordered scan             | Depends on scan and bit orientation; differs already on three points.              |
| Isomorphism types             | Quotient well-orders by abstract order isomorphism                                          | Native enumeration lex does not descend to this quotient.                          |
| Birthday/simplicity variants  | Birthday ranks, sign strings, or simplicity predecessors                                    | Birthday ties need a separate well-order; simplicity is only partial.              |
| Definable or computable codes | A specified syntactic class with an evaluator                                               | Restricts the available objects; syntax alone does not supply universal truth.     |
| Higher-universe totality      | All relevant relations become sets in a larger universe                                     | Results depend on the class realization and external well-foundedness.             |

This table is exhaustive at the level of the structural choices just listed, not a claim to enumerate every artificially possible encoding. Once arbitrary encodings and arbitrary scans are allowed, one can manufacture many further linearizations. The mathematically meaningful task is to say which properties are intrinsic to the chosen order and which depend on its presentation.

### 34.3.1 The historical Kanovei–Shelah construction

The original construction uses

$$A = \{a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N}) : \text{ran}(a) \text{ is an ultrafilter on } \mathbb{N}\},$$

ordered lexicographically in the initial ordinal  $\mathfrak{c}$  coordinates, with  $\mathcal{P}(\mathbb{N})$  itself ordered through characteristic functions. Maps may repeat entries, and different maps may represent the same

ultrafilter. This is an important precedent for ordering presentations without selecting a preferred presentation. It is not literally an order of all well-orders of  $\mathbb{R}$  or of **No** [16, Section 1].

### 34.4 Source 16: a systematic map of the interpretations

Three choices account for most natural readings: the carrier to be well-ordered, whether numerical labels are retained, and the coding used for comparison. A fourth choice, the treatment of termination, becomes necessary when carriers or word lengths vary. There cannot be a literal list of every possible encoding: composing any encoding with an arbitrary permutation can manufacture another order. The following table covers the principal mathematical interpretations and explains how the remaining variants arise.

| Interpretation                                   | Objects and comparison                                                                    | Size and main issue                                                                                        |
|--------------------------------------------------|-------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------|
| Fixed set of labels<br>$X \subseteq \mathbf{No}$ | Bijections $\alpha \rightarrow X$ ; first unequal entry compared numerically              | A set in ZFC; the order on enumerations is usually far from a well-order.                                  |
| Fixed enumeration type                           | Only bijections $\alpha \rightarrow X$ , with $\alpha$ fixed                              | Changing $\alpha$ changes topology and may change embedding invariants.                                    |
| Variable set carrier                             | Injective set-length words in <b>No</b>                                                   | An ordinary class of set codes; proper-prefix comparison must be specified.                                |
| Numerically well-ordered subsets                 | Increasing enumerations in the numerical order                                            | No arbitrary auxiliary well-order remains on each carrier; proper class subsets can still be non-set-like. |
| Set-like global well-orders                      | Class bijections $\text{Ord} \rightarrow \mathbf{No}$                                     | A predicate on class variables; not an ordinary class of such graphs.                                      |
| Arbitrary global class well-orders               | Class relations on all of <b>No</b> ; compare after the common labelled prefix            | Common prefixes can be proper classes; ordinal-coordinate comparison alone is insufficient.                |
| Relation-table encoding                          | Binary membership tables for order relations, read along an auxiliary well-order of pairs | Gives a different, coding-dependent lexicographic order.                                                   |
| Abstract order types                             | Forget surreal labels and identify isomorphic well-orders                                 | Numerical first-disagreement comparison no longer descends to the quotient.                                |
| Larger-universe interpretation                   | Regard internal classes as sets in an explicit containing universe                        | Makes entire collections available, while changing the meaning of “set”, “class”, and “all”.               |

#### 34.4.1 Fixed labels versus abstract types

For a linearly ordered set  $(X, <)$ , write

$$\mathcal{W}_\alpha(X) = \{e : \alpha \xrightarrow{\sim} X\}, \quad \mathcal{W}(X) = \bigcup_{|\alpha|=|X|} \mathcal{W}_\alpha(X).$$

A bijection is identified with the well-order it induces on  $X$ . Distinct exhaustive enumerations cannot be proper initial segments of one another: the shorter enumeration has already used every

label, leaving no fresh next entry for the longer one. Therefore every distinct pair has a first unequal entry, with no termination convention needed.

If labels are discarded, the order types are simply the ordinals  $\alpha$  of cardinality  $|X|$ . Their ordinary ordinal comparison is meaningful, but it is not numerical lexicography. Even two permutations of a finite set have the same abstract order type and different lexicographic positions. For arbitrary class well-orders, a single class of all abstract “class ordinals” is not supplied by GB or KM. Direct labelled comparison will avoid this issue entirely.

### 34.4.2 Relation tables genuinely change the answer

Choose an auxiliary well-order  $j : \delta \rightarrow X \times X$  and encode a relation  $R$  by the binary word  $\chi_R(j(\xi))$ . The earliest differing bit defines a linear comparison, but its answer depends on  $j$  and the bit convention. For example, on  $X = \{0, 1, 2\}$  the enumeration  $(0, 2, 1)$  precedes  $(1, 0, 2)$  numerically. In row-major relation-table order, their first differing entry is the pair  $(0, 1)$ : its bits are respectively 1 and 0. The table comparison therefore gives the opposite inequality. A class version needs a specified class ordering of the pairs and appropriately stratified quantification; the word “lexicographic” alone does not choose one.

### 34.4.3 The Kanovei–Shelah connection

The motivating analogy should not be mistaken for an identification. Kanovei and Shelah use the index

$$A = \{a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N}) : \text{ran}(a) \text{ is an ultrafilter on } \mathbb{N}\},$$

ordered at the first differing coordinate by binary characteristic-function order on  $\mathcal{P}(\mathbb{N})$ . Repetitions are permitted, and the displayed definition admits ultrafilters generally. The point is a definable order on redundant codes, used in an ultrapower construction. It is not literally the space of all bijective enumerations or all well-orders of  $\mathbb{R}$  [16, §2 in the published version; §1 in the preprint].

## 34.5 Source 17: what can “all well-orders of surreal numbers” mean?

We use the sign-sequence presentation and numerical order of surreal numbers; standard background is given in [11, 12]. A well-ordering relation and the numerical order of its labels are distinct. An enumeration of a well-order need not be numerically increasing. This single distinction already produces two different research programs.

[merge] Source 17’s Subsection 2.1 (“Labelled well-orders of a fixed set”) is printed in Part VI (section 32.3). Its displayed word code keeps its number as (S17.1).

### 34.5.1 Set-length words and varying supports

Every well-order of a set-sized subset of **No** is represented by an injective word  $w : \alpha \rightarrow \mathbf{No}$ . Now one word can be a proper prefix of another. We use the *shorter-prefix-first* convention unless specified otherwise. The resulting carrier is an ordinary class of sets. Allowing repeated entries gives a larger class of words, but such a word no longer represents a well-order of its range without an additional occurrence labelling.

There is a useful explicit compression, also present in the source. Represent  $x \in \mathbf{No}$  by its sign sequence. Replace a minus sign by  $--$ , a plus sign by  $++$ , and append the terminal block  $-+$ . Call the resulting prefix-free code  $c(x)$ . The comparison

$$-- < -+ < ++$$

encodes the surreal convention “minus < termination < plus”. For any set-length word put

$$\Phi(w) = \bigcap_{i < \alpha} (+ \cap c(w(i))). \quad (\text{S17.1})$$

At a first differing entry the prefix-free coefficient codes determine the comparison; at a proper word prefix the next sign is +, so the longer word is larger. Hence  $\Phi$  is an order embedding into  $\mathbf{No}$ , with birthday

$$\text{bd } \Phi(w) = \sum_{i < \alpha} (1 + 2 \cdot \text{bd}(w(i)) + 2).$$

Products and sums in this formula are ordinal operations. All lengths are sets. The empty word is least, so the entire word order is not isomorphic to the endpoint-free surreal line, despite embeddings in both directions. Using  $-$  instead of the leading  $+$  in each entry block gives the longer-prefix-first convention and makes the empty word greatest.

Length-first comparison, often called shortlex, is another legitimate linear order, but is not this dictionary order. It should not be silently substituted in an embedding or topology theorem.

### 34.5.2 Numerically well-ordered subsets

A different interpretation asks for subsets  $A \subseteq \mathbf{No}$  whose *inherited numerical order* is a well-order. Their set-sized increasing enumerations form a suborder of the injective word order. They include every singleton, so their lexicographic order contains a copy of  $(\mathbf{No}, <)$  and is not a well-order. They inherit the embedding (S17.1). Every set-sized increasing word admits a longer increasing extension, because a set of surreal numbers has a strict upper bound.

There is no numerically increasing exhaustive well-order of the whole surreal line: the sequence  $0, -1, -2, \dots$  already witnesses the failure of well-foundedness of the numerical order. This does not prohibit an arbitrary labelled class well-order of  $\mathbf{No}$ .

Proper-class *subsets* with their inherited numerical order must also be distinguished from the entire numerical line. They can be non-set-like well-orders. For example,

$$\left\{ -\frac{1}{\alpha + 1} : \alpha \in \text{Ord} \right\} \cup \{0\}$$

is increasingly well-ordered in type  $\text{Ord} + 1$ . The reciprocal is surreal field reciprocal, and  $\alpha$  denotes its ordinal surreal value. The set of predecessors of 0 in this class order is proper. A collection of all such class subsets again lives at the higher logical level. For varying supports, proper-prefix comparisons require an explicit termination convention, just as for set words. Our main raw comparison keeps the carrier fixed and therefore has no termination ambiguity.

### 34.5.3 Global enumerations and unrestricted relations

A *set-like* class well-order is one in which each element has a set of predecessors. A set-like well-order of the proper class  $\mathbf{No}$  has order type  $\text{Ord}$ , and is equivalently a class bijection

$$E : \text{Ord} \longrightarrow \mathbf{No}.$$

Write  $\mathfrak{W}_{\text{sl}}$  for this predicate on class relations, and  $\mathfrak{J}$  for the analogous predicate of injective, not necessarily exhaustive,  $\text{Ord}$ -words. These symbols are not names of ordinary GB classes whose elements are class functions.

Write  $\mathfrak{W}_{\text{all}}$  for arbitrary class well-orders of  $\mathbf{No}$ . Orders of type  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ , and many other non-set-like types belong here. For example, enumerate  $\mathbf{No} \setminus \{a, b\}$  first and append  $a, b$ .

Interchanging those last two labels creates a first disagreement after a proper-class prefix, not at a set ordinal.

One can also fix a particular class well-order  $J$  and compare bijections  $J \rightarrow \mathbf{No}$  at their least differing  $J$ -position. This is legitimate when least elements of nonempty admitted subclasses of  $J$  are part of the hypothesis. It is a fixed-domain alternative, not a universal set ordinal index for every class well-order.

### 34.5.4 Relation codes, isomorphism types, and ordinal-valued rankings

Fix a class bijection  $d : \text{Ord} \rightarrow \mathbf{No} \times \mathbf{No}$ . A class relation  $R$  has binary code  $\xi \mapsto \mathbf{1}_R(d(\xi))$ , which can be compared lexicographically. This yields a valid order on the admitted well-order relations, but depends on  $d$  and the bit convention. It is generally not the native labelled-enumeration order. Even on  $\{0, 1\}$ , listing coordinate  $(0, 1)$  first and using  $0 < 1$  compares the two well-orders in the reverse of their first-label comparison.

Abstract isomorphism types form yet another subject. For set well-orders they are ordinals, naturally ordered by initial-segment embeddability. The native lexicographic order does not descend to this quotient: the two enumerations  $(a, b)$  and  $(b, a)$  have the same abstract type but opposite label order when  $a < b$ . A rank function, a birthday-first code, or a chosen well-order of relation codes introduces additional structure rather than recovering a canonical lexicographic comparison from the abstract types.

## 34.6 Source 18: interpretations and foundational conventions

### 34.6.1 A map of the natural interpretations

| Object                                           | What a point represents                                                                           | Size and comparison                                                                       |
|--------------------------------------------------|---------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------|
| $\mathcal{W}(X)$ , $X \subset \mathbf{No}$ a set | A labelled well-order of the fixed carrier $X$ , in any possible ordinal type                     | A set; compare unique exhaustive ordinal enumerations                                     |
| $\mathcal{W}_\alpha(X)$                          | A well-order whose type is the specified ordinal $\alpha$                                         | A stratum of $\mathcal{W}(X)$ ; nonempty exactly when $ \alpha  =  X $                    |
| Injective set words                              | A well-order of a variable set-sized subset of $\mathbf{No}$                                      | A genuine proper class of sets; a termination convention is needed                        |
| Increasing set words                             | A subset well-ordered by the numerical surreal order, with its unique increasing enumeration      | A subclass of the previous word class; no arbitrary reordering of a fixed subset          |
| $\mathfrak{W}_{\text{sl}}(\mathbf{No})$          | A set-like global well-order, equivalently a class bijection $\text{Ord} \rightarrow \mathbf{No}$ | A predicate on class relations; distinct enumerations have a set ordinal first difference |
| $\mathfrak{W}_{\text{all}}(\mathbf{No})$         | Any class well-order of the entire surreal carrier                                                | A predicate on class relations; the common labelled prefix can be proper                  |
| Inherited class well-orders                      | A subclass on which numerical $<$ is a well-order                                                 | A different restriction: $\mathbf{No}$ itself is not numerically well-ordered             |
| Order types modulo isomorphism                   | Labels are forgotten                                                                              | Numerical lexicography does not descend to this quotient                                  |

| Object                        | What a point represents                                                         | Size and comparison                                                             |
|-------------------------------|---------------------------------------------------------------------------------|---------------------------------------------------------------------------------|
| Characteristic-relation codes | A well-order relation encoded by its membership bits in a chosen order of pairs | A valid auxiliary lex order, usually different from enumeration comparison      |
| Containing-universe objects   | All orders admitted by a specified smaller set/class universe                   | Sets in an external universe; “all” is relative to the chosen class realization |

There are indefinitely many artificial encodings. The table covers the natural mathematical choices by varying carrier, enumeration type, admissible order, label retention, comparison rule, and size level. An arbitrary encoding cannot be expected to preserve the results for another row.

[merge] Source 18’s Subsections 2.2 and 2.3 (sign sequences with its lemma on surreal order tools, and set and class theories) are foundations, not interpretations, and are not printed in this Part. Its Subsection 2.4 follows.

### 34.6.2 Why the Kanovei–Shelah connection needs qualification

Kanovei and Shelah’s published construction [16, §2] orders maps  $a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters, using characteristic-function lexicography on  $\mathcal{P}(\mathbb{N})$ . Repetitions are allowed in those maps and in the ultrafilter presentation. Their index is therefore not literally  $\mathcal{W}(\mathbb{R})$  or a permutation order of the reals. The useful connection is the method of linearly ordering many codes without choosing one privileged code. The present article studies different, precisely specified orders inspired by that method. This correction was already explicit in the repository’s reals report [1].

*Note 34.2* ([merge]; what the six maps share). All six separate the same carriers as the batch-80 sources (sections 2 and 4.3): a fixed set with all types or one type, varying set carriers (injective words, with a termination convention), unrestricted words, numerically well-ordered subsets, set-like and arbitrary class well-orders, relation codes and abstract types.

- *Termination.* Sources 13, 14, 16 and 17 name the three placements of a terminator (first, last, inside the alphabet) and length-first order as a fourth choice; source 14’s warning that the Conway sign order uses  $- < \text{end} < +$  and is not prefix-first dictionary order is the convention printed in section 5.
- *Increasing subclasses.* The example  $\{-1/(\alpha + 1) : \alpha \in \text{Ord}\} \cup \{0\}$  of numerical type  $\text{Ord} + 1$  is source 12’s (section 18); sources 14, 15, 16, 17 and 18 repeat it.
- *Relation codes.* The two- and three-point examples of sources 14, 16, 17 and 18 make the point of source 12’s shipped example and of proposition 17.1; source 15 proves theorems about these orders (theorem 38.2 and corollary 38.3).
- *Abstract types.* That enumeration lexicography does not descend to abstract order types (sources 13, 14, 15, 16, 17) is printed with source 15’s non-convexity example in section 38; source 14’s argument that the type order  $\mu^+$  cannot embed uses note 32.5.
- *Kanovei–Shelah.* The Kanovei–Shelah subsections of sources 13, 15, 16 and 18 printed here (sources 14 and 17 discuss it elsewhere in their texts) make source 08’s point (section 4.4): the index there is a lexicographically ordered family of redundant codes, not a space of well-orders. Source 16 cites Section 2 of the published version and Section 1 of the preprint; source 15 cites “Section 1”.
- *Prefix-freeness.* Source 13’s lemma 34.1 is the prefix-freeness of exhaustive enumerations used in section 6.

### 35 Shorter-first words: three classes, one prefix order (source 16; routes of sources 13, 14 and 18)

[merge] Source 16's Section 7, printed whole; its  $\mathcal{T}$ ,  $\mathcal{T}^{\text{inj}}$ ,  $\mathcal{T}^{\text{inc}}$  are printed  $\mathcal{T}$ ,  $\mathcal{I}$ ,  $\mathcal{T}^{\text{inc}}$  (section 1.3.1), and its equations keep their numbers as (S16. $n$ ). Its references to its own fresh-separator lemma, universality proposition, set-cut display and raw-comparison section are printed as references to lemma 5.2, proposition 5.13, and definition 5.1 and theorem 14.2, which state the same facts. The word orders of Part II (part II) are the cases  $\mathcal{T}$  and  $\mathcal{I}$ ; what this section adds is the increasing class  $\mathcal{T}^{\text{inc}}$  and the isomorphism of the three (theorem 35.1). Source 18 proves the isomorphism independently, with the uniformity of the back-and-forth made explicit (section 35.5); source 13's and source 18's word sections and source 14's explicit codes follow as notes and routes.

Let  $\mathcal{T}$  be the class of all set functions  $f : \alpha \rightarrow \mathbf{No}$  with  $\alpha$  an ordinal. Let  $\mathcal{I}$  be its injective subclass, and  $\mathcal{T}^{\text{inc}}$  its numerically strictly increasing subclass. Members of all three are sets. In  $\mathcal{I}$  the word imposes a well-order on its image; in  $\mathcal{T}^{\text{inc}}$  that well-order is the restriction of the numerical order. Initially give all three the convention that a proper prefix is smaller than its extension.

The empty word is then a minimum. More substantially, if  $f$  has nonzero limit length  $\lambda$ , its proper prefixes are cofinal below it, giving

$$\text{cf}(\mathcal{T}_{<f}) = \text{cf}(\lambda). \quad (\text{S16.5})$$

At successor-length words there is no set cofinal family below the point, and above any word there is no set coinitial family. For the unrestricted and injective cases these facts appear in the earlier report; they follow by choosing a fresh next letter between the set of active coordinates and the coordinate of the given word. Equation (S16.5) already prevents an isomorphism with  $\mathbf{No}$ , even if the empty word is removed: a surreal cannot be the supremum of a set lying strictly below it, by the set-cut property (definition 5.1).

**Theorem 35.1** (Three interpretations with the same prefix order). *In GBC,*

$$\mathcal{T} \cong \mathcal{I} \cong \mathcal{T}^{\text{inc}}$$

*under shorter-prefix-first comparison. There are isomorphisms preserving word length, the prefix relation, unions of set-length prefix chains, and every singleton word. The same assertion holds for the convention that proper prefixes are larger than their extensions.*

*Proof.* For an admissible output prefix  $q$ , its possible next letters form, respectively,

$$\mathbf{No}, \quad \mathbf{No} \setminus \text{ran}(q), \quad U(q) = \{x \in \mathbf{No} : \forall y \in \text{ran}(q) (y < x)\}.$$

Each is a proper class with the set-cut property. For the second use the fresh-separator lemma (lemma 5.2). For the third, given sets  $A < B$  in  $U(q)$ , fill the cut  $A \cup \text{ran}(q) < B$ ; this also proves the property with an empty side. Uniform back-and-forth as in class universality (proposition 5.13) gives, for every set parameter  $q$ , an order isomorphism  $h_q$  from  $\mathbf{No}$  onto its available-letter class. Take  $h_\emptyset$  to be the identity. A single class relation  $H(q, x, y)$  defines all these maps: a pair belongs when it appears in the uniquely specified set-length back-and-forth history. No choice of a proper class for each index is hidden here.

For a free word  $f : \alpha \rightarrow \mathbf{No}$ , define its output by set recursion:

$$q(i) = h_{q \upharpoonright i}(f(i)) \quad (i < \alpha).$$

The output is injective or increasing according to the target rule. Conversely, an admissible output  $q$  uniquely recovers  $f(i) = h_{q|i}^{-1}(q(i))$ . These operations are inverse and preserve prefixes and lengths. At a first differing coordinate, both inputs use the same strictly increasing local map, so their comparison is preserved. The endpoint termination rule depends only on the prefix relation, which is also preserved. The recursive definition makes compatibility with unions immediate, and the choice at the empty prefix fixes singletons.  $\square$

This is an isomorphism theorem, not a literal identification of the objects. Longer labels generally change. In particular, the theorem does not turn an arbitrary chosen well-order of a subset into the numerical order on the *same* subset. It shows that the bare lexicographic order does not recover that conceptual distinction.

### 35.1 Increasing proper classes are a further case

The preceding theorem concerns set-length words. A numerically well-ordered proper subclass can itself be non-set-like. For example, the increasing class

$$\left\{ -\frac{1}{\xi + 1} : \xi \in \text{Ord} \right\} \cup \{0\}$$

has order type  $\text{Ord} + 1$ ; the point 0 has a proper class of predecessors. The simpler subclass of nonnegative ordinal surreals has type  $\text{Ord}$ . In GBC, class universality ([proposition 5.13](#)) embeds every class well-order into the numerical surreal line, so every such abstract order can occur on a numerically well-ordered subclass. No increasing enumeration can exhaust **No**: it has a first value and omits every smaller surreal.

If distinct proper class carriers are allowed, comparison must also say what happens when one whole labelled class order is an initial segment of another. The direct common-prefix method of Part III ([theorem 14.2](#)), with an explicitly placed termination symbol, supplies the corresponding variant. It is a different problem from comparing well-orders on the same fixed carrier.

*Note 35.2* ([merge]; what transfers from Part II). Display (S16.5) and the two sentences after it are [theorem 10.1](#) (sources 11 and 09: [note 11.4](#)). Because the isomorphisms of [theorem 35.1](#) preserve length and the prefix relation, every statement of Part II about  $\mathcal{T}$  or  $\mathcal{I}$  that is phrased by lengths and prefixes holds in GBC for  $\mathcal{T}^{\text{inc}}$ : the exact local characters ([theorem 10.1](#)), the word-cut classification ([theorem 11.1](#)) and the successor-word corollary ([corollary 11.2](#)). Source 18 makes this remark for the cut classification ([section 35.3](#)); its direct proof of the characters of  $\mathcal{T}^{\text{inc}}$  needs no global choice ([note 35.5](#)). Part II's explicit code ([theorem 9.1](#)) restricts to  $\mathcal{T}^{\text{inc}}$  without choice. The example of source 16's Subsection 7.1 is source 12's ([section 18](#)).

### 35.2 Source 13: set-length words and their first obstruction

[merge] Source 13's Section 5, printed whole. Its proposition is [theorem 10.1](#) (1) of Part II (and source 09's [note 11.4](#)) and is printed as a note.

Let  $\mathcal{T}$  be the ordinary class of all set-length words over **No**, and let  $\mathcal{I} \subseteq \mathcal{T}$  be the injective words. The latter is exactly the class of well-orderings of arbitrary set-sized subsets, represented by their increasing enumeration in the auxiliary order. In this section the terminal symbol precedes every label.

*Note 35.3* (Source 13, Proposition 5.1, "Limit-prefix character"). *Suppose  $p$  has nonzero limit length  $\lambda$ . In either  $\mathcal{T}$  or  $\mathcal{I}$  when  $p$  is injective, the proper prefixes of  $p$  are cofinal below  $p$ . The cofinality of the strict lower side at  $p$  is exactly  $\text{cf}(\lambda)$ .* This is [theorem 10.1](#) (1), with the same proof.

*Source 13's proof.* If  $q < p$ , then either  $q$  is a proper prefix of  $p$ , or its comparison with  $p$  is decided by a smaller letter at some coordinate  $\xi < \lambda$ . In either case a sufficiently long proper prefix of  $p$  lies above  $q$  and below  $p$ . Restricting to a cofinal sequence of lengths gives the upper bound  $\text{cf}(\lambda)$ .

For the converse, assign to each  $q < p$  a bound  $\xi_q < \lambda$  beyond which proper prefixes of  $p$  lie above  $q$ . A family of cardinality less than  $\text{cf}(\lambda)$  has a common such bound. A later proper prefix then witnesses its failure to be cofinal.  $\square$

Every point of **No** has no set-sized cofinal family strictly below it: a proposed family together with that point is a set cut and has a strict interpolant. Thus the displayed word orders are not isomorphic to **No**, even after the empty minimum is deleted. They nevertheless embed into **No** by class universality ([proposition 5.13](#)), and **No** embeds back through singleton words. The earlier report gives explicit sign-coding embeddings and a more detailed end-first analysis ([sections 9 to 11](#); Sections 9–11 of this report at the pin).

The same limit-prefix proof applies to numerically increasing set words, since every proper prefix remains increasing. By reversing the position of termination, one obtains the corresponding small *right-hand* character. [Section 36.4](#) proves that a central termination convention has a fundamentally different outcome.

### 35.3 Source 18: set-length dictionary words and numerical increase

Let  $\mathcal{T}$  be the class of all functions  $f : \alpha \rightarrow \mathbf{No}$  with  $\alpha$  a set ordinal, and let  $\mathcal{I}$  and  $\mathcal{T}^{\text{inc}}$  be its injective and strictly numerically increasing subclasses. These are ordinary classes: their members are set graphs. In  $\mathcal{I}$  a point represents a well-order of its own range; in  $\mathcal{T}^{\text{inc}}$  that well-order is the inherited numerical order. No point exhausts **No**.

First use ordinary dictionary comparison: compare first unequal entries, and put a proper prefix before every proper extension. This convention is sometimes described by a formal terminator below all surreal letters. Such a terminator is not a surreal number.

*Note 35.4* (Source 18, Proposition 6.1, “Explicit order coding; repository result”). *There is an explicit order embedding  $\mathcal{T} \hookrightarrow \mathbf{No}$ , requiring no Global Choice. Singleton words embed **No** into each of  $\mathcal{T}, \mathcal{I}, \mathcal{T}^{\text{inc}}$ . Thus all three word orders and **No** are equimorphic, but the word orders are not isomorphic to **No**.* This is [theorem 9.1](#), with the same letter code  $K(x) = C(x) = (+) \cap D(s_x) \cap (+, -)$ ; source 18 labels it a repository result.

*Source 18's proof.* Duplicate each sign in the sign expansion  $s_x$  and write the result as  $D(s_x)$ . The code

$$K(x) = (+) \cap D(s_x) \cap (+, -)$$

is prefix-free and numerically order-preserving. A terminated source word is correctly compared with a longer one because its delimiter satisfies  $(-, -) < (+, -) < (+, +)$ . Concatenate the  $K(f(i))$  in ordinal domain order. Replacement and ordinal summation give a set sign word. At the first unequal entry prefix-freeness preserves the comparison; at the end of a proper prefix the next block begins with  $+$ , so the shorter word is smaller. The code length is exactly

$$\sum_{i < \alpha} (1 + 2 \cdot \text{bd}(f(i)) + 2).$$

This proves the embedding. The nonisomorphism follows from the next proposition and holds even after removing the empty word.  $\square$

*Note 35.5* (Source 18, Proposition 6.2, “The prefix-supremum obstruction”). *The empty word is the minimum of each dictionary word order. For any word  $f$  of nonzero limit length  $\alpha$ , its proper prefixes are cofinal below it, and the left character of  $f$  is  $\text{cf } \alpha$ . At every successor-length word the left segment has no set cofinal subset. At every word the right segment has no set coinital subset. These assertions hold in  $\mathcal{T}$ ,  $\mathcal{I}$ , and  $\mathcal{T}^{\text{inc}}$ . For  $\mathcal{T}$  and  $\mathcal{I}$  this is [theorem 10.1](#). The case  $\mathcal{T}^{\text{inc}}$  also follows in GBC from [theorem 35.1](#), which preserves lengths and prefixes; source 18’s proof below needs no global choice.*

*Source 18’s proof.* At a limit length, a smaller word is either a proper prefix or differs at a coordinate below  $\alpha$ . A sufficiently long proper prefix exceeds it. A cofinal set of prefix lengths therefore gives the upper bound of  $\text{cf } \alpha$ ; fewer than that many comparison coordinates are bounded and cannot be cofinal. At successor length, interpolate at the last entry above all relevant lower next values and below that entry. In the injective case avoid earlier labels; in the increasing case also stay above all earlier labels. These are set constraints and the surreal cut property satisfies them. To defeat a proposed set coinital family above  $f$ , append a new value below all of its relevant next values. In the increasing case impose the additional lower bound  $\text{ran } f$ . Every family member extending  $f$  already satisfies that bound, so a separator still exists.  $\square$

In particular, an increasing word of length  $\omega$  is the supremum of its finite prefixes. No surreal number is the supremum of a set strictly below it, since the surreal set-cut property inserts a smaller upper bound. This invariant distinguishes the word orders from **No**; mutual embeddings do not preserve suprema in the ambient order.

The repository proves a sharper dictionary cut criterion for arbitrary and injective words ([theorem 11.1](#)): a set cut  $A < B$  fails to have an interpolant exactly when  $B$  contains the empty word, or when  $B$  has a minimum of nonzero limit length and  $A$  is cofinal below that minimum. A common-prefix search proves this: unequal next-value sets can be separated, while a forced common entry is appended; the search is bounded by the input word lengths. Its only terminal failure is a forced upper minimum reached at a limit. Restricting to nonzero successor-length words removes both failures and gives a copy of **No** in GBC. The prefix-tree isomorphism proved below transfers this criterion to increasing dictionary words as well.

The following sections give the genuinely different outcomes obtained by placing termination near zero. They treat zero exclusion, zero padding, and a distinct terminator separately; these choices cannot be conflated.

### 35.4 Source 14: an explicit word embedding with a termination convention

[merge] The first subsection of source 14’s Section 11; it gives a second explicit code for the prefix-first word order (a second route to [theorem 9.1](#)) and a code for the prefix-last order. The rest of that section (binary class words, the no-coding theorem and the Kanovei–Shelah remark) is not printed in this Part; its relation-code subsection is in [section 38.8](#). The ordinary class of all set-length surreal words is much smaller in logical sort than the virtual collection  $\mathfrak{W}_{\text{sl}}$ . An explicit coding makes its embeddability into **No** transparent and illustrates why the terminal symbol matters. The underlying compression idea is inherited from the predecessor ([section 9](#); Section 9 of this report at the pin); we spell out a version that also permits repeated letters.

For a surreal  $x$ , let  $c(x)$  be its binary sign code: replace each minus by 00, each plus by 11, and append 01. The three blocks encode  $- < \text{end} < +$ . Different complete codes are prefix-incomparable, and their first-difference order is the numerical order of their labels. For a word  $p : \lambda \rightarrow \mathbf{No}$ , concatenate the codes  $c(p(\alpha))$  in ordinal order. Now replace each binary 0 by 01 and

each binary 1 by 11, and append 00 to terminate the entire word. Finally read 0, 1 as surreal signs  $-$ ,  $+$ .

**Proposition 35.6** (Source 14, Proposition 11.1, “Prefix-first word coding”). *This construction is an order embedding of the class of all set-length surreal words, with prefix-first lexicography, into  $\mathbf{No}$ . Its output birthday is*

$$\sum_{\alpha < \lambda} (4 \cdot \text{bd}(p(\alpha)) + 4) + 2,$$

where every sum and multiplication is ordinal arithmetic.

*Proof.* All lengths and concatenations are sets. At the first differing label, the prefix-free numerical codes determine the correct binary comparison; the outer replacement preserves it. If one whole word is a proper prefix of the other, its outer terminal block 00 is compared with one of the data blocks 01, 11, making the shorter word smaller. Complete outer codes are prefix-incomparable, so their comparison as surreal sign sequences never reaches an ambiguity about termination. The length of a label code is  $2 \cdot \text{bd}(x) + 2$  and outer replacement doubles that length on the left. Summing those lengths and adding the last two signs gives the displayed formula.  $\square$

For prefix-last order, use outer data blocks 00, 10 and terminal block 11 instead. The same proof applies. The embeddings do not claim that these word orders are isomorphic to the entire surreal line: for example the empty word is the least point in the prefix-first order. Nor do they turn an Ord-length class word into a set-length surreal. The birthday formula is explicitly a *set* ordinal expression.

### 35.5 Source 18’s route: shorter-first increasing words are not a new order type in GBC

[merge] The first part of source 18’s Section 10: a second proof of [theorem 35.1](#), written without knowledge of source 16. Its proof makes explicit that the family of local isomorphisms is one class given by one elementary formula from a set-like global well-order, and its statement adds that zero may be excluded from any of the alphabets. The corollary of that section, on cones of centered increasing words, is printed with them ([corollary 37.9](#)).

The preceding centered results should not be transferred to the shorter-first convention. For shorter-first words a stronger identification is possible, despite the constraints on coordinates.

**Theorem 35.7** (A prefix-preserving tree isomorphism). *In GBC, the classes of arbitrary, injective, and strictly increasing set-length surreal words, all with shorter prefixes first, are pairwise order-isomorphic. Isomorphisms can be chosen to preserve every word length and the prefix relation. The conclusion also holds if zero is excluded from any of the alphabets.*

*Proof.* For a permitted target prefix  $p$ , its admissible next-letter class is respectively

$$\mathbf{No}, \quad \mathbf{No} \setminus \text{ran}(p), \quad D_p = \{x \in \mathbf{No} : \text{ran}(p) < x\}.$$

If zero is excluded, delete it as well. Each class is proper and fills every set cut. For the increasing case, simply add  $\text{ran}(p)$  to the lower side of the proposed cut; every upper-side letter already exceeds that range. For the injective case use set avoidance.

Fix a set-like global well-order  $\prec$ . There is a single uniformly defined family of order isomorphisms

$$\theta_p : \mathbf{No} \longrightarrow D_p,$$

where  $D_p$  now denotes the relevant admissible class in any of the cases. Here is a construction that makes the uniformity and the choice strength explicit. Restrict  $\prec$  to  $\mathbf{No}$  and to  $D_p$ ; these give ordinal enumerations, definably in the set parameter  $p$ . Run the deterministic back-and-forth that, at each stage, treats the least unmatched source point and then the least unmatched target point, always choosing the  $\prec$ -least unused filler of the required cut. Every partial map and every cut at an ordinal stage is a set. For each set ordinal, ordinary set recursion defines the unique initial construction, with  $p$  and  $\prec$  as parameters. The assertion that a pair occurs in some such initial construction is one elementary formula with these parameters. Elementary class comprehension therefore gives all the  $\theta_p$ 's as one class relation.

In particular, we have not selected an arbitrary class isomorphism independently for each of a proper class of prefixes. No extra class-choice principle, and no recursion with proper-class-valued stages, has been used.

For an arbitrary source word  $f : \alpha \rightarrow \mathbf{No}$ , construct a target word by set recursion. Given its prefix  $p$  at position  $\xi$ , put the next target entry equal to  $\theta_p(f(\xi))$ ; take unions at limits. The output is a permitted word of the same length. Conversely, from any permitted target word  $g$  recover

$$f(\xi) = \theta_{g|_\xi}^{-1}(g(\xi)).$$

These procedures are inverse. They preserve prefixes, and the first unequal entries are transformed by the same increasing map  $\theta_p$ . Thus they preserve the shorter-first lexicographic order.  $\square$

This theorem sharpens equimorphism: under the displayed choice assumption the three shorter-first word orders are actually the same order type. It does not identify that type with  $\mathbf{No}$ . Their positive-length limit prefixes still have the familiar small left cofinalities and nontrivial set suprema.

### 36 Termination conventions: the criterion and all isomorphism types (source 16; routes of sources 13 and 18)

[merge] Source 16's Section 8, printed whole, as the base of this section: it decides, for every placement of a formal terminator in the alphabet  $\mathbf{No}$ , whether the unrestricted and the injective word orders fill every set cut ([theorem 36.1](#)), and lists every isomorphism type that occurs ([theorem 36.2](#)). Its termination types  $\mathcal{T}_{\min}$ ,  $T_\kappa$  are printed  $\mathbf{T}_{\min}$ ,  $\mathbf{T}_\kappa$ ; its references to its own universality proposition and set-cut display are printed as references to [proposition 5.13](#) and [definition 5.1](#). Source 13 ([section 36.4](#)) and source 18 ([section 36.5](#)) prove the central case independently, with the same letter code ([note 36.3](#)).

Choose an initial/final partition  $\mathbf{No} = L_\varepsilon + R_\varepsilon$  and adjoin a formal symbol  $\varepsilon$ , distinct from every surreal, with

$$L_\varepsilon < \varepsilon < R_\varepsilon.$$

Compare words at the first differing coordinate, treating a terminated word as having the symbol  $\varepsilon$  there. This includes prefix-first and prefix-last as the two extreme placements. The Conway convention for sign expansions,  $- < \varepsilon < +$ , uses a two-letter alphabet; it must not be confused with prefix-first dictionary order over all surreals.

**Theorem 36.1** (Termination criterion). *Let  $\mathcal{V}$  be either  $\mathcal{T}$  or  $\mathcal{I}$ . Its termination order has a strict interpolant for every separated pair of sets, including empty sides, if and only if:*

1.  $L_\varepsilon$  and  $R_\varepsilon$  are nonempty;
2.  $L_\varepsilon$  has a greatest member or has no set cofinal subset;

3.  $R_\varepsilon$  has a least member or has no set coinital subset.

The equivalence uses GB and the surreal set-cut property. In GBC these conditions are also equivalent to this word order being isomorphic to **No**.

*Proof.* If either side of the threshold is empty, the empty word is an endpoint. If  $L_\varepsilon$  has no maximum but a set cofinal subset  $C$ , the singleton words  $(c)$ ,  $c \in C$ , lie below the empty word and have no strict interpolant below it. Any proposed interpolant has a first letter  $x \in L_\varepsilon$ , and some  $c \in C$  is larger than  $x$ , placing  $(c)$  above it. The right-side argument is dual. This proves necessity.

For sufficiency, start with a separated set cut  $A < B$  of words. Follow a common prefix  $p$ , keeping active precisely the input words extending it, including equality. Every discarded lower word is below every extension of  $p$ , and every discarded upper word is above every such extension. At the next coordinate let  $U, V$  be the sets of active lower and upper symbols, using  $\varepsilon$  for a word ending at  $p$ . Every  $u \in U$  is at most every  $v \in V$ .

If  $U$  and  $V$  meet, their common member is unique. It cannot be  $\varepsilon$ , which would put the same word  $p$  on both sides. Append the common surreal letter and continue. In the injective case a witness among the active words ensures freshness. Take unions at limits. The search cannot reach an ordinal larger than every input word length, so eventually  $U < V$  are disjoint.

If neither set contains  $\varepsilon$ , choose a fresh surreal strictly between them and append it. Suppose  $\varepsilon \in U$ , so  $V \subseteq R_\varepsilon$ . If a numerical member of  $U$  already lies in  $R_\varepsilon$ , ordinary fresh separation works. Otherwise all numerical lower symbols lie in  $L_\varepsilon$ . If  $R_\varepsilon$  has no set coinital subset, choose  $r \in R_\varepsilon$  below the whole set  $V$ , and then a fresh letter strictly between  $r$  and  $V$ . If  $R_\varepsilon$  has a least member  $r$  not in  $V$ , the same interval above  $r$  works.

The remaining case is that  $r = \min R_\varepsilon$  belongs to  $V$ . Append  $r$ , which is fresh in the injective case because an active upper word supplies it. All lower comparisons are now decided. For the upper words continuing through  $r$ , collect their next numerical letters and choose a fresh  $d$  below this set and below some fixed member of  $L_\varepsilon$ . The extension  $p \frown (r, d)$  is below all those upper words, including any terminating just after  $r$ , and above every lower word. Thus two letters handle the possible adjacency between the termination symbol and a numerical letter. The case  $\varepsilon \in V$  is the reversed construction using  $\max L_\varepsilon$  when needed.

This proves interpolation using only a bounded set recursion. The word carrier is proper, since it contains all singleton surreals. In GBC, class universality ([proposition 5.13](#)) gives the claimed isomorphism with **No**.  $\square$

### 36.1 Concrete consequences and explicit encodings

Write  $0^-$  for the formal symbol immediately below numerical zero, and  $0^+$  for the one immediately above zero. All labels, including zero, remain available. For  $0^-$  the sides are  $x < 0$  and  $x \geq 0$ ; for  $0^+$  they are  $x \leq 0$  and  $x > 0$ . [Theorem 36.1](#) gives

$$\mathcal{T}_{0^-} \cong \mathcal{I}_{0^-} \cong \mathbf{No}, \quad \mathcal{T}_{0^+} \cong \mathcal{I}_{0^+} \cong \mathbf{No} \quad \text{in GBC.} \quad (\text{S16.6})$$

This includes the empty word and all limit-length words.

There are also explicit embeddings that do not use global choice. For a sign sequence  $s_x$ , let  $D(s_x)$  duplicate each sign, and put

$$C_-(x) = D(s_x) \frown (+, -), \quad C_+(x) = D(s_x) \frown (-, +).$$

Both letter codes are prefix-free and preserve numerical comparison, because either terminal block lies strictly between  $(-, -)$  and  $(+, +)$ . The first sign of  $C_-(x)$  is negative exactly when  $x < 0$ , and

that of  $C_+(x)$  exactly when  $x \leq 0$ . Concatenating the codes of the entries therefore embeds the corresponding termination order into **No**. The encoded birthday is

$$\sum_{i < \alpha} (2 \cdot \text{bd}(f(i)) + 2). \quad (\text{S16.7})$$

The operations are ordinal operations; the 2 is on the left. At regular infinite birthday cutoffs, words of length below the cutoff whose entries are below it remain below it under this encoding. Singular cutoffs do not satisfy that closure assertion.

For prefix-first words, add an initial + to each letter code. This makes every continued block begin above termination and again gives an explicit embedding into **No**. Singleton words embed **No** back. Thus equimorphism persists even where local characters prevent isomorphism.

An interior threshold alone does not guarantee saturation. Place it between the surreals bounded above by some natural number and those larger than every natural number. The singleton natural-number words are cofinal below the empty word, so the termination order fails the criterion. Furthermore, (S16.6) does not extend to increasing words: a positive increasing word of length  $\omega$  still has its finite prefixes cofinal below it. Its permissible continuation letters are all positive. Hence the centered order on  $\mathcal{T}^{\text{inc}}$  is not  $\eta_{\text{Ord}}$ . The isomorphism of Theorem 35.1 specifically uses an endpoint termination convention.

### 36.2 Complete isomorphism classification of the termination family

There is a stronger classification for unrestricted and injective words. For an infinite regular cardinal  $\kappa$ , place the formal terminator at the threshold

$$L_\kappa = \{x : \exists \alpha < \kappa (x < \alpha)\}, \quad R_\kappa = \{x : \forall \alpha < \kappa (\alpha < x)\},$$

and call the resulting unrestricted word order  $\mathbf{T}_\kappa$ . The two classes partition **No**: the regular infinite cardinal  $\kappa$  is a limit ordinal. Its left side has cofinality  $\kappa$ , while its right side has no set coinital family, since the set of ordinals below  $\kappa$  can be separated from any proposed such family by the set-cut property (definition 5.1).

**Theorem 36.2** (All termination types). *In GBC, the isomorphism types obtained from every formal termination cut, for either unrestricted or injective set words, are exactly*

$$\mathbf{T}_{\min}, \quad \mathbf{T}_{\min}^{\text{op}}, \quad \mathbf{No}, \quad \mathbf{T}_\kappa, \quad \mathbf{T}_\kappa^{\text{op}} \quad (\kappa \text{ infinite regular}). \quad (\text{S16.8})$$

*There are no repetitions in this list. Here  $\mathbf{T}_{\min}$  uses shorter-prefix-first comparison. At every point of  $\mathbf{T}_\kappa$  the left cofinality is  $\kappa$  and there is no set coinital family on the right; its dual has the reversed profile.*

*Proof.* The endpoint placements give the first two types, by Theorem 35.1 and numerical negation. For an interior placement, Theorem 36.1 gives **No** unless one threshold side has no endpoint and a set cofinal or coinital family. Both sides cannot fail this way: the two sets would contradict the set-cut property (definition 5.1). The one small character is an infinite regular cardinal, say  $\kappa$ .

For a maximum-free left threshold of cofinality  $\kappa$ , extensions  $p \frown (c)$  with  $c$  in a cofinal subset of the left threshold are cofinal below any word  $p$ . In the injective case one may move these letters through intervening nonempty intervals to avoid  $\text{ran}(p)$ . Conversely, the next letters of a set cofinal below  $p$ , among its extending members, must be cofinal in that threshold. This proves the left character  $\kappa$ . The right threshold has no set coinital family, and the same next-letter argument excludes one above  $p$ . If a threshold side has an endpoint instead, two-letter extensions as in

**Theorem 36.1** exclude small local character on that side. These observations also distinguish the profiles in the list.

Two maximum-free threshold cuts with left cofinality  $\kappa$  are conjugate by a numerical automorphism of **No**. Choose increasing cofinal sequences of length  $\kappa$  on their left sides, match them, and extend this set partial isomorphism by back-and-forth. Each left side is determined as the initial closure of its sequence, so the automorphism carries the whole threshold cut to the other one. Applying it entrywise identifies the unrestricted word orders, and likewise the injective ones. The right-sided case is dual.

To identify unrestricted and injective words in this remaining case, fix the cofinal left sequence. For every set  $S$ , choose uniformly a cofinal sequence of the same type in  $L_\varepsilon \setminus S$ , using fresh points in intervening surreal intervals. Start back-and-forth with the matching of these two set sequences. It gives a uniform isomorphism  $h_S : \mathbf{No} \rightarrow \mathbf{No} \setminus S$  preserving both threshold sides. Taking  $h_\emptyset$  as the identity, the recursion

$$q(i) = h_{\text{ran}(q \upharpoonright i)}(f(i))$$

is a length- and prefix-preserving isomorphism from free words to injective words, now preserving comparison with the middle terminator as well. All preparatory sequences and stage histories are sets. The saturated cases were already identified with **No**.

Finally endpoints distinguish the first two types. The surreal type has no small character on either side of any point, whereas the  $\mathbf{T}_\kappa$  types have the displayed one-sided character. Those characters distinguish the different regular cardinals and their duals. This proves exhaustiveness and absence of repetitions.  $\square$

Every termination order in this list is nevertheless equimorphic with **No**, even without global choice. For an arbitrary threshold, the increasing map  $\phi(x) = x/(1 + |x|)$  can be rescaled separately on its two sides into  $(-1, 0)$  and  $(0, 1)$ . This preserves all letter comparisons and puts termination at zero. The duplicated-sign codes above then give an explicit word embedding into **No**; singleton words supply an embedding in the opposite direction. Thus equimorphism leaves a proper class of different isomorphism types undistinguished. This classification excludes numerically increasing words with an interior terminator, whose behavior depends on the prefix as explained above.

### 36.3 Length-first ordering is another independent choice

In shortlex order one compares the ordinal lengths first, and compares entries only when those lengths agree. It is the ordered sum of the fixed-length layers over **Ord**, rather than one of the termination orders above. Its empty word is a minimum, and two words can be ordered by their lengths even when they disagree numerically at their first entry. This variant is rigorously definable on set codes but should be named explicitly; none of the global-exhaustive results implicitly uses it.

*Note 36.3* ([merge]; one letter code, five spellings). With  $D(s)$  the sign sequence  $s$  with every sign doubled, the letter codes of the six sources and of Part II are the following; each is prefix-free and order-preserving because its terminal block lies strictly between  $(-, -)$  and  $(+, +)$ .

- $D(s_x) \cap (+, -)$ : source 16's  $C_-$  (S16.7), source 13's  $c(x)$  (proposition 36.5) and source 18's centered  $C(x)$  (proposition 36.7); birthday  $2 \cdot \text{bd}(x) + 2$  per letter, as in (S16.7). Source 16's  $C_+$  is  $D(s_x) \cap (-, +)$ .
- $(+) \cap D(s_x) \cap (+, -)$ : Part II's prefix-first code (theorem 9.1), source 16's “add an initial +” and source 18's  $K(x)$  (note 35.4); birthday  $1 + 2 \cdot \text{bd}(x) + 2$  per letter. Source 17's code (S17.1) is  $(+) \cap D(s_x) \cap (-, +)$ , with the same birthday.

- 00, 11, 01 for  $-$ ,  $+$  and termination, read as signs: source 14's inner code ([proposition 35.6](#) and its Subsection 2.3) and source 15's entry code ([lemma 31.1](#)); this is source 16's  $C_+$ . Source 14 doubles it once more for the outer word, which gives  $4 \cdot \text{bd}(x) + 4$  per letter and 2 for the end.

Source 16 does not cite Part II for its prefix-first code. No source claims that any of these codes is optimal; source 11's question on optimal birthday bounds ([research question 113.6](#)) stays open ([section 39](#)).

### 36.4 Source 13's route: central termination restores a surreal word order

[merge] Source 13's Section 12, printed whole as a route to the central case of [theorem 36.1](#). Its order  $\mathcal{T}_0$  is the termination order of the alphabet  $\mathbf{No} \setminus \{0\}$  with the terminator in the place of the reserved zero, i.e. with threshold sides the negative and the positive surreals; neither side has an endpoint or a set cofinal (resp. coinital) subset, so [theorem 36.1](#), transported along an isomorphism  $\mathbf{No} \setminus \{0\} \cong \mathbf{No}$  in GBC, gives [theorem 36.4](#). The proofs are the same common-prefix search. Its code ([proposition 36.5](#)) is source 16's code  $C_-$  (S16.7), with the same birthday. Source 13's own caveat stands: it does not classify all placements of a marker; source 16 does ([theorem 36.2](#)). Its references to its fresh-separator lemma, class universality and core interpolation are printed as references to [lemma 5.2](#), [proposition 5.13](#), and [theorem 19.10](#).

The end-first convention of [Section 35.2](#) treats every extension as larger than its prefix, irrespective of the sign of the new label. We now keep a genuine middle termination value. To avoid collapsing distinct words, that value must not also be an ordinary letter.

#### 36.4.1 The precise alternative

Let  $A = \mathbf{No} \setminus \{0\}$ . A word  $p : \alpha \rightarrow A$  is padded by the surreal number 0 at every coordinate at or beyond  $\alpha$ . Compare two different words at the first difference of these padded functions, using numerical comparison in  $\mathbf{No}$ . Call this *central termination*, and denote the arbitrary-word and injective-word orders by  $\mathcal{T}_0$  and  $\mathcal{I}_0$ , respectively.

For example,

$$(-1) < () < (1), \quad p \frown (-1) < p < p \frown (1),$$

whenever the displayed appended letters are allowed. The empty word is now an interior point, not an endpoint. For injective words, fresh negative and positive letters can always be used in place of  $-1, 1$ .

Distinct words really are distinguished by padding: at the end of a proper prefix, the longer word has a nonzero letter. If 0 were also allowed as a letter,  $p$  and  $p \frown (0)$  would have identical padded functions. The resulting rule would fail even to define an antisymmetric order on raw words. Reserving the marker is essential.

**Theorem 36.4** (Central-word isomorphism). *In GBC,*

$$\mathcal{T}_0 \cong \mathbf{No}, \quad \mathcal{I}_0 \cong \mathbf{No}.$$

*Both isomorphisms concern ordinary classes of set codes. They do not identify the word structure, concatenation, or birthdays with surreal arithmetic.*

*Proof.* It suffices to prove set-cut saturation. Let a set of lower words be strictly below a set of upper words. Choose an ordinal  $\delta$  strictly above all their lengths. We use an active-prefix argument similar to the interpolation theorem of the core (source 13's Theorem 7.2, [theorem 19.10](#)), but now an active word that ends exactly at the current prefix contributes the value 0.

At a current nonzero-letter prefix  $p$  of length  $\beta$ , an active bound agrees with  $p$  and has length at least  $\beta$ . Let  $L_\beta$  and  $U_\beta$  be its next letters, or 0 for a bound ending there. Every cross lower value is at most every upper value. If there is a shared value  $t$ , it is unique. It cannot be 0: a lower word and an upper word both ending at  $p$  would be identical, contradicting the strict cut. Append  $t$  and retain the active rows with next value  $t$ . In the injective case  $t$  is fresh, because it belongs to an active injective word extending  $p$ .

If no value is shared, choose a strict separator  $x$  between the two sets, avoiding 0, and also avoiding  $\text{ran}(p)$  in the injective case. The fresh-separator lemma (lemma 5.2) supplies it. The *terminated* word  $p \frown x$  now lies strictly between every original bound. Every comparison is already decided at this new coordinate or an earlier one, so its termination afterwards is immaterial.

At limits, take the union of the earlier prefixes. The procedure cannot continue indefinitely: after all input lengths have been passed, no bound can remain active. More specifically, a shared nonzero letter extends some active word and so cannot occur at a stage  $\beta \geq \delta$ . The construction stops at a set stage. It also works with an empty side or with both sides empty. This proves set-cut saturation of each order. Their elements are sets; apply class universality (proposition 5.13) to obtain the two isomorphisms.  $\square$

This answers the termination-convention direction for an important interior convention. It is not a classification of all possible placements of a marker in every class alphabet. By translating labels, one may reserve any specified surreal  $c$  instead of 0. Since  $\mathbf{No} \setminus \{0\} \cong \mathbf{No}$ , the construction can also be transported to an abstract alphabet order-isomorphic to the full surreal line. Such a transport is not the identity on numerical labels and should not be hidden in the notation.

### 36.4.2 An explicit sign-code embedding

The isomorphism proof uses class back-and-forth. There is also a direct order embedding, useful for calculations and finite tests.

Given a surreal letter  $x$  with sign sequence  $s_x$  of length  $\alpha$ , replace each  $-$  by  $--$  and each  $+$  by  $++$ , then append the pair  $+ -$ . Write the resulting sign block as

$$c(x) = \text{double}(s_x) \frown (+, -).$$

The family of these blocks is prefix-free. If two original sign sequences first differ by actual signs, their doubled versions decide the comparison in the same direction. If one sequence ends first, its terminal pair  $+ -$  lies lexicographically between the two possible continuation pairs  $--$  and  $++$ . Thus the same statement holds when the original comparison used termination.

**Proposition 36.5** (Direct central-word coding). *For a set word  $p : \lambda \rightarrow \mathbf{No} \setminus \{0\}$ , concatenate the blocks  $c(p(i))$  in order and regard the result as a surreal sign sequence. This defines an order embedding  $C : \mathcal{T}_0 \hookrightarrow \mathbf{No}$ , and hence also an embedding of  $\mathcal{I}_0$ , with*

$$\text{bd}(C(p)) = \sum_{i < \lambda} (2 \cdot \text{bd}(p(i)) + 2).$$

*All sums and products in this formula are ordinal operations.*

*Proof.* Every block has positive set-ordinal length and the concatenation has set-ordinal length, so it is a surreal. At a first unequal letter, prefix-freeness and order preservation of the block code decide the same comparison before either block is exhausted.

If one outer word is a proper prefix of the other, its code terminates at the beginning of the next block. Because the next letter is nonzero, the first sign of its block has the sign of that

letter. Comparison of termination with this sign has exactly the central termination direction. Thus all comparisons are strict and preserved. The birthday formula is the definition of ordinal concatenation.  $\square$

No claim of surjectivity is made for this explicit map. The order isomorphism in [Theorem 36.4](#) is a separate conclusion. The code is a central-termination adaptation of the prefix-free sign-block methods used in the earlier set-word analysis of Part II ([theorem 9.1](#)); the accompanying finite tests check it by independent dyadic evaluation.

### 36.4.3 Why the obstruction disappears

At a limit-length central word  $p$ , the proper prefixes are not uniformly below it: their comparison depends on the next nonzero letter of  $p$ . More importantly, a set of lower approximants can be separated from  $p$  by a fresh next value at the decisive active stage. The set-cut proof supplies this separator regardless of a particular sign pattern. Hence the small cofinality invariant of [Note 35.3](#) no longer obstructs an isomorphism with **No**.

The two constructions therefore illustrate a general warning: lexicographic comparison of variable-length words is not a minor technical variation of fixed-domain lexicography. A termination convention can change endpoints, point characters, and the entire isomorphism type.

## 36.5 Source 18's route: centered termination changes the order

[merge] Source 18's Section 7, printed whole as a third proof of the central case. Its classes  $\mathcal{C}$ ,  $\mathcal{C}_{\text{inj}}$ ,  $\mathcal{C}_{\text{inc}}$  are printed  $\mathcal{T}_c$ ,  $\mathcal{I}_c$ ,  $\mathcal{T}_c^{\text{inc}}$  ([section 1.3.1](#)). Its centered order is source 13's  $\mathcal{T}_0$  (the terminator compared as zero with the next entry), and its code  $C(x)$  is source 13's  $c(x)$  and source 16's  $C_-(x)$ . Nothing in it is new against sources 13 and 16 except the remark that singleton words also embed **No** into  $\mathcal{T}_c^{\text{inc}}$ , which the next section uses. Source 18 was written before sources 13–17 arrived.

For a set word  $p$ , write  $\ell(p)$  for its ordinal length and  $p \smallfrown \langle x \rangle$  for ordinal concatenation. The surreal set-cut property used throughout this section is the following: if  $L < R$  are sets of surreals, possibly empty, there is a surreal strictly between them. The interpolant can also be required to avoid any prescribed set. Indeed, first find a nonempty surreal interval between the two sides, and then use the set-cut property inside that interval to escape the forbidden set. No global choice is needed for these interpolation statements.

Put  $D = \mathbf{No} \setminus \{0\}$ . Let  $\mathcal{T}_c$  be all set-length words over  $D$ , and let  $\mathcal{I}_c$  and  $\mathcal{T}_c^{\text{inc}}$  be its injective and strictly numerically increasing subclasses. Include the empty word in all three classes. Compare unequal words at their first unequal entry. If one word is a proper prefix of the other, compare its termination symbol  $\dagger$  with the next entry of the longer word, using

$$x < \dagger \quad (x < 0), \quad \dagger < x \quad (x > 0).$$

Thus  $\dagger$  occupies the missing numerical position of zero. This is a strict linear order, called the centered order below. The definition is not the shorter-first convention.

**Theorem 36.6** (Centered arbitrary and injective words). *Both  $\mathcal{T}_c$  and  $\mathcal{I}_c$  fill every set cut. Consequently, in GBC, both are order-isomorphic to **No**. They have no endpoints; neither side of any point has a set cofinal or a set coinital subset, respectively.*

*Proof.* For a prefix  $p$ , its cone consists of all words extending  $p$ , including  $p$  itself. A cone is convex. A word outside it is uniformly below the whole cone or uniformly above the whole cone: the comparison has already been decided before  $p$  ends.

Given a set cut  $A < B$ , start with the empty prefix. Maintain the invariant that discarded members of  $A$  are below its whole cone, and discarded members of  $B$  are above its whole cone. At a current prefix  $p$  of length  $\delta$ , assign next tokens to the active words: an actual next entry to a proper extension, and the numerical token 0 to  $p$  itself. Let  $L_p, R_p$  be the two sets of tokens. Every member of  $L_p$  is at most every member of  $R_p$ . Their intersection therefore has at most one member.

If the token sets are disjoint, choose

$$L_p < c < R_p, \quad c \notin \{0\} \cup \text{ran}(p).$$

Then  $p \smallfrown \langle c \rangle$  interpolates the original cut. Avoiding the range is needed only for the injective version. If the token sets meet, their common token cannot be zero: zero would mean that the same word  $p$  belonged to both sides. Append their common nonzero entry and continue. The new prefix is injective when required, since it is an actual prefix of a witnessing injective word. At a limit stage take the union. The cone invariant persists.

Choose an ordinal strictly above every length occurring in  $A \cup B$ . The search cannot keep finding common actual entries that long. It therefore terminates with a successor-length interpolant. Empty sides cause no difficulty. Taking one side to be a singleton gives the asserted local character properties.

In GBC, restrict a fixed set-like global well-order to each of the two proper classes and to **No**. An ordinal back-and-forth constructs an isomorphism: at each stage its partial map is a set, and the new point is chosen in the cut imposed by that set. Freshness follows from the set-avoidance version of interpolation. This is a recursion with set-sized partial maps, not an appeal to choice for arbitrary families of proper classes.  $\square$

The contrast with shorter-first words is substantive. At a limit word, the centered convention still permits extensions on both sides. These extensions prevent the proper prefixes from creating a one-sided set-cofinal obstruction.

**Proposition 36.7** (An explicit centered sign embedding). *There is an explicit order embedding of  $\mathcal{T}_c$  into **No**, without global choice. Conversely, **No** embeds into each of  $\mathcal{T}_c$ ,  $\mathcal{I}_c$ , and  $\mathcal{T}_c^{\text{inc}}$ .*

*Proof.* For a nonzero surreal  $x$ , let  $s_x$  be its nonempty sign expansion. Duplicate each sign, writing  $D(s_x)$ , and put

$$C(x) = D(s_x) \smallfrown (+, -).$$

This is a prefix-free order-preserving code. When one original sign expansion ends, the delimiter  $(+, -)$  is compared with the next doubled block; the inequalities

$$(-, -) < (+, -) < (+, +)$$

give exactly the surreal comparison at termination. The first sign of  $C(x)$  is the sign of  $x$ . For a word  $f$ , concatenate the blocks  $C(f(i))$  in ordinal domain order. Replacement makes the resulting sign expansion a set. First disagreements are preserved by prefix freedom; proper-prefix comparisons are preserved by the first sign of the next block. This proves the first assertion. For the reverse embedding send 0 to the empty word and send  $x \neq 0$  to  $\langle x \rangle$ .  $\square$

## 37 Centered increasing words and the entry zero (source 18)

[merge] Source 18's Sections 8, 9 and 11 and the corollary of its Section 10, printed whole; no other source treats these orders. Source 16 observed the first obstruction (end of its Subsection 8.1: a

positive increasing word of length  $\omega$  is the supremum of its finite prefixes, so the centered order on  $\mathcal{T}^{\text{inc}}$  is not  $\eta_{\text{Ord}}$  and asked for the classification of increasing words with an interior terminator (its question “Centered increasing words”); source 18 gives it for the threshold at zero (theorem 37.2), and settles the three ways of treating an actual entry zero (propositions 37.4 and 37.5 and corollary 37.7). Its proofs use the common-prefix search of theorem 11.1 with the termination token evaluated as zero.

### 37.1 Centered increasing words: an exact cut classification

Strict numerical increase changes which continuations remain available. An all-negative prefix admits fresh negative and positive continuations. Once a positive entry has occurred, every valid continuation is positive. This distinction gives the entire obstruction below.

**Theorem 37.1** (Local characters of centered increasing words). *Let  $f \in \mathcal{T}_c^{\text{inc}}$  have length  $\alpha$ . If  $\alpha$  is a nonzero limit and  $f$  has a positive entry, then*

$$\text{cf}((\mathcal{T}_c^{\text{inc}})_{<f}) = \text{cf}(\alpha).$$

*At every other point the open initial segment has no set cofinal subset. At every point the open final segment has no set coinital subset. The order has no endpoints and is dense.*

*Proof.* If  $f$  has a positive entry and has limit length, its sufficiently long proper prefixes form an increasing cofinal family below it. Every smaller word either terminates before  $f$ , or first differs at a smaller entry before  $\alpha$ ; it cannot properly extend  $f$ , since all such extensions are larger. It is consequently below every sufficiently long prefix. A cofinal sequence of prefix lengths proves the upper bound  $\text{cf}(\alpha)$ . Conversely, for each smaller word choose a prefix exceeding it. Fewer than  $\text{cf}(\alpha)$  chosen lengths are bounded, so that many words cannot be cofinal.

Suppose next that every entry of  $f$  is negative; this includes the empty word. Given a set  $A < f$ , collect the next entries of those members of  $A$  that properly extend  $f$ . They are all negative. Choose a negative  $d$  above this set and above  $\text{ran}(f)$ . The set-cut property permits this even when the range of  $f$  has no largest member. Then

$$A < f \frown \langle d \rangle < f.$$

Members of  $A$  that do not extend  $f$  first differ earlier with a smaller entry. They are also below this new word.

If  $f = p \frown \langle x \rangle$  and  $x > 0$ , a smaller word sharing  $p$  either stops there or has next entry below  $x$ . For a set of such words, choose  $d < x$  above all their next entries, above zero, and above  $\text{ran}(p)$ . The word  $p \frown \langle d \rangle$  is a strictly larger lower bound for  $f$  than any member of the given set. This handles the remaining successor case.

Finally, given a set  $B > f$ , the next entries of members that extend  $f$  are positive. Choose a positive  $d$ , above the range of  $f$ , but below all those entries. Then

$$f < f \frown \langle d \rangle < B.$$

All other members of  $B$  are above the whole cone of  $f$ . This proves the right-hand assertion and, with empty sets, the absence of endpoints.

For density, if two words first differ, choose a new coordinate strictly between their different entries. It is automatically above the common prefix. If the comparison is a proper-prefix comparison with next entry  $x > 0$ , choose a coordinate strictly between the set  $\{0\} \cup \text{ran}(p)$  and  $x$ . For a next entry  $x < 0$ , choose one strictly between  $\{x\} \cup \text{ran}(p)$  and zero.  $\square$

**Theorem 37.2** (All set-cut obstructions). *A set cut  $A < B$  in  $\mathcal{T}_c^{\text{inc}}$  has no interpolant if and only if  $B$  has a minimum  $b$  such that*

1.  $\ell(b)$  is a nonzero limit ordinal;
2.  $b$  has a positive entry;
3.  $A$  is cofinal in the open initial segment below  $b$ .

*In every other case an interpolant of nonzero successor length can be chosen.*

*Proof.* The stated obstruction plainly prevents interpolation. For the converse use the common-prefix search from [Theorem 36.6](#), evaluating the termination token as zero. Common actual coordinates can still be appended, since each is witnessed by an increasing word.

At a stage where the next-token sets are disjoint, a permissible new coordinate must satisfy

$$L_p \cup \text{ran}(p) < c < R_p, \quad c \neq 0.$$

Every actual token on the right exceeds the whole range of  $p$ . Thus these are consistent strict surreal constraints unless zero is a right token and  $p$  already has a positive entry. When zero is a right token and all entries of  $p$  are negative, the constraints are still consistent and a negative interpolating coordinate can be chosen. Empty right sides are harmless.

The sole exceptional event is therefore reaching  $p \in B$  after  $p$  has acquired a positive entry. Every proper extension of  $p$  is larger, so the active lower side is then empty and  $p = \min B$ . This event cannot occur at a successor length: the last common coordinate had a witness in  $A$  extending that successor prefix, which would be at least  $p$ , contradicting  $A < B$ . It also cannot occur at length zero.

It can occur at a limit length  $\alpha$ . For every sufficiently large  $\xi < \alpha$ , a lower-side witness supplied the coordinate  $p(\xi)$ . That witness extends  $p \upharpoonright (\xi + 1)$ , is at least this prefix, and remains below  $p$ . The sufficiently long prefixes are cofinal below  $p$  by [Theorem 37.1](#); hence  $A$  is cofinal there. As before, a bound on all input word lengths ensures that the search terminates using only set recursion.  $\square$

**Corollary 37.3.** *The centered increasing-word order is equimorphic with  $\mathbf{No}$ , but is not isomorphic to  $\mathbf{No}$ , even in GBC. Its successor-length suborder fills every set cut and is isomorphic to  $\mathbf{No}$  in GBC. The larger suborder obtained by adjoining the empty word and every all-negative limit word also fills every set cut and has the same isomorphism conclusion.*

*Proof.* Use the explicit embeddings of [Proposition 36.7](#). The increasing word  $\langle 1, 2, 3, \dots \rangle$  is the supremum of its finite prefixes in this word order. Such a nontrivial set supremum cannot occur in  $\mathbf{No}$ , by its set-cut property. For either stated suborder, an upper set cannot contain the exceptional minimum in [Theorem 37.2](#), and the proof returns a successor word in the suborder itself. Apply class back-and-forth in GBC.  $\square$

Every nonempty open interval in the centered increasing-word order contains an order copy of  $\mathbf{No}$ . The density proof can choose a whole surreal interval of permissible new coordinates, rather than one coordinate. This supplies the copy. Thus rich interval universality coexists with the precise limit-word obstructions.

### 37.2 What if the entry zero is allowed?

Saying only that termination lies “between negatives and positives” does not settle its relation to an actual entry equal to zero. There are at least three different mathematical constructions.

### 37.2.1 Zero padding and its quotient

One may pad each set word by zeros at every later ordinal coordinate. First-difference comparison then gives a total preorder, not a strict linear order on the original words. For instance the empty word and  $\langle 0 \rangle$  become equal. In general put

$$\sigma(f) = \sup\{\xi + 1 : \xi < \ell(f), f(\xi) \neq 0\}, \quad \rho(f) = f \upharpoonright \sigma(f).$$

Two padded words are equivalent exactly when their reduced words  $\rho(f)$  agree. A class of canonical set representatives is therefore available: trim the entire terminal zero tail. A limit-length reduced word has nonzero entries cofinal in its length. Reduction preserves injectivity and strict numerical increase.

**Proposition 37.4** (The zero-padding quotient). *For all set words, and separately for injective set words, the zero-padding quotient fills every set cut and is isomorphic to **No** in GBC. For strictly increasing set words, the quotient has exactly the cut obstruction in [Theorem 37.2](#), applied to the reduced representatives. Its exceptional points are precisely the reduced limit words having a positive entry.*

*Proof.* Work with reduced representatives. A set of input representatives has lengths bounded by a set ordinal  $\mu$ . Pad them by zeros through coordinate  $\mu$  and perform the numerical common-prefix search. This search now allows a common coordinate equal to zero.

In the injective case, the prefix produced by the search remains injective. A common nonzero coordinate is an actual coordinate of every witness. If zero is common, at least one witness has an actual zero at that coordinate: otherwise a witness on each side would have terminated already and, agreeing at all previous coordinates, would represent the same padded word. An actual witness certifies that the enlarged prefix is injective. At a separation step choose a nonzero coordinate outside the range of the prefix, using the surreal set-cut property. This returns a reduced injective word. At coordinate  $\mu$ , two distinct input classes cannot both remain active, so termination is guaranteed. This proves the first claim.

For increasing words the same witness argument makes every common prefix strictly increasing. At a separating step add its range to the lower numerical constraints. The only potential failure is an upper padded-zero token together with a nonnegative entry in the current prefix.

If the prefix has a positive entry, an increasing extension cannot consist of an extra padded zero. The active upper word must therefore be exactly this reduced prefix. As in the proof of [Theorem 37.2](#), a successor stopping stage contradicts the preceding lower-side witness, while a limit stopping stage gives the stated cofinal-prefix obstruction.

The remaining apparent failure would be a prefix  $p = q \smallfrown \langle 0 \rangle$ , where  $q$  is all-negative, and an active upper representative equal to  $q$ . This stage cannot be reached. The common zero that produced it would require a lower witness. If that witness has terminated, it represents  $q$  itself; if it has an actual zero, its reduced increasing continuation has a positive entry and lies above  $q$ . Both possibilities contradict the cut. There are no further failures. The converse obstruction is again supplied by cofinal proper prefixes of a positive limit word.  $\square$

For labeled well-orders the quotient is a change of subject that must be stated explicitly. It identifies distinct codes with different underlying sets: an all-negative increasing word and that word followed by zero are different labeled well-orders, although the padding convention makes them equivalent.

### 37.2.2 A distinct terminator immediately below or above zero

Alternatively, retain every word as a distinct object and use one of the two enlarged alphabets

$$\mathbf{No}_{<0} < \dagger_- < 0 < \mathbf{No}_{>0}, \quad \mathbf{No}_{<0} < 0 < \dagger_+ < \mathbf{No}_{>0}.$$

The indicated neighboring symbols are adjacent in the enlarged alphabet. These are genuine linear orders on the original words.

**Proposition 37.5.** *For arbitrary set words, and separately for injective set words, both distinct-terminator conventions fill every set cut. Each resulting class order is isomorphic to  $\mathbf{No}$  in GBC.*

*Proof.* Use the common-prefix search with tokens in the enlarged alphabet. At a strict token separation an unused surreal can normally be inserted. The only exception is its displayed adjacent pair.

For  $\dagger_- < 0$ , the exceptional separation has the current prefix  $p$  on the lower side, and upper active words with next entry zero. No lower word has next entry zero, since that would have caused a common-coordinate step. Append zero and then append a sufficiently small negative, unused coordinate. The resulting word is above the original lower side and below every upper word in the zero cone, including its root if that root occurs. For  $0 < \dagger_+$ , use the reverse construction: append zero and then a sufficiently large positive, unused coordinate. The existence of a zero cone certifies that zero has not already been used when injectivity is required. All choices avoid the remaining set of used entries. This resolves the only additional cases, and the length bound still makes the search a set recursion.  $\square$

Increasing words behave differently. The following general fact isolates the reason, independently of any surreal coding.

**Lemma 37.6** (Adjacency test for increasing words). *Let  $D$  be a linearly ordered alphabet with a distinct termination symbol  $\dagger$ . Suppose every allowed increasing set word has a further admissible entry above  $\dagger$ . In the corresponding order of all increasing set words,  $f < g$  are adjacent if and only if*

$$g = f \smallfrown \langle c \rangle, \quad c = \min\{x \in D : \text{ran}(f) < x, \dagger < x\}.$$

*The minimum in this assertion must exist.*

*Proof.* If  $f$  is not a prefix of  $g$ , append a positive-side admissible entry to  $f$ . The new word is above  $f$ , and its comparison with  $g$  was already settled before the appended entry; hence it remains below  $g$ . Such a pair is not adjacent.

If  $f$  is a proper prefix of  $g$ , its first new entry  $c$  must be above  $\dagger$ . All subsequent entries exceed  $c$ , so if  $g$  has any further entries, the one-letter extension  $f \smallfrown \langle c \rangle$  lies strictly between. For this one-letter extension to be adjacent, no admissible entry strictly between  $\dagger$  and  $c$  can exist. Conversely, if  $c$  is the stated minimum, every word in between would have to extend  $f$ ; its first new entry could neither be below  $c$  nor above it, and a proper continuation after  $c$  would be larger than  $g$ . No such word exists.  $\square$

**Corollary 37.7** (Exactly where the zero jump appears). *For increasing surreal words with  $\dagger_-$ , the adjacent pairs are exactly*

$$p < p \smallfrown \langle 0 \rangle \quad \text{with every entry of } p \text{ negative.}$$

*The empty prefix is allowed. With  $\dagger_+$ , or with zero excluded and centered termination, there are no adjacent pairs.*

*Proof.* Every set of surreal entries has a strictly larger positive surreal, so the lemma applies. With  $\dagger_-$ , an all-negative prefix has zero as its least positive-side admissible entry. Once a nonnegative entry is present, the admissible upper class has no least member, by the surreal set-cut property. With  $\dagger_+$ , its positive-side admissible class consists of positive surreals above the prefix and has no least member. The same argument applies when zero is excluded.  $\square$

Thus a convention that differs only in the placement of actual zero can create adjacent pairs even among finite increasing words. The absence of an eligible letter between termination and the zero entry is decisive: increasing words cannot use the negative two-letter detour from [Proposition 37.5](#).

For completeness, the same common-prefix argument gives the full set-cut classification for increasing words with the distinct terminators. With  $\dagger_+$ , only the positive limit-word obstruction of [Theorem 37.2](#) remains. With  $\dagger_-$ , one must additionally allow the adjacent-pair obstruction

$$\max A = p, \quad \min B = p \smallfrown \langle 0 \rangle, \quad \text{ran}(p) < 0.$$

Indeed, at the exceptional token gap the word  $p \smallfrown \langle 0 \rangle$  itself interpolates unless it is the upper minimum and  $p$  is the lower maximum. All other separating-coordinate steps work as before. A positive limit stopping stage is unchanged. For  $\dagger_+$ , the zero-then-positive detour is increasing and always resolves the adjacent token gap.

*Note 37.8* ([merge]; two of the zero conventions are source 16's). For arbitrary and injective words, the conventions  $\dagger_-$  and  $\dagger_+$  of [proposition 37.5](#) are source 16's  $0^-$  and  $0^+$ , and that proposition is (S16.6), a case of [theorem 36.1](#); both proofs resolve the adjacent pair by the same two-letter detour. New in source 18 are the zero-padding quotient ([proposition 37.4](#)) and, for increasing words, the exact adjacent pairs ([lemma 37.6](#) and [corollary 37.7](#)).

### 37.3 Cones of centered increasing words (source 18, Corollary 10.2)

**Corollary 37.9** (Two kinds of centered increasing cones). *Work in GBC, with zero excluded and centered termination. The cone above an all-negative increasing prefix  $p$ , including its root  $p$ , is isomorphic to the entire centered increasing-word order  $\mathcal{T}_c^{\text{inc}}$ . If  $p$  has a positive entry, its cone is isomorphic to the shorter-first arbitrary-word order, including that order's minimum. These isomorphisms can preserve the rooted prefix tree and the lengths of tails after the root.*

*Proof.* At an all-negative prefix, the two admissible classes

$$\{x : \text{ran}(p) < x < 0\}, \quad \{x : 0 < x\}$$

are both proper and fill every set cut relative to themselves. Once a positive coordinate is chosen, the negative admissible class disappears, and the positive admissible class continues to fill all set cuts. Use the uniform construction in the proof of [Theorem 35.7](#) separately on the negative and positive parts whenever both are present. The source and target therefore pass from the all-negative case to the positive case at the same coordinate, and both entry and termination comparisons are preserved. This proves the first assertion. In the positive case every later entry is above termination, so the rooted cone uses precisely shorter-first comparison. The one-part version of the same construction proves the second assertion.  $\square$

### 37.4 Regular set stages

The cut arguments also give a set-sized version. Let  $\kappa$  be regular infinite, restrict entries to  $\mathbf{No}_{<\kappa}$ , and restrict word lengths to be below  $\kappa$ . With zero excluded and centered termination, the arbitrary

and injective word orders are  $\eta_\kappa$ . Their increasing-word successor suborders are  $\eta_\kappa$  as well. The proof of every relevant cut statement uses fewer than  $\kappa$  input words, has its prefix length bounded below  $\kappa$ , and adds fewer than  $\kappa$  coordinate constraints or forbidden entries. Regularity and the  $\eta_\kappa$  property of  $\mathbf{No}_{<\kappa}$  supply the last coordinate. If  $2^{<\kappa} = \kappa$ , these orders have cardinality  $\kappa$  and are isomorphic to  $\mathbf{No}_{<\kappa}$  by ordinary set back-and-forth.

The complete increasing-word order retains every positive limit-length obstruction that is present below the cutoff. When  $\kappa = \omega$  no nonzero limit word length is allowed, so this particular obstruction disappears. These statements should not be extrapolated to singular cutoffs or to unrestricted word lengths over a fixed set alphabet: a prefix can then exhaust the available one-sided room. For example, over the nonzero dyadic rationals, an increasing negative word  $\langle -1, -1/2, -1/4, \dots \rangle$  has no further negative entry above its whole range, whereas every set of negative surreals does have such a continuation in the full surreal class.

*Note 37.10* ([merge]; regular stages in Part II). For shorter-first words the regular-stage statements are Part II's [section 12](#) and [proposition 9.2](#) (1); source 18's paragraph gives the centered analogues. Its warning about singular cutoffs is the one printed after [proposition 9.2](#).

## 38 Other comparison orders (source 15; remarks of sources 13, 14, 16, 17 and 18)

[merge] Source 15's Section 10, printed whole as the base: three lexicographies on three labels, inverse-rank lexicography ([theorem 38.1](#)), relation tables and the transfer of their endpoints ([theorem 38.2](#) and [corollary 38.3](#)), the failure of restriction-monotone linearizations ([theorem 38.5](#)), the isomorphism quotient, the normal-form embedding ([proposition 38.6](#)) and the birthday and simplicity remarks. Its macros  $\mathfrak{W}_{\text{sl}}$ ,  $\mathfrak{W}_{\text{all}}$ ,  $\mathcal{D}$  print as in this report; its rk, bl are this report's rank and  $\ell_2$ . The relation-code remarks of the other sources follow in [section 38.8](#).

### 38.1 Three lexicographies disagree on three labels

On  $0 < 1 < 2$ , an enumeration is a permutation word. Its inverse-rank vector lists the positions of labels 0, 1, 2. For table lexicography scan the directed pairs in this order:

$$(0, 1), (0, 2), (1, 0), (1, 2), (2, 0), (2, 1),$$

and use bit 1 when the first label precedes the second.

| Enumeration | Inverse ranks | Relation table |
|-------------|---------------|----------------|
| 012         | 012           | 110100         |
| 021         | 021           | 110001         |
| 102         | 102           | 011100         |
| 120         | 201           | 001110         |
| 201         | 120           | 100011         |
| 210         | 210           | 001011         |

The increasing orders on the same six objects are respectively

enumeration: 012, 021, 102, 120, 201, 210,  
inverse rank: 012, 021, 102, 201, 120, 210,  
table: 210, 120, 102, 201, 021, 012.

The table comparison is not just the reverse of enumeration comparison. As abstract finite orders, all three are of course the same six-point chain. The difference here concerns which labelled object precedes which; the next results distinguish abstract infinite order types as well.

### 38.2 Inverse-rank lexicography

Fix a baseline  $q : \text{Ord} \rightarrow \mathbf{No}$ . For a set-like well-order  $R$ , let  $r_R : \mathbf{No} \rightarrow \text{Ord}$  be its rank map. Compare the permutations

$$p_R = r_R \circ q : \text{Ord} \longrightarrow \text{Ord}$$

lexicographically, using the ordinal order on the values. Conversely, every class permutation  $p$  corresponds to the enumeration  $q \circ p^{-1}$ . This comparison uses ordinal ranks of fixed labels, rather than numerical labels at fixed positions. For a non-set-like order an ordinal rank does not exist at every label, so this version needs a further coding choice before it can be applied to all raw orders.

**Theorem 38.1** (Endpoint and character of inverse ranks). *The inverse-rank order of set-like global well-orders has a least element, the baseline order, and no greatest element. It is dense. For every nonzero limit ordinal  $\lambda$ , it has a point  $M_\lambda$  with left cofinality  $\text{cf}(\lambda)$ . No point has a set coinital family strictly above it. In particular this order is not isomorphic to native enumeration lexicography.*

*Proof.* The identity permutation is least. If  $p$  first differs from the identity at  $\alpha$ , all smaller ordinals have already appeared, so  $p(\alpha) > \alpha$ . On every tail of a permutation there is an ascending pair: otherwise a countable subsequence would descend through the ordinals. Swapping that ascending pair makes the permutation lexicographically larger. If  $p < q$ , perform such a swap strictly after their first disagreement; the result lies strictly between them. This also proves no greatest point. For a set family of points above  $p$ , bound all their first disagreements with  $p$  and perform an ascending swap later; the result is above  $p$  and below the entire family.

Let  $M_\alpha$  begin with  $\alpha$  and then list the remaining ordinals in increasing order. This is a permutation of type  $\text{Ord}$  and is the least permutation with first value  $\alpha$ , since it always chooses the least unused ordinal thereafter. For limit  $\lambda$ ,

$$M_\lambda = \sup_{\alpha < \lambda} M_\alpha.$$

Indeed, a point below  $M_\lambda$  has first value below  $\lambda$ ; some larger  $\alpha < \lambda$  therefore gives a point  $M_\alpha$  above it. A cofinal family below  $M_\lambda$  must have first values cofinal in  $\lambda$ , proving the exact character. Native enumeration  $\text{lex}$  has no least element and no set cofinal family below any point.  $\square$

For a set carrier  $X$  of cardinality  $\mu$ , scanning the labels by a bijection  $q : \mu \rightarrow X$  gives a least inverse-rank code among all well-orders, again the  $q$  order. On a fixed-type slice of type  $\alpha$ , a least inverse-rank code exists exactly when  $\alpha = \mu$ : a least rank vector can have no inversion, since swapping an inverted pair lowers it, and an increasing bijection of its ranks forces precisely that type. Thus even fixed-type endpoint behavior depends on the representation.

### 38.3 Relation tables and a theorem about all their endpoints

Choose a well-ordered scan of  $X \times X$ . For a proper class carrier assume the scan is set-like, so every proper initial part of the scan is a set. The table of a strict relation  $R$  is its characteristic function, compared with  $0 < 1$ . The native numerical order on  $\mathbf{No}^2$  cannot itself serve as a scan with a universal first-difference principle.

**Theorem 38.2** (Endpoint transfer for relation tables). *For a set-like scan, a well-order table is least among all well-order tables if and only if it is least among all strict linear-order tables. The dual statement holds for greatest elements. Both assertions also hold with the class of set-like well-orders in place of all well-orders.*

*Proof.* Suppose  $R$  is a claimed minimum and a linear order  $T$  has a smaller table. At the first differing entry  $(x, y)$ , one has  $xRy$  and  $yTx$ . The earlier bits impose a set  $P$  of directed order constraints: a true off-diagonal bit gives its indicated direction, and a false one gives the reversed direction. Both  $R$  and  $T$  satisfy these constraints.

Let  $D$  be the downward closure of  $y$  under finite  $P$ -paths, including  $y$ . It is a set, contained in  $\{y\}$  and the vertices of the earlier scan. Since  $T$  satisfies  $P$  and  $yTx$ , one has  $x \notin D$ . Move  $D$  to the front of  $R$ , preserving the old order within  $D$  and within its complement. The resulting relation  $R'$  is a well-order. It satisfies every earlier constraint because  $D$  is  $P$ -downward closed. It puts  $y$  before  $x$ , so its first changed table bit is smaller, a contradiction. If  $R$  was set-like,  $R'$  is still set-like: new predecessor classes are contained in an old predecessor set together with  $D$ . The proof for a maximum moves the appropriate opposite endpoint at the first larger bit. The reverse implications are immediate.  $\square$

**Corollary 38.3** (Exactly three possible endpoint patterns). *On an infinite carrier, table lexicography of well-orders has at most one endpoint. By choosing the scan, each of the following can occur: a minimum only, a maximum only, or neither. The same patterns occur for set-like class well-orders of **No**.*

*Proof.* Reversing a linear order complements all off-diagonal bits, so it reverses the table comparison. If a minimum and maximum well-order both existed, [Theorem 38.2](#) would make them endpoints among all linear orders, and hence reversals of one another. An order and its reversal cannot both be well-orders on an infinite carrier: the first  $\omega$  points of one form a descending sequence in the other.

For any given linear order  $T$ , scan each unordered pair in a two-entry block, putting its  $T$ -false direction first and its  $T$ -true direction second. Scan the blocks set-likely. Then  $T$  is the least linear-order table: a different order changes the first entry of its earliest changed block from 0 to 1. Reversing the two entries makes  $T$  greatest. Take  $T$  to be a well-order for the one-endpoint cases, and a linear order such that neither it nor its reverse is well-founded for the no-endpoint case. Such an order exists on every infinite carrier; on **No** its native order suffices. Endpoint transfer finishes the argument.  $\square$

A scan built around a non-set-like  $R$  makes  $R$  the minimum among all well-orders but leaves no minimum among set-like well-orders. The greatest linear-order table is then  $R^{\text{op}}$ , not a well-order, so the set-like subcollection has neither endpoint. Therefore a relation table may erase the natural numerical comparison while retaining or losing particular well-order types according to the chosen scan.

**Example 38.4** (Failure of a numerical pair scan). On the integer labels, compare the enumerations

$$0, -1, 1, -2, 2, -3, 3, \dots, \quad 0, 1, -1, 2, -2, 3, -3, \dots,$$

then append the same set-like enumeration of the remaining surreals. The resulting set-like orders disagree on the directed pairs  $(-n, n)$  and  $(n, -n)$ ,  $n \geq 1$ . Their numerical-lexicographic disagreement set in **No**<sup>2</sup> has no least pair, because its first coordinates include arbitrarily negative integers. A genuine well-ordered scan avoids this problem; the numerical order alone does not.

### 38.4 Restrictions, extensions, and relabelling

Restriction to a smaller carrier can reverse enumeration lexicography:  $021 < 102$  on  $0 < 1 < 2$ , but on  $\{1, 2\}$  the restrictions are  $21 > 12$ . The obstruction is stronger than a bad choice of lexicographic convention.

**Theorem 38.5** (No total linearization respects every restriction). *There is no total order on the six well-orders of a three-element carrier making all three restrictions to two-element carriers monotone, no matter which of the two orders is chosen on each two-element well-order space.*

*Proof.* Encode each pair restriction by 0 or 1 according to its chosen order. The three restrictions determine the original relation, so the six well-orders map injectively to  $\{0, 1\}^3$ . If all restrictions were monotone, the six objects in increasing order would give a coordinatewise increasing chain of six distinct Boolean vectors. Every strict step raises the sum of the coordinates, whose possible values are 0, 1, 2, 3. Such a chain has at most four points, a contradiction.  $\square$

Thus arbitrary restrictions do not form a monotone system automatically. The theorem does not rule out a carefully chosen nested filtration or restricted family. In the other direction, fixing a well-order  $Q$  of  $X \setminus Y$  makes  $R \mapsto R + Q$  an order embedding from the native well-order space of  $Y$  into that of  $X$ . First disagreement occurs before the fixed tail. Prepending a common labelled prefix works as well.

No linearization can be invariant under every relabelling of a carrier with at least two labels. A transposition acts as a nontrivial involution on its well-orders, since well-orders are rigid. But an increasing involution of a linear order must be the identity:  $x < f(x)$  would imply  $f(x) < f(f(x)) = x$ . Some auxiliary label structure is indispensable. Increasing automorphisms of the numerical surreal line preserve native enumeration lex; a table scan or baseline must instead be transported along with the labels.

### 38.5 The quotient by order isomorphism is a new construction

On the numerical carrier  $\mathbb{N}$ , let

$$R = (0, 1, 2, \dots), \quad S = (1, 2, 3, \dots, 0), \quad T = (2, 0, 1, 3, 4, \dots).$$

Their types are  $\omega, \omega + 1, \omega$ , respectively, and their first labels give  $R < S < T$ . Thus the equivalence class of type  $\omega$  is not convex. A linear-order quotient requires convex classes, so labelled lexicography does not descend to abstract order types.

One may separately order the possible set types by ordinal comparison. For  $|X| = \mu$  infinite they are precisely  $\mu \leq \alpha < \mu^+$ ; in that comparison their order type is  $\mu^+$ . The original labelled order embeds no ordinal  $\mu^+$ , by [Note 32.3](#). This is a particularly sharp sign that the quotient-type order is a different object. For set-like well-orders of all **No**, quotienting by class-order isomorphism collapses everything to the one type **Ord**. Arbitrary non-set-like class types require their own collection and comparison framework; raw labelled lexicography provides neither automatically.

### 38.6 Numerically well-ordered subsets and a normal-form embedding

Let  $A, B \subseteq \mathbf{No}$  be sets or classes well-ordered by the inherited numerical order. Their union is well-ordered: a nonempty subclass has its least member among the minima of its intersections with  $A$  and  $B$ . Consequently  $\min(A \triangle B)$  exists whenever  $A \neq B$ . This makes an intrinsic characteristic comparison possible without a global scan of the entire numerical line:

$$A <_{\chi} B \iff \min(A \triangle B) \in A.$$

It uses membership bits with  $1 < 0$ . Transitivity is first-difference transitivity on the well-ordered union of three carriers. For increasing enumerations it agrees with numerical first difference and *longer prefixes first*. The empty carrier is greatest. The shorter-first convention agrees on genuine unequal next labels but reverses proper-prefix pairs and makes the empty carrier least.

**Proposition 38.6** (Coefficient-one normal forms realize set supports). *For a set-sized naturally well-ordered subset  $A \subseteq \mathbf{No}$ , the map*

$$H(A) = - \sum_{a \in A} \omega^{-a}$$

*is a well-defined surreal, and  $A <_{\chi} B$  if and only if  $H(A) < H(B)$ .*

*Proof.* The exponent support  $\{-a : a \in A\}$  is reverse well-ordered and is a set, so the displayed Conway normal form is legitimate. At the least  $a$  in the symmetric difference, the largest differing exponent is  $-a$ . The set containing  $a$  has coefficient  $-1$  there rather than  $0$ , and therefore gives the smaller surreal. Uniqueness of normal form gives injectivity [11, 12].  $\square$

This particular construction does not admit proper-class support: the normal form of one surreal has set support. Naturally well-ordered proper subclasses nevertheless exist with every class well-order type by surreal universality. For example

$$\left\{ -\frac{1}{\alpha + 1} : \alpha \in \text{Ord} \right\} \cup \{0\}$$

has natural type  $\text{Ord} + 1$ . Its final point has a proper class of earlier points. The reciprocal and addition in this example are surreal operations on the embedded ordinal labels.

At a set limit-length increasing word, shorter-first order makes the word the supremum of its proper prefixes; longer-first order makes it their infimum. The associated one-sided cofinality is the cofinality of the length. These features expose the termination convention in the order itself, even when both conventions admit embeddings into  $\mathbf{No}$ .

### 38.7 Birthday and simplicity do not secretly provide a scan

Simplicity, interpreted as initial sign-sequence extension, is a partial tree order. The one-sign strings  $+$  and  $-$  are incomparable by it. Numerical sign comparison instead uses the middle termination symbol  $- < \text{undefined} < +$  and gives the surreal line, not a well-order.

Even birthday-first ordering with numerical tie-breaking fails. The strings

$$s_n = -^n \frown +^\omega \quad (n < \omega)$$

all have birthday  $\omega$ , since  $n + \omega = \omega$ , and satisfy  $s_{n+1} < s_n$ . Thus the birthday- $\omega$  level already contains a descending sequence under numerical tie-breaking. A genuine birthday-compatible global well-order requires well-ordering each level with additional coherent choice data. That choice must be stated; it is not supplied by birthdays or simplicity alone.

*Note 38.7* ([merge]; repository counterparts of source 15's Section 10). Relation-table lexicography is source 08's relation-code order ([proposition 17.1](#): equimorphic with  $\mathbb{B}_{\text{Ord}}$  for every coordinate enumeration) and source 12's remark with its three-point check ([section 18](#)). New in source 15 are the endpoint transfer ([theorem 38.2](#)) and the three endpoint patterns ([corollary 38.3](#)), which show that the endpoints of a relation-code order are artifacts of the scan; inverse-rank lexicography ([theorem 38.1](#)); the restriction theorem ([theorem 38.5](#)); and the normal-form embedding ([proposition 38.6](#)). The birthday tie-break example is source 12's ("Birthday is not a canonical global well-order", after [theorem 13.2](#)), and source 18 repeats it ([section 38.8](#)). The non-convexity of type classes is made by sources 13, 14, 16 and 17 in their maps ([section 34](#)).

### 38.8 Relation-code remarks of sources 13, 14 and 18

[merge] Three further remarks on relation codes, each printed whole: source 13's (from its foundations section), source 14's (from its Section 11) and source 18's (from its section on global well-orders). Source 16's is in its map (section 34.4), source 17's in its map (section 34.5). They make one point, that relation-code lexicography depends on the scan and the bit convention and is not enumeration lexicography; they prove no theorem about it beyond proposition 17.1 and section 38.

#### 38.8.1 Source 13: relation-bit lexicography is a different order

Fix a set-like global enumeration of the ordered pairs of surreal labels. Read the characteristic bits of a raw relation in this order and compare at the first different bit. This is a legitimate code-dependent class lexicography. It is not in general the labeled common-prefix comparison of theorem 14.2: the first edge in a chosen code order need not reveal the first disagreement of the enumerated labels.

The preceding report analyzes this relation-code alternative and its binary-word equimorphism (proposition 17.1; Section 17 of this report at the pin). A choice of pair enumeration is indispensable. Replacing the label order by birthday order or comparing raw Conway construction trees would impose still other auxiliary data. Such choices can be studied rigorously, but no one of them should be advertised as *the* lexicographic order without identifying the coding convention.

#### 38.8.2 Source 14: relation-code lexicography really is another order

One may instead fix a class bijection scheduling  $\mathbf{No} \times \mathbf{No}$  by  $\mathbf{Ord}$ , and compare characteristic functions of well-order relations at their first differing scheduled pair. This defines a linear comparison on the admitted relations but depends on the schedule and on the convention  $0 < 1$ .

The difference is visible with three labels. Let numerical order be  $0 < 1 < 2$ , and let the enumerations be  $e = (0, 1, 2)$  and  $f = (1, 0, 2)$ . Enumeration lex gives  $e < f$ . If the relation-coordinate schedule begins with  $(0, 1)$ , their strict-relation bits there are 1 and 0, so the relation-code comparison gives  $e > f$ . Starting instead with  $(1, 0)$  reverses those bits and that conclusion. This counterexample does not involve any proper-class complication. Results proved for numerical first-disagreement order cannot simply be transported to relation codes.

#### 38.8.3 Source 18: inherited numerical well-orders and relation codes

Numerical  $<$  on  $\mathbf{No}$  is not a well-order; the negative integers already descend. Nevertheless, many subclasses are numerically well-ordered. The ordinals give type  $\mathbf{Ord}$ , and

$$\{-1/(\alpha + 1) : \alpha \in \mathbf{Ord}\} \cup \{0\}$$

has numerical order type  $\mathbf{Ord} + 1$ . Under Global Choice, class universality gives a numerically ordered copy of every supplied class well-order. This concerns the range of an embedding in the surreal line, not a well-order of every surreal label.

One can instead order well-order *relations* by characteristic bits. Choose a set-like class enumeration of  $X \times X$ , and compare the bits of two relations at their first unequal pair. The resulting comparison is well-defined, but is a different auxiliary order. Even on  $\{0, 1\}$  the enumerations  $(0, 1) < (1, 0)$  compare in the opposite direction if the first tested pair is  $(0, 1)$  and  $0 < 1$  for relation bits. The enumeration rule tests first labels, while the relation rule tests a chosen predicate membership. Its dependence on the chosen pair order should be recorded explicitly.

Finally, ordering birthday first and then ordering sign expansions lexicographically does not produce a global well-order. The fixed birthday- $\omega$  slice already contains descending sequences. A genuine birthday-first global well-order must use an auxiliary well-order within each birthday level, not its numerical sign order.

### 39 What this Part answers

[merge] Dated notes, 3 October 2026, in the form of [section 33](#); where the question index of [section 113](#) (dated 2 October 2026) says otherwise, these notes supersede it.

- (a) *Source 09's direction "Other termination conventions for set words"* ([section 113.3](#)): **answered** for unrestricted and injective words. Exactly the placements of a formal terminator satisfying the three conditions of [theorem 36.1](#) give the set-cut property, hence (in GBC) an order isomorphic to **No**; every placement gives one of the types of [theorem 36.2](#); the distinguished internal value is [theorems 36.4](#) and [36.6](#), and the prefix-free codes are listed in [note 36.3](#). For increasing words with the terminator at zero see (b).
- (b) *Source 08's question 14, increasing-subset and alternate-termination orders* ([section 113.4](#)): **answered** for prefix-small, prefix-large and centered conventions on unrestricted and injective words ([theorems 36.1](#) and [36.2](#)), for shorter-first increasing words (isomorphic to the other two classes in GBC, [theorem 35.1](#)), and for centered increasing words up to their isomorphism type: local characters, all set-cut obstructions, equimorphism without isomorphism ([theorems 37.1](#) and [37.2](#) and [corollary 37.3](#)). Open: the isomorphism type of the centered increasing order (source 18's own question) and increasing words with an interior terminator at a threshold other than zero.
- (c) *Source 13's question "A classification of termination cuts"* (for a class alphabet isomorphic to **No**): answered by source 16 ([theorems 36.1](#) and [36.2](#)), transported along an isomorphism of the alphabet with **No** in GBC.
- (d) *Source 16's question "Centered increasing words"*: answered by source 18 for the threshold at zero (with zero excluded, padded, or adjacent to a distinct terminator: [section 37](#)); open for other interior thresholds.
- (e) *Source 08's question 9 and source 09's direction "Non-set-like well-order relations"* (relation-code orders; [sections 113.3](#) and [113.4](#)): answered in part. Which endpoints a relation-code order of well-orders has is an artifact of the scan: a minimum only, a maximum only, or neither, each by a suitable scan, and never both on an infinite carrier ([theorem 38.2](#) and [corollary 38.3](#)). The isomorphism question for two scans stays open.
- (f) *Source 11's question on optimal birthday bounds* ([research question 113.6](#)): not answered. Sources 13, 14, 16, 17 and 18 give explicit codes with birthdays  $\sum(2 \cdot \text{bd} + 2)$ ,  $\sum(4 \cdot \text{bd} + 4) + 2$  and  $\sum(1 + 2 \cdot \text{bd} + 2)$  ([note 36.3](#)); none is claimed optimal.

Sources 16 and 18 also ask how much of the word isomorphisms survives without a global well-order; source 18's proof ([section 35.5](#)) shows that one set-like global well-order suffices as a parameter, so the question is whether that parameter can be removed. It is open.

[merge] Dated note, 3 October 2026 (batch 83). Items (b), (d) and (e) are answered in part by Part XII: the centered increasing order is  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ , no marker saturates increasing words, and two scans of one carrier can give different orders with the same spectrum, while a dense set-coded core exists for every set-like scan ([section 85](#); [section 113.25](#) (j), (k)).

## Part VIII

# Cuts of the set-coded core: recognition, automorphisms, support and class realizations

[merge] (3 October 2026.) The third Part of the batch-81 addition ([section 1.8](#); notation in [section 1.3.1](#)). Part IV ([part IV](#)) built the core, the ordinary class of set codes for bounded-support perturbations of one baseline enumeration  $b$ , proved that it interpolates every uniformly set-indexed cut, and asked which of its class cuts come from global enumerations ([research question 113.1](#); source 09’s third direction in [section 113.3](#)). All six batch-81 sources answer that question, by one argument. This Part prints the answer and what the sources prove around it: source 14’s foundations for the class-level results ([section 40](#)); the core and its cylinders ([section 41](#)), with the five other sources’ re-proofs of Part IV ([section 42](#)); the classification of every proper class cut of the core into a cylinder edge, a numerical gap or a branch ([section 43](#)) and its characters ([section 44](#)); the recognition of the cuts of global enumerations ([section 45](#)) and the five further proofs of it ([section 46](#)); automorphisms of the core ([section 47](#)); class extensions ([section 48](#)); and support-restricted suborders and the exact reserve of a partial injection ([section 49](#)). [Section 50](#) records which questions the Part answers.

The base is source 14 throughout, by generality: it alone classifies *every* proper class cut with unique data, gives the complete orbit invariant, the absoluteness theorem and the support hierarchy. Source 17 is the base for the exact reserve cardinal, the automorphism extension criterion and the clause that every proper class extension adds a represented cut; source 15 adds the finest first-failure partition (a forbidden repeated label) and source 13 the non-rigidity of the cylinder family. The represented-cut theorem itself is printed once as source 14’s [theorems 43.3](#) and [45.1](#), and the other five proofs follow as routes, each whole, because each source builds different examples and corollaries on its own proof ([note 46.1](#)). Source 18 was written before sources 13–17 arrived.

Notation ([section 1.3.1](#)): the core is printed  $\mathcal{P}_s(b)$  in the support coding of sources 13, 14, 17 and 18 (their  $\mathcal{D}$ ,  $\mathcal{P}_b$ ,  $\mathcal{C}_b$ ,  $\mathcal{C}_b$ ; source 18’s macro  $\backslash\text{Pbd}$ ), and  $\mathcal{P}_{bd}(b)$  in the normalized-permutation coding of sources 15 and 16 (their  $\mathcal{D}$  and  $\mathcal{P}_b$ ); the two codings have the same evaluations. Cylinders of codes are printed  $\mathcal{C}_p$  (source 13’s  $\mathcal{D}_p$  is printed  $\mathcal{P}_s(b)_p$ , source 17’s  $\mathcal{C}_p$  and source 18’s  $\mathcal{C}_b(p)$  are printed  $\mathcal{C}_p$ ). Source 14’s  $\mathfrak{E}$ ,  $\mathfrak{J}$ ,  $\mathfrak{W}$  are printed  $\mathfrak{W}_{sl}$ ,  $\mathfrak{J}$ ,  $\mathfrak{W}_{all}$ , its relation macro  $\backslash\text{lex}$  as  $<_{lex}$ ; in its support section its  $\tau = \text{cf } \kappa$  is printed  $r$ , its decreasing sequence  $(r_i)$  is printed  $(u_i)$ , and the generic regular cardinal of its definition of  $\eta_\tau$ -orders is printed  $\theta$ . A cylinder meeting both sides of a cut *crosses* it in sources 13, 14 and 15 (source 15 also calls such cuts *persistent*) and *straddles* it in sources 16, 17 and 18; the two words mean the same. All six use  $\text{Ord}$  as a character symbol for “a uniform  $\text{Ord}$ -indexed cofinal family exists and no set-sized one does”, never as a cardinal. Labels written for the merge in this Part begin `swo:viii:`.

## 40 Foundations and the audited starting point (source 14)

### 40.1 Sets, classes, and uniform families

We use sign sequences as canonical set representatives of surreals. Each surreal has a set ordinal birthday. This avoids treating a proper class of equivalent game forms as an individual set.

In GBC, a class  $E \subseteq \text{Ord} \times \mathbf{No}$  may be the graph of a global enumeration. It cannot then be an element of a set or an ordinary class. Expressions such as

$$E \in \mathfrak{W}_{sl} = \text{Bij}(\text{Ord}, \mathbf{No})$$

are convenient predicate notation. They mean that the class variable  $E$  satisfies the indicated formula. They are not membership assertions in a powerclass object. The same convention applies to the virtual collection  $\mathfrak{C}(\mathcal{P}_s(b))$  of class cuts.

A uniformly set-indexed family  $(E_i)_{i \in I}$  is one class relation  $U \subseteq I \times \text{Ord} \times \mathbf{No}$  whose  $i$ -th section is  $E_i$ , with  $I$  a set. Replacement with the parameter  $U$  produces a set of first disagreement ordinals or a set of evaluated prefix values. Merely writing “a set of proper-class functions” does not provide such a family.

A class well-order is a class linear order for which every nonempty subclass has a least member. Under the choice assumptions used here, the standard set-subset well-foundedness formulation is equivalent; see [27, Section 3]. Internal well-foundedness in an arbitrary model is not asserted to be external well-foundedness.

## 40.2 Why a baseline is an assumption, not a notation

Global Choice supplies a set-like class well-order and hence a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . Conversely, the predecessor report proves over GB without even assuming set Choice that a class well-order of the sign-sequence surreals implies Global Choice (theorem 13.1; Section 13 of this report at the pin). The proof uniformly well-orders the power sets  $V_{\beta+1}$  ([merge] the delivered text says “coherently”; the orders need not extend one another, as corrected in this report on 3 October 2026, commit 0f52c0dca, after source 14’s pin) and constructs rank-by-rank presentations; it is stronger than the observation that each already well-orderable set embeds into  $\mathbf{No}$ . We use that reported equivalence as background, rather than claim to re-prove its choiceless direction here.

There is no paradox in using  $\text{Ord}$  as the domain of  $b$ : it is a proper class domain. There would be a paradox in calling it a set ordinal or applying a set power-set operation to it inside the same universe.

## 40.3 Elementary comprehension versus class-valued recursion

The new constructions use formulas with set quantifiers and previously given class parameters. For example, “a set prefix has a core completion on each side of this cut” quantifies over set codes, not over classes. The union of all such coherent prefixes is consequently an ordinary class obtained by elementary comprehension.

Set-valued recursion of length  $\text{Ord}$  with set histories at each stage can be implemented by coherent set-length recursions in GBC. This must not be conflated with recursions that choose an entire class at each stage, or with recursions along arbitrary non-set-like class well-orders. The literature proves that ETR implies abstract class-well-order comparability [27, Theorem 6]; our labelled comparison and prefix reconstruction are different operations and do not invoke that implication in reverse.

## 40.4 Repository audit and status of the inputs

The inspected report lives at

```
Algebra/SurrealNumbers/docs/foundations-and-computation/surreal-well-orders/article.tex.
```

Its README records a 115-page merged report, four source manuscripts, and a pending collection-level review; it explicitly says the report is not formalized (its README at the pin; [merge] the page count and the number of sources have grown with this addition, and the report is still not formalized). We inspected the introduction, set-supported and binary-coding sections, universe

discussion, and research questions relevant to the present work. This is a targeted audit, not a certification of the entire repository.

We also inspected the actual Lean file

Algebra/SurrealNumbers/Surreal/Foundations/SignSequenceSimplicity.lean.

It proves uniqueness and prefix properties of simplest separators *assuming existence*. In particular, `existsUnique_simplest_separator` takes an existence hypothesis. It is not a theorem supplying all small-cut separators by itself [10]. This distinction matters for the proposed formalization. [merge] The pinned tree already supplies the existence half and composes the two: `small_cut_fillers` in `SignSequenceCut.lean` [8] proves that small cuts have fillers, and `cut` in `SignSequenceCutOperation.lean` [9] is defined from `existsUnique_simplest_separator` applied to it (section 1.5). Source 14’s recommendation to compose them is therefore already carried out.

The present main theorems have written proofs below. Their novelty claim is only that they extend the inspected predecessor results; historical priority has not been established by the literature check.

## 41 The set-coded skeleton and its cylinders (source 14)

For the remainder of the class-level development we work in GBC and fix a class bijection  $b : \mathbf{Ord} \rightarrow \mathbf{No}$ . All occurrences of a class parameter mean a class belonging to the chosen class realization.

### 41.1 Canonical support codes

A *support code* is a set bijection  $\sigma : S \rightarrow S$  with no fixed points, where  $S$  is a set of ordinals. The empty code is permitted. Extend it by the identity to a class permutation  $\hat{\sigma}$  of  $\mathbf{Ord}$ , and set

$$E_\sigma = b \circ \hat{\sigma}, \quad \text{supp}(\sigma) = S.$$

Let  $\mathcal{P}_s(b)$  be the ordinary class of these codes, ordered by  $\sigma < \tau$  if  $E_\sigma <_{\text{lex}} E_\tau$ . The codes are canonical: two of them have the same extension exactly when they are equal. Every class permutation with set support is represented, because its support is invariant under the permutation and its restriction has no fixed points. A set of ordinals is bounded, so “set support” and “bounded support” are equivalent here. This does not mean finite support.

Let  $\mathfrak{W}_{\text{sl}}$  stand for the virtual collection of class bijections  $\mathbf{Ord} \rightarrow \mathbf{No}$ , and  $\mathfrak{J}$  for that of class injections. A statement quantifying over  $\mathfrak{W}_{\text{sl}}$  or  $\mathfrak{J}$  is a statement with class variables; these symbols do not name additional class objects. Two distinct members of  $\mathfrak{J}$  have a least differing ordinal. Their common initial segment has set length, so first-difference comparison is unambiguous.

**Lemma 41.1** (Fresh separators). *If  $A, B, U$  are sets of surreals and  $A < B$ , there is a surreal  $x \notin U$  such that  $A < x < B$ . Consequently  $\mathbf{No} \setminus U$  has no endpoints and fills all cuts specified by sets of its elements.*

*Proof.* The ordinary surreal set-cut theorem supplies a separator ([15]; lemma 5.2). In fact there are more than  $|U|$  separators: recursively for  $|U|^+$  many steps choose a separator above the earlier choices and  $A$ , and below  $B$ . Every stage uses set options, and the resulting choices are distinct. At least one is outside  $U$ . The same argument permits either option set to be empty. This uses set recursion and the usual surreal cut existence theorem, not a purported cut with proper-class options.  $\square$

**Lemma 41.2** (Completion of a set prefix). *Every injective set word  $p : \lambda \rightarrow \mathbf{No}$  extends to some  $E_\sigma$  with  $\sigma \in \mathcal{P}_s(b)$ .*

*Proof.* Choose an infinite initial cardinal  $\nu$  strictly greater than  $\lambda$  and all the ordinals in  $b^{-1}[\text{ran } p]$ . The map  $\alpha \mapsto b^{-1}(p(\alpha))$  is a partial injection from  $\nu$  to itself with domain of cardinality  $< \nu$  and equally small range. Both complements have cardinality  $\nu$ . Choose a bijection between them to extend the partial map to a permutation of  $\nu$ , and fix every ordinal outside  $\nu$ . Restricting the resulting permutation to its moved points gives the required canonical code.  $\square$

**Definition 41.3** (Cylinder and residual alphabet). For an injective set prefix  $p : \lambda \rightarrow \mathbf{No}$ , put

$$C_p = \{\sigma \in \mathcal{P}_s(b) : E_\sigma \upharpoonright \lambda = p\}, \quad A_p = \mathbf{No} \setminus \text{ran } p.$$

The empty prefix has cylinder  $C_\emptyset = \mathcal{P}_s(b)$ .

**Proposition 41.4** (Cylinder geometry). *Every  $C_p$  is a nonempty convex proper class. It has neither an endpoint nor a set-sized cofinal or cointial subset. Its immediate subdivisions are*

$$C_p = \bigcup_{x \in A_p} C_{p \smallfrown (x)},$$

*in increasing order of  $x$ . The union is an elementary class statement, not a set-indexed union. Cylinders of two prefixes are either nested or disjoint and strictly ordered.*

*Proof.* Completion proves nonemptiness. If a word between two extensions of  $p$  first differed from  $p$  before  $\lambda$ , it would lie on the same side of both extensions, proving convexity. The child cylinders partition  $C_p$  by the value at coordinate  $\lambda$ , and first difference puts them in numerical order. [Lemma 41.1](#) and completion give a child below or above any specified set of child labels. Thus a set of members of  $C_p$  is neither cofinal nor cointial: take their next labels, choose a fresh label above or below all of them, and complete. In particular  $C_p$  cannot itself be a set. Finally, incomparable prefixes first differ at a set coordinate, which orders their entire cylinders; comparable prefixes give nested cylinders.  $\square$

**Lemma 41.5** (Density around injective branches). *If  $F, G \in \mathfrak{J}$  and  $F <_{\text{lex}} G$ , there is a code  $\sigma \in \mathcal{P}_s(b)$  with  $F <_{\text{lex}} E_\sigma <_{\text{lex}} G$ . For every  $F \in \mathfrak{J}$  and every set ordinal  $\alpha$ , there are codes below and above  $F$  agreeing with  $F$  before  $\alpha$  and differing from it at  $\alpha$ .*

*Proof.* For the first assertion use the first disagreement  $\delta$ , choose  $x$  strictly between  $F(\delta)$  and  $G(\delta)$  outside their common prefix range, and complete  $(F \upharpoonright \delta) \smallfrown (x)$ . For the second, choose fresh values below and above  $F(\alpha)$  and complete the two prefixes. A fixed global well-order of set codes makes all these choices uniform when a uniform family is needed.  $\square$

These elementary cylinder facts, rather than a powerclass completion, are the main engine of the next result. The predecessor proves the stronger statement that  $\mathcal{P}_s(b)$  interpolates every uniformly set-indexed strict cut of  $\mathfrak{W}_{\text{sl}}$  ([theorem 19.10](#); Section 19 of this report at the pin). We will also recover the ordinary set-cut property of  $\mathcal{P}_s(b)$  from our cut classification and its character calculation.

*Note 41.6* ([merge]; Part IV counterparts of source 14's Section 4). Source 14's support codes are source 09's coding  $\mathcal{P}_s(b)$  ([section 1.3](#)); its [lemma 41.1](#) is [lemma 5.2](#), its [lemma 41.2](#) is [lemma 19.4](#) with the cardinality check of [remark 19.7](#), its [proposition 41.4](#) is the code-level form of [proposition 19.25](#) (sources 11 and 09), and the two-sided approximants of [lemma 41.5](#) are those of [proposition 19.27](#).

Source 14 credits the interpolation theorem (theorem 19.10) and does not re-prove it; the elementary cylinder facts are what its classification uses. The class  $T_D$  of crossing prefixes of a cut, defined in the next section, is the class-scale form of the reals report's cut spine (`lwo:sp:lem:cutspine`, for  $\mathcal{W}(\mathbb{R})$ ); source 14 does not cite it.

## 42 The core as re-proved in sources 13, 15, 16, 17 and 18

[merge] Each of the other five sources re-proves the core layer of Part IV before its recognition theorem, and each credits it to this report. Their sections are printed here whole, in source order, as re-proofs of the following results of Part IV; none is new against the repository.

- *Fresh separators*: lemma 5.2 (source 13's lemma 42.1, source 17's lemma 42.12).
- *Class universality, uniqueness and uniform complements*  $h_S : \mathbf{No} \cong \mathbf{No} \setminus S$ : proposition 5.13 and theorem 5.17 (source 13's lemma 42.2, source 17's corollary 42.15). Source 16's termination section (section 36) uses the same family  $h_S$ .
- *Prefix completion*: lemma 19.4 with remark 19.7 (lemmas 42.3, 42.8, 42.9 and 42.17; source 17 obtains it from its reserve theorem, corollary 49.10).
- *Interpolation and the core isomorphic to  $\mathbf{No}$* : theorem 19.10 and corollary 19.15 (theorems 42.4, 42.10, 42.13 and 42.18 and corollaries 42.5, 42.11 and 42.14; source 15 cites them).
- *Approximants at a branch*: proposition 19.27 (lemma 42.6).
- *The diagonal theorem*: theorems 19.37 and 19.38 (theorems 42.7, 42.16 and 42.19).
- *Canonical first block and residual fibres* of a raw order: theorem 15.1, proposition 15.3, and remark 15.4 (source 16's Subsection 11.1 below, with displays (S16.12) and (S16.13)).
- *Global choice is an assumption*: theorem 13.1 (end of source 13's Section 3).

The proofs differ only in bookkeeping. Sources 13, 15, 16 and 18 complete a prefix inside an infinite initial cardinal, as Part IV does; source 17 completes it with the least possible reserve (section 49). Source 13's warning after lemma 42.3 is the point of remark 19.7. Source 16's Subsection 11.1 refers to its block decomposition, printed in Part IX (section 52.2); source 17's Section 8 and source 18's Section 14 are printed together with their remarks on what density does not give.

### 42.1 Source 13: surreal cuts and the size of the universe

#### 42.1.1 Signs, birthdays, and small cut filling

We use the sign-sequence presentation of the surreal numbers. A surreal  $x$  is a sequence of signs  $-$  and  $+$  indexed by a set ordinal  $\text{bd}(x)$ . Extend the sequence by 0 after its domain; comparison is at the first unequal coordinate using  $- < 0 < +$ . Here 0 in the sign alphabet is a termination value, not an extra sign before the birthday. This is also the representation used by the inspected Lean carrier [7]. General context for the universal ordered-continuum viewpoint is given in [15].

For sets  $A, B \subseteq \mathbf{No}$  with  $A < B$ , a surreal lies strictly between them. More precisely, if an ordinal  $\gamma$  strictly exceeds all their birthdays, there is such a separator of birthday exactly  $\gamma$ . The stronger statement is implemented at the source level by `exists_cut_separator_of_birthday_lt` [8]. We use it in the following form.

**Lemma 42.1** (Fresh set-cut separator). *Let  $A, B, S$  be sets of surreals and suppose  $A < B$ . There is an  $x \notin S$  with  $A < x < B$ . Empty sides are allowed.*

*Proof.* Choose  $\gamma$  strictly larger than every birthday occurring in  $A \cup B \cup S$ . A separator of birthday  $\gamma$  cannot belong to  $S$ .  $\square$

The adjective “set” cannot be removed. There is no surreal above every ordinal: any surreal is smaller than a sufficiently long all-plus sign sequence. Likewise, a proper-class sign sequence is not another surreal at a larger birthday.

#### 42.1.2 Set-cut orders and class back-and-forth

Call an ordinary class linear order *set-cut saturated* when every pair of sets  $A < B$  has a strict interpolant, including when a side is empty. This is sometimes expressed by an  $\eta_{\text{Ord}}$  terminology; we use the explicit condition rather than assigning a set cardinal to it.

**Lemma 42.2** (Class universality and uniqueness in GBC). *Every ordinary class linear order embeds into  $\mathbf{No}$ . Any two nonempty set-cut saturated ordinary class orders are order-isomorphic. In particular, for every set  $S \subseteq \mathbf{No}$ ,*

$$\mathbf{No} \setminus S \cong \mathbf{No}.$$

*The complement isomorphisms can be chosen as a single uniform class family  $h_S : \mathbf{No} \rightarrow \mathbf{No} \setminus S$ , indexed by sets  $S$ .*

*Proof.* Global choice supplies a set-like enumeration of any proper class of sets; for a set carrier use a set well-order. At a stage of the usual order-embedding recursion, the images already chosen form a set. Their lower and upper parts determine a set cut in  $\mathbf{No}$ , and a fresh interpolant gives the next image. The recursion has a set partial map at each set-ordinal stage.

For uniqueness, alternate the two enumerations. A forth step puts the next unused source point into the target cut determined by the current partial isomorphism; a back step does the same for the inverse. Strict interpolation keeps each map injective. Every point on both sides is visited, so the union is an isomorphism. A set-cut saturated nonempty order cannot be a set, since using all its points as a lower side would require a point above itself.

[Lemma 42.1](#) says that  $\mathbf{No} \setminus S$  has the same set-cut property. To make its isomorphism uniform, fix the global well-order and always choose its least eligible witness. For each set parameter  $S$  and each set stage, the partial history is a set satisfying a fixed recursive specification. Its existence and uniqueness are established by set-length recursion. Elementary class comprehension, quantifying over such set histories, gives one relation  $h(S, x, y)$ . No choice of a class witness for each  $S$  is being assumed.  $\square$

This is not an appeal to elementary transfinite recursion with *class-valued* stages. Our stages are sets, even though their total union is a class. Keeping that distinction explicit will matter in [source 13's](#) sections on asymmetric products and on foundational interpretations ([\[merge\]](#) its Sections 10 and 13, printed in Part IX as [sections 55](#) and [57.3](#)).

#### 42.1.3 Global choice is a real assumption

The earlier report proves, over GB without set choice, that the existence of a class well-order of  $\mathbf{No}$  is equivalent to global choice ([theorem 13.1](#); Theorem 13.1 at the pin). Thus a global enumeration is not a choice-free consequence of the numerical order of surreals. We work in GBC for the main global constructions and fix a baseline bijection

$$b : \text{Ord} \xrightarrow{\sim} \mathbf{No}.$$

The particular  $b$  affects the chosen dense core but not the definition of the full enumeration comparison.

## 42.2 Source 13: the global enumeration order and its dense core

### 42.2.1 Uniformity and the code carrier

Let  $\mathfrak{J}$  denote the virtual domain of injective class functions  $F : \text{Ord} \rightarrow \mathbf{No}$ , and let  $\mathfrak{W}_{sl} \subseteq \mathfrak{J}$  require surjectivity. Their lexicographic comparison is at the least disagreement ordinal. A nonempty class of ordinals has a least member: find one member and take the least member below it. Thus this comparison is elementary in its class parameters.

A *uniformly set-indexed family*  $(F_i)_{i \in I}$  means a set  $I$  and a single class relation coding all values  $F_i(\alpha)$ . A phrase such as “choose a class  $F_i$  for each  $i$ ” is not a substitute for this uniform family. We consistently use the latter.

Fix  $b : \text{Ord} \simeq \mathbf{No}$ . A set-supported permutation  $\sigma$  of  $\text{Ord}$  is the identity except on a set of ordinals. Code it by the set graph of its moved points, omitting all fixed points. Such normalized codes form an ordinary class  $\mathcal{P}_s(b)$ , and a code  $d$  evaluates to

$$E_d = b \circ \widehat{d}.$$

Equivalently, a code is a set bijection  $d : S \rightarrow S$ , where  $S$  is a set of ordinals and  $d(\xi) \neq \xi$  for every  $\xi \in S$ ; the empty code is allowed. This is an elementary condition on sets, so defining  $\mathcal{P}_s(b)$  does not require quantification over a collection of class permutations. Different normalized codes have different evaluations. Order  $\mathcal{P}_s(b)$  by these evaluations. The support of each code is bounded by a set ordinal, but there is no common set bound for all codes.

For an injective set word  $p$ , define

$$C_p = \{E \in \mathfrak{W}_{sl} : E \upharpoonright \text{dom}(p) = p\}, \quad \mathcal{P}_s(b)_p = \{d \in \mathcal{P}_s(b) : E_d \upharpoonright \text{dom}(p) = p\}.$$

$C_p$  is virtual notation;  $\mathcal{P}_s(b)_p$  is an ordinary class of set codes. Both are convex in their respective orders.

### 42.2.2 Completion with the missing cardinality check

**Lemma 42.3** (Set-prefix completion). *Every injective set prefix  $p : \alpha \rightarrow \mathbf{No}$  has a completion in  $\mathcal{P}_s(b)$ . The completion can be chosen uniformly from  $p$ .*

*Proof.* The class inverse of  $b$ , restricted to the set range of  $p$ , gives a set injection  $f = b^{-1} \circ p : \alpha \rightarrow \text{Ord}$ . Choose an infinite initial cardinal  $\delta$  strictly above  $\alpha$  and every member of  $\text{ran}(f)$ . Both  $\delta \setminus \alpha$  and  $\delta \setminus \text{ran}(f)$  then have cardinality  $\delta$ . A bijection between these complements extends  $f$  to a permutation of  $\delta$ . Extend it by the identity outside  $\delta$  and retain only its moved points as a code. Global choice makes the choices uniform.  $\square$

It would be incorrect to assert that every partial injection of a set into itself extends to a permutation without checking the complements. For instance, a bijection from a proper subset onto the entire carrier has no such extension. Enlarging to the cardinal  $\delta$  is exactly what prevents this obstruction.

### 42.2.3 The active-prefix interpolation argument

The next theorem is the earlier dense-core interpolation result ([theorem 19.10](#); Section 19 at the pin). We include the algorithm because both cut classification and the central-word theorem depend on its logic.

**Theorem 42.4** (Uniform set-cut interpolation). *Let  $(A_i)_{i \in I}$  and  $(B_j)_{j \in J}$  be uniform set-indexed families in  $\mathfrak{J}$ , with  $A_i < B_j$  for every cross pair. There is an injective set prefix  $p$  such that all its global completions lie strictly between the two families. In particular, a code in  $\mathcal{P}_s(b)$  interpolates the cut.*

*Proof.* For a cross pair let  $d(i, j)$  be its least disagreement. Class replacement gives a set of these ordinals. Put

$$\theta = \sup\{d(i, j) + 1 : i \in I, j \in J\},$$

with supremum 0 for an empty set. We construct an injective common prefix, keeping as *active* the rows that agree with it so far. Every inactive lower row is already strictly below all completions; every inactive upper row is already strictly above them.

At stage  $\beta$ , let  $L_\beta$  and  $U_\beta$  be the sets of next letters of the active lower and upper rows. Every  $l \in L_\beta$  is at most every  $u \in U_\beta$ , since otherwise the corresponding cross pair would be reversed. There are two cases.

If  $L_\beta \cap U_\beta$  is nonempty, it is a singleton  $\{t\}$ . Append  $t$ , which is fresh because the active rows are injective. Keep only the rows whose next letter is  $t$ . A dropped lower row has next letter less than  $t$ , and a dropped upper row has next letter greater than  $t$ , so the invariant is maintained.

If the intersection is empty, then  $L_\beta < U_\beta$ , allowing empty sides. Choose a fresh strict separator  $x$  outside the earlier range by Lemma 42.1, and append it. Every remaining active comparison is now strict. This prefix is the required  $p$ .

At a limit stage take the union of the earlier set prefixes and keep exactly the rows agreeing with it. The construction cannot continue with a shared letter through stage  $\theta$ : surviving active rows on both sides would agree beyond their first disagreement. It therefore stops by that stage. The prefix has length at most  $\theta + 1$ . Apply Lemma 42.3 to obtain a code.  $\square$

The histories in this proof have set length and set entries. Nothing requires collecting a set of class-valued choices, taking a surreal cut with proper-class sides, or invoking a class-valued recursion principle.

**Corollary 42.5** (The core and its cylinders).  *$\mathcal{P}_s(b) \cong \mathbf{No}$ , and every  $\mathcal{P}_s(b)_p \cong \mathbf{No}$ . The core is order-dense among global enumerations and among distinct injective class words. Every interval specified by a uniform set cut in  $\mathfrak{W}_{sl}$  contains a whole cylinder  $C_p$ .*

*Proof.* The theorem says that  $\mathcal{P}_s(b)$  fills all its set cuts, so Lemma 42.2 applies. To keep a prescribed prefix  $p$ , run the same active-row construction after  $p$ , forbidding  $\text{ran}(p)$  as well as the later used values; all forbidden values at a stage still form a set. This proves the set-cut property of  $\mathcal{P}_s(b)_p$ , including empty sides. The other assertions follow directly from the strict cylinder conclusion of the theorem.  $\square$

#### 42.2.4 Approximating one branch

**Lemma 42.6** (Two-sided ordinal approximants). *For  $F \in \mathfrak{J}$  there are uniform sequences of codes  $a_\alpha, b_\alpha$  indexed by Ord such that, for  $\alpha < \beta$ ,*

$$E_{a_\alpha} < E_{a_\beta} < F < E_{b_\beta} < E_{b_\alpha}.$$

*They are respectively cofinal and coinital among code evaluations strictly below and above  $F$ . Neither punctured side has a set-sized cofinal or coinital family.*

*Proof.* Complete  $F \upharpoonright \alpha$  followed by a fresh letter below  $F(\alpha)$  to obtain  $a_\alpha$ , and use a fresh letter above for  $b_\alpha$ . The inequalities are decided at the earlier index. A code differing from  $F$  at  $\xi$  lies on the appropriate far side of every approximant with index greater than  $\xi$ . Uniform choices come from the least completion code in the fixed global well-order. Finally, Theorem 42.4, with  $F$  on one side, puts a code strictly beyond any proposed set family on the other side.  $\square$

#### 42.2.5 The diagonal limitation on all set codes

**Theorem 42.7** (No exhaustive uniform evaluator). *No single class relation with set indices can have, among its rows, every class bijection  $\text{Ord} \rightarrow \mathbf{No}$ .*

*Proof.* Extend an alleged evaluator to all set indices by giving unused indices empty rows. Fix a class bijection  $\alpha \mapsto c_\alpha$  from  $\text{Ord}$  to the universe of sets. Partition  $\text{Ord}$  into pairs

$$(2 \cdot \alpha, 2 \cdot \alpha + 1).$$

The multiplication is ordinal multiplication with 2 on the left; these adjacent pairs partition all ordinals.

On pair  $\alpha$ , use the two values  $b(2 \cdot \alpha), b(2 \cdot \alpha + 1)$ . Put the second value first if the row  $c_\alpha$  reports  $b(2 \cdot \alpha)$  at coordinate  $2 \cdot \alpha$ ; otherwise put the first value first. Put the other value second. This elementary class construction defines a bijection  $E$ . Whenever the row  $c_\alpha$  is the graph of a function, it differs from  $E$  at that even coordinate. Thus every valid row misses  $E$ .  $\square$

The theorem does not say that  $\mathcal{P}_s(b)$  is too small to be dense. It says that density and exhaustive representation are different notions. It also does not prohibit defining some enumerations from set parameters; it prohibits one uniform evaluator from covering *all* of them.

### 42.3 Source 15: the ordinary class of bounded-support codes

Fix a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . A set-supported permutation of  $\text{Ord}$  equals the identity outside some ordinal. Code it by a permutation  $\pi : \gamma \rightarrow \gamma$  and extend it by the identity. Normalize  $\gamma = \sup\{\xi + 1 : \pi(\xi) \neq \xi\}$ , using  $\gamma = 0$  and the empty code for the identity. This makes codes unique. Let  $\mathcal{P}_{\text{bd}}(b)$  be the ordinary class of these set codes, with evaluation

$$E_d(\xi) = b(\pi_d(\xi)).$$

The values of an evaluation are sets; the whole evaluation is a class function uniformly given by a class relation.

**Lemma 42.8** (Every injective set prefix has a core completion). *Every injective set word  $p : \alpha \rightarrow \mathbf{No}$  extends to some  $E_d$ ,  $d \in \mathcal{P}_{\text{bd}}(b)$ , and a completion can be chosen uniformly.*

*Proof.* The map  $q = b^{-1} \circ p$  is a set injection into  $\text{Ord}$ . Choose an infinite initial cardinal  $\nu$  greater than  $\alpha$  and every member of  $\text{ran}(q)$ . The complements of  $\alpha$  and of  $\text{ran}(q)$  in  $\nu$  both have cardinality  $\nu$ . A bijection between them extends  $q$  to a permutation of  $\nu$ . Extend by the identity and normalize. The least permissible  $\nu$  and a fixed global well-order choose a particular complement bijection, so the construction is uniform.  $\square$

We use the following established core theorem from the prior report:  $\mathcal{P}_{\text{bd}}(b)$ , with the induced native lexicographic order, fills every set cut and is class-order-isomorphic to  $\mathbf{No}$  (theorem 19.10 and corollary 19.15; Theorem 19.10 and Corollary 19.15 at the pin, which source 15 cites as “Theorems

19.10 and 19.15"). Its proof combines prefix completion with fresh separators and then applies the ordinary class back-and-forth theorem. This is a statement about a class of sets, so it falls within surreal universality.

For an injective set word  $p : \alpha \rightarrow \mathbf{No}$ , its cylinder is

$$C_p = \{d \in \mathcal{P}_{\text{bd}}(b) : E_d \upharpoonright \alpha = p\}.$$

Cylinders are nonempty and convex. Those of a fixed length partition  $\mathcal{P}_{\text{bd}}(b)$  and are strictly ordered by their different prefixes. Each cylinder has no set cofinal or cointial subset: given a set of its codes, choose a fresh label above or below all their values at coordinate  $\alpha$ , append it to  $p$ , and complete it using [Lemma 42.8](#).

#### 42.4 Source 16: the bounded-support core of global enumerations

Work in GBC and fix a baseline bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . A normalized bounded-support code is a set permutation  $\sigma : \lambda \rightarrow \lambda$  of an ordinal satisfying

$$\lambda = \sup\{\xi + 1 : \sigma(\xi) \neq \xi\}.$$

The empty permutation is permitted. Extend  $\sigma$  by the identity above  $\lambda$ , obtaining  $\hat{\sigma}$ , and evaluate the code as  $E_\sigma = b \circ \hat{\sigma}$ . Let  $\mathcal{P}_{\text{bd}}(b)$  be the ordinary class of these set codes, ordered by comparison of their evaluations. Normalization makes the coding injective. The evaluations are class functions, but their codes are sets; the distinction is essential.

**Lemma 42.9** (Uniform completion of every set prefix). *Every injective set function  $p : \delta \rightarrow \mathbf{No}$  extends to an evaluation  $E_q$  with  $q \in \mathcal{P}_{\text{bd}}(b)$ . A completion can be selected uniformly in  $p$ .*

*Proof.* The function  $b^{-1} \circ p$  is a set injection into  $\text{Ord}$ . Choose an infinite initial cardinal  $\gamma$  strictly above  $\delta$  and all the ordinals in its range. The unused positions and unused values below  $\gamma$  both have cardinality  $\gamma$ . A bijection of their complements extends this injection to a permutation of  $\gamma$ . Extend by the identity and normalize. Choose the least suitable set bijection in a fixed global well-order to make the construction uniform.  $\square$

**Theorem 42.10** (Uniform set-cut interpolation). *Let  $(F_i)_{i \in I}$  and  $(G_j)_{j \in J}$  be uniformly set-indexed families in  $\mathfrak{J}$  satisfying  $F_i < G_j$  for all cross pairs. Either side may be empty. Some injective set prefix  $p$  has every continuation in  $\mathfrak{J}$  strictly between the families. In particular, a member of  $\mathcal{P}_{\text{bd}}(b)$  interpolates them.*

*Proof.* When both sides are nonempty, their cross first-disagreement ordinals form a set by Class Replacement. Bound them strictly below  $\beta$ ; otherwise put  $\beta = 0$ . Follow a prefix  $p$ , calling an input row active if it agrees with the whole prefix. Discarded lower rows are below every continuation and discarded upper rows above every continuation.

At coordinate  $\delta = \text{dom}(p)$ , let  $A$  and  $B$  be the sets of next values of the active lower and upper rows. Every value of  $A$  is at most every value of  $B$ . If they are disjoint, use the fresh-separator lemma ([lemma 5.2](#)) to append an unused value strictly between them and stop. This also handles empty sides. If they meet, their intersection is a singleton; append that forced value and retain only the rows using it. A surviving injective row guarantees freshness. At limits take unions of the set histories.

The process cannot retain both a lower and an upper row through length  $\beta$ , since such rows would agree beyond their bounded first disagreement. Thus it stops at a set stage, with all comparisons decided. [Lemma 42.9](#) provides the bounded-support completion. Surjectivity was not used for any input row.  $\square$

**Corollary 42.11** (A surreal-sized dense core). *The ordinary class order  $\mathcal{P}_{\text{bd}}(b)$  satisfies the set-cut property and is isomorphic to  $\mathbf{No}$ . It is dense in both  $\mathfrak{J}$  and  $\mathfrak{W}_{\text{sl}}$  in the sense of their definable comparisons. It has no set cofinal or coinitial subset. The interpolation theorem works for every chosen baseline, including constraints whose rows do not belong to that baseline's core.*

*Proof.* Apply Theorem 42.10 to evaluations of sets of codes. The core is proper, since transpositions of position zero with arbitrary ordinal positions give distinct codes. Class universality and uniqueness (proposition 5.13 and theorem 5.17) then gives the isomorphism. The remaining assertions are instances of the same interpolation theorem.  $\square$

**Status.** The completion and interpolation theorems, and the core isomorphism, are results of the earlier report (Part IV: lemma 19.4, theorem 19.10, and corollary 19.15). They are proved here because they are the inputs to the new recognition theorem below. Neither  $\mathcal{P}_{\text{bd}}(b) \cong \mathbf{No}$  nor its density says that all global enumerations can be coded by sets.

#### 42.4.1 Canonical first cores and residual fibers

For  $R \in \mathfrak{W}_{\text{all}}$ , the first block of source 16's canonical block decomposition (its Theorem 10.1, [merge] theorem 52.6) is

$$I_R = \{x \in \mathbf{No} : \{y : yRx\} \text{ is a set}\}.$$

It is always a proper class and has a unique enumeration  $F_R : \text{Ord} \rightarrow I_R$ . If  $I_R$  were a set, the least point outside it would have exactly that set of predecessors, a contradiction.

Conversely every  $F \in \mathfrak{J}$  occurs as such a first core: enumerate its range by  $F$  and then append any class well-order of its complement. The points in the range have set predecessors; every residual point has that whole proper range before it. Restriction and concatenation therefore identify the fiber over  $F$  with

$$\mathcal{W}(Y_F), \quad Y_F = \mathbf{No} \setminus \text{ran}(F), \quad (\text{S16.12})$$

where for a proper  $Y_F$  the notation denotes the raw class comparison. Each fiber is convex. Distinct fibers are ordered by the first ordinal disagreement of their cores. Symbolically,

$$\mathfrak{W}_{\text{all}} \cong \sum_{F \in \mathfrak{J}} \mathcal{W}(Y_F). \quad (\text{S16.13})$$

This is a summary of uniform relational constructions, not a same-level class sum whose index elements are proper classes. The set-like order  $\mathfrak{W}_{\text{sl}}$  consists precisely of the exhaustive, empty-residual fibers. A singleton fiber need not be exhaustive: omitting one label produces a unique raw completion of type  $\text{Ord} + 1$ .

#### 42.5 Source 17: the ordinary class core inside the global comparison

From now on work in GBC and fix  $b : \text{Ord} \rightarrow \mathbf{No}$ . Let  $\mathfrak{J}$  be the predicate of injective class functions  $\text{Ord} \rightarrow \mathbf{No}$ , and let  $\mathfrak{W}_{\text{sl}}$  be its surjective subpredicate. Comparisons are made at the least ordinal of first disagreement. These are predicates on class variables, not classes whose members are proper classes.

### 42.5.1 Canonical codes and interpolation

A *support code* is a set bijection  $\sigma : S \rightarrow S$ , where  $S \subseteq \text{Ord}$  is a set and  $\sigma(\xi) \neq \xi$  for every  $\xi \in S$ . The empty code is allowed. Extend it by the identity off  $S$  and put  $E_\sigma = b \circ \hat{\sigma}$ . Let  $\mathcal{P}_s(b)$  be the ordinary class of these codes, ordered by the associated enumerations. The fixed-point-free condition makes the coding unique. A global enumeration has such a code exactly when it agrees with  $b$  at every sufficiently large ordinal. By [Corollary 49.10](#), every injective set prefix occurs in this core.

We recall the central interpolation theorem of the source, with its proof because the later recognition results depend on its full strength for *injective, possibly nonexhaustive* rows.

**Lemma 42.12** (Avoiding a set of labels). *If  $L, R, Z$  are sets of surreal numbers with  $L < R$ , there is  $z \notin Z$  with  $L < z < R$ . Either side of the cut may be empty.*

*Proof.* The surreal set-cut property supplies a strict separator of any two separated sets. Repeat that construction  $|Z|^+$  times, each time adding all earlier chosen separators to the lower side. Every stage has a set history and gives a new separator below all of  $R$ . The resulting set has more elements than  $Z$ , so one separator is not forbidden. This is set-valued recursion with class parameters, not class-valued recursion.  $\square$

**Theorem 42.13** (Core interpolation; source result). *Let  $(A_i)_{i \in I}$  and  $(B_j)_{j \in J}$  be uniformly set-indexed families in  $\mathfrak{J}$ , with  $A_i <_{\text{lex}} B_j$  for every  $i, j$ . There is an injective set prefix  $p$  such that every row in  $\mathfrak{J}$  extending  $p$  lies strictly between both families. In particular there is such a row with a code in  $\mathcal{P}_s(b)$ . Empty index sets are permitted.*

*Proof.* When both sides are nonempty, Class Replacement collects their cross first-difference coordinates into a set. Choose an ordinal  $\beta$  strictly above all these coordinates. If one side is empty take  $\beta = 0$ .

Build an injective prefix, retaining as *active* the rows agreeing with it. At stage  $\alpha$  form the sets of active next labels

$$L_\alpha = \{A_i(\alpha) : A_i \text{ active}\}, \quad R_\alpha = \{B_j(\alpha) : B_j \text{ active}\}.$$

Every lower label is at most every upper label. Their intersection has at most one member. If it is empty, choose a fresh strict separator by [Lemma 42.12](#), append it, and stop. All active inequalities are now strict. If the intersection is  $\{z\}$ , append  $z$  and keep only rows with next value  $z$ . This value is fresh because a surviving row is injective. A discarded lower row is below every later extension; a discarded upper row is above every later extension. This is the invariant throughout the construction. At limits take unions of the set histories.

Both sides cannot still be active after a common prefix of length  $\beta$ , since an active cross pair would disagree only at or beyond  $\beta$ . Thus the procedure stops by the next step. Complete the final prefix in  $\mathcal{P}_s(b)$  using [Corollary 49.10](#). All recursions and collections in this proof have set-sized stages and values.  $\square$

**Corollary 42.14** (A dense surreal order core; source result). *The class order  $\mathcal{P}_s(b)$  is isomorphic to the numerical order of  $\mathbf{No}$ . It is order-dense in the global comparisons of both  $\mathfrak{W}_{\text{sl}}$  and  $\mathfrak{J}$ : between any two distinct rows there is a coded row. Every uniformly set-indexed separated cut of those comparisons has a core interpolant.*

*Proof.* The last statements are [Theorem 42.13](#). In particular  $\mathcal{P}_s(b)$  has the same set-cut interpolation property as  $\mathbf{No}$ . Under Global Choice enumerate each of these proper classes in a set-like well-order. Construct a back-and-forth partial order-isomorphism along  $\text{Ord}$ . At each stage its domain and range

are sets, so the required cut is a set cut; interpolation provides a fresh image or preimage. Global choice selects a least permissible choice. Every history at a set ordinal is a set, so elementary class comprehension together with set-valued transfinite recursion gives the full class map. Alternating forth and back ensures exhaustiveness on both sides.  $\square$

This is an isomorphism of *linear orders*, not of surreal fields or of structures with the simplicity relation. The additional structure studied in [14] cannot be inferred from numerical order alone. Nor is the core exhaustive in  $\mathfrak{W}_{\text{sl}}$ .

**Corollary 42.15** (Universality for ordinary class linear orders). *Every given linear order on a class of sets embeds by a class map into  $\mathcal{P}_s(b)$ , hence into  $\mathbf{No}$ ,  $\mathfrak{W}_{\text{sl}}$ , and  $\mathfrak{W}_{\text{all}}$  in their stated senses.*

*Proof.* Global choice supplies a set-like enumeration of the given class (or a set enumeration if its carrier is a set). At each stage, previous images form a set. Partition them by whether their source labels are below or above the next source label; interpolation in  $\mathcal{P}_s(b)$  supplies a fresh image. This forth-only recursion gives the required embedding. The core inclusion and Corollary 42.14 give the other targets. This is the source’s class-universality argument.  $\square$

The hypothesis “class of sets” cannot be dropped and replaced with “all class well-orders”. The latter is the higher-order predicate  $\mathfrak{W}_{\text{all}}$ , not a carrier to which this recursion theorem applies. This distinction is compatible with the no-coding theorem that follows.

#### 42.5.2 Why a dense class of codes is not a universal list

**Theorem 42.16** (Uniform diagonal obstruction; source result). *No ordinary class of set indices with one uniform evaluation relation lists all class well-orders of  $\mathbf{No}$ . A missing order can always be chosen set-like.*

*Proof.* Global choice permits reindexing a proposed nonempty list by  $\text{Ord}$ ; a set-sized list can be extended by repetitions. Write its rows as  $R_\alpha$ . Partition the baseline labels into the pairs

$$\{b(2 \cdot \alpha), b(2 \cdot \alpha + 1)\} = \{a_\alpha, c_\alpha\}, \quad a_\alpha < c_\alpha.$$

The products here are ordinal products with 2 on the left, so these successive two-element blocks partition  $\text{Ord}$ . In block  $\alpha$ , list the two labels in the order opposite to their relative order under  $R_\alpha$ . Keep the blocks in increasing  $\alpha$  order. Elementary comprehension defines a class bijection  $E : \text{Ord} \rightarrow \mathbf{No}$ . Its induced well-order disagrees with  $R_\alpha$  on that pair, for every  $\alpha$ . The empty-list case is immediate.  $\square$

Each input row and the diagonal output are legitimate classes. The forbidden object is a same-level exhaustive decoder, not an individual large relation. Strengthening comprehension does not make a class into a permissible element of another class of the same two-sorted theory. An external set universe, a higher sort, or a stated uniform operator provides a different, legitimate interpretation.

#### 42.6 Source 18: the set-like global order and its ordinary class core

Assume GBC and fix a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . The set-like global order can be studied through its ordinal enumerations: if  $e \neq f$ , the nonempty class  $\{\alpha : e(\alpha) \neq f(\alpha)\}$  has a least ordinal. Numerical comparison there agrees with source 18’s Theorem 12.3 ([merge] theorem 51.16; theorem 14.7).

### 42.6.1 Canonical bounded-support codes

A permutation  $\pi$  of  $\mathbf{Ord}$  with set-sized support can be encoded by the set graph of its nonfixed pairs; it is the identity elsewhere. This representation is unique. Let  $\mathcal{P}_s(b)$  be the genuine class of all such set codes, ordered by their evaluated global enumerations  $b \circ \pi$ . The notation distinguishes the set code from the class function that it evaluates.

**Lemma 42.17** (Completion of every set prefix). *Every injective set word  $p : \delta \rightarrow \mathbf{No}$  extends an evaluated member of  $\mathcal{P}_s(b)$ .*

*Proof.* The  $b$ -indices of the labels in  $\text{ran } p$  form a set. Choose an infinite initial cardinal  $\lambda$  greater than  $\delta$  and all these indices. The first  $\lambda$  values of  $b$  contain  $\text{ran } p$ . List  $p$  first, followed by a bijection of the unused values of this initial block in length  $\lambda$ . Since  $\delta + \lambda = \lambda$ , the result permutes that entire block. Leave all later positions unchanged. This is a bounded-support permutation extending  $p$ .  $\square$

**Theorem 42.18** (Uniform set-cut interpolation). *Let  $(e_i)_{i \in I}$  and  $(f_j)_{j \in J}$  be uniformly presented set-indexed families of global ordinal enumerations, and suppose  $e_i < f_j$  for all  $i, j$ . There is  $g \in \mathcal{P}_s(b)$  strictly between them. In particular,  $\mathcal{P}_s(b)$  fills every set cut and is order-isomorphic to  $\mathbf{No}$  in GBC. It is order dense in  $\mathfrak{W}_{\text{sl}}$ .*

*Proof.* When both families are nonempty, the first disagreements of all pairs  $(e_i, f_j)$  form a set of ordinals by Class Replacement. Take a bound on them. Run a common-prefix search: keep only the family members extending the current prefix; numerical next values on the lower side are at most those on the upper side. If the sets of next values meet, they meet in a unique value, which is appended. If they do not meet, choose a fresh surreal strictly between them, append it, and stop. At a limit stage take the union of the preceding set prefixes.

The search cannot continue through the bound on all pairwise first disagreements while both active sides remain nonempty. When a side becomes empty, the surreal set-cut property also supplies a fresh next value. If one original side is empty, the search stops at the first step. Each inactive lower member is below the whole current cone, and each inactive upper member is above it. Thus the resulting successor prefix puts every completion strictly between the given families. Apply [Lemma 42.17](#).

For the isomorphism, perform set-valued back-and-forth along fixed set-like enumerations of the two proper classes  $\mathcal{P}_s(b)$  and  $\mathbf{No}$ . At each stage only a set of previously matched points must be respected, and interpolation supplies the next point. Taking singleton families in the first assertion proves density in  $\mathfrak{W}_{\text{sl}}$ .  $\square$

The conclusion is stronger than pairwise density and weaker than filling arbitrary proper-class cuts. For example, choose an injective  $\mathbf{Ord}$  word that enumerates  $\mathbf{No} \setminus \{x\}$ . It determines a cut of  $\mathcal{P}_s(b)$  but cannot itself be a global enumeration of  $\mathbf{No}$ . The next section makes the distinction exact.

Class universality of  $\mathbf{No}$  now implies that every supplied class linear order embeds into  $\mathfrak{W}_{\text{sl}}$ , through  $\mathcal{P}_s(b)$ . The same is true inside any nonempty open interval of  $\mathfrak{W}_{\text{sl}}$ : a sufficiently long set prefix and a free numerical interval place a copy of the same core inside it. This is a statement about uniform class-indexed subfamilies. It does not say that  $\mathfrak{W}_{\text{sl}}$  itself is an ordinary class.

### 42.6.2 An elementary obstruction to exhaustive class coding

**Theorem 42.19** (No ordinary class of codes for all global well-orders). *There is no class-indexed uniform evaluator whose values include every class well-order of  $\mathbf{No}$ . The same holds if only set-like orders are required as values.*

*Proof.* Under Global Choice any class of set codes can be listed in an Ord-indexed family, repeating values if the code class is a set. Suppose  $(R_\alpha)_{\alpha \in \text{Ord}}$  were exhaustive. Split the fixed baseline  $b$  into consecutive pairs

$$\{b(2 \cdot \alpha), b(2 \cdot \alpha + 1)\}, \quad \alpha \in \text{Ord}.$$

In pair  $\alpha$ , choose the orientation opposite to the relative order of these two labels in  $R_\alpha$ . Keep the pair blocks in their original ordinal order. This is a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ , hence a set-like well-order. It differs from  $R_\alpha$  on the relative order of its designated pair, for every  $\alpha$ , contradicting exhaustiveness. The orientation class is defined elementarily from the proposed evaluator.  $\square$

This is the relevant Cantor-style diagonal. It blocks a uniform “all codes are sets” shortcut. Individual global well-orders can still be parameters, and any specified uniform family can be studied. Kelley–Morse comprehension strengthens which classes exist; it does not make proper classes into members of other ordinary classes.

## 43 A trichotomy for class cuts of the skeleton (source 14)

### 43.1 Normalization and the three constructions

A *proper normalized cut* of  $\mathcal{P}_s(b)$  is a class  $D \subseteq \mathcal{P}_s(b)$  which is nonempty, proper, downward closed, and has no greatest member. Its complement is allowed to have a least member. Thus the point  $\sigma$  is represented by the lower set  $\{\tau : \tau < \sigma\}$ , not by the lower set that includes  $\sigma$ . This convention is essential when we calculate characters.

We write  $D_p^-$  and  $D_p^+$  for the two edges of a nonempty-prefix cylinder:

$$\begin{aligned} D_p^- &= \{\sigma : (\forall \tau \in C_p) \sigma < \tau\}, \\ D_p^+ &= \{\sigma : (\exists \tau \in C_p) \sigma < \tau\}. \end{aligned}$$

Since  $C_p$  has no endpoints,  $D_p^-$  consists of the codes below the whole cylinder, whereas  $D_p^+$  consists of those codes together with all of  $C_p$ . Both are proper normalized cuts. The empty-prefix edges are the improper endpoint cuts and are excluded.

For a set prefix  $p$  and a nonempty proper initial class  $H \subset A_p$  with no greatest member and with  $A_p \setminus H$  having no least member, define a *numerical-gap cut*

$$D_{p,H} = D_p^- \cup \{\sigma \in C_p : E_\sigma(\lambda) \in H\}, \quad \lambda = \text{dom } p.$$

Here  $D_\emptyset^- = \emptyset$  by convention. The nonprincipality conditions prevent this notation from duplicating the two edges of a child cylinder.

Finally, for  $F \in \mathfrak{J}$  define the *branch trace*

$$D_F = \{\sigma \in \mathcal{P}_s(b) : E_\sigma <_{\text{lex}} F\}.$$

[Lemma 41.5](#) shows that it is a proper normalized cut. The branch need not be exhaustive. If  $F = E_\sigma$ , the cut is principal in the normalized sense; otherwise it has no point of the skeleton at its boundary.

### 43.2 Crossing cylinders and reconstruction

**Definition 43.1.** A prefix  $p$  *crosses*  $D$  if its cylinder meets both sides:

$$\text{Cross}_D(p) \iff (\exists \sigma \in C_p \cap D)(\exists \tau \in C_p \setminus D).$$

Let  $T_D$  be the class of crossing set prefixes.

All displayed witnesses are sets. Therefore  $T_D$  is obtained by *elementary* class comprehension from  $D$  and  $b$ .

**Lemma 43.2** (The crossing-chain lemma). *For every proper normalized cut  $D$ , the class  $T_D$  contains the empty prefix, is downward closed under prefix restriction, and is a chain under prefix extension. It contains at most one prefix of any given length. Its union is an injective function with domain either a set ordinal or all of Ord.*

*Proof.* Properness gives the empty prefix, and any ancestor of a crossing cylinder also crosses. If incomparable prefixes  $p, q$  both crossed, order their disjoint cylinders as  $C_p < C_q$ . An excluded point of  $C_p$  would then lie below an included point of  $C_q$ , contradicting downward closure. Thus they are comparable, which also proves uniqueness at each length. Their union is a function and is injective because every two of its coordinates occur together in a sufficiently long member of the chain. Its domain is an initial subclass of Ord. Such a subclass is all of Ord or a set ordinal. In the latter case, class Replacement on that set domain makes the union a set function.  $\square$

**Theorem 43.3** (Boundary trichotomy). *Every proper normalized class cut  $D$  of  $\mathcal{P}_s(b)$  has exactly one of the following forms:*

- (i) a cylinder edge  $D_p^-$  or  $D_p^+$  for a nonempty injective set prefix  $p$ ;
- (ii) a numerical-gap cut  $D_{p,H}$  with the nonprincipality conditions specified above;
- (iii) a branch trace  $D_F$  for an injective class function  $F : \text{Ord} \rightarrow \mathbf{No}$ .

*The data within the appropriate form, including the edge direction, are unique. The alternatives and their data can be recovered from the crossing-prefix class by elementary formulas with class parameters.*

*Proof.* We distinguish whether the lengths occurring in  $T_D$  are unbounded.

*Unbounded case.* Let  $F = \bigcup T_D$ . Its domain is Ord. For a code  $\sigma$  with  $E_\sigma \neq F$ , let  $\delta$  be their first disagreement. Take a crossing prefix of length greater than  $\delta$ . If  $E_\sigma <_{\text{lex}} F$ , then  $\sigma$  is below that entire cylinder and in particular below one of its included points, so  $\sigma \in D$ . If  $F <_{\text{lex}} E_\sigma$ , it is above an excluded point of that cylinder and cannot belong to  $D$ . If  $E_\sigma = F$ , membership in  $D$  would make  $\sigma$  its greatest member, since all larger codes have just been excluded. This is prohibited by normalization. Therefore  $D = D_F$ .

*Bounded case with no longest crossing prefix.* The union  $p$  has nonzero limit length  $\lambda$ . It does not cross, so either  $C_p \subseteq D$  or  $C_p \cap D = \emptyset$ . For every code outside  $C_p$ , its first disagreement with  $p$  occurs before  $\lambda$ ; a longer crossing prefix then decides its membership exactly as in the unbounded case. Hence  $D = D_p^+$  in the first alternative and  $D = D_p^-$  in the second.

*Bounded case with a longest crossing prefix  $p$ .* No child  $C_{p \frown (x)}$  crosses. Each child is consequently wholly included or wholly excluded. Let

$$H = \{x \in A_p : C_{p \frown (x)} \subseteq D\}.$$

It is an initial class of  $A_p$ . Because  $C_p$  crosses and the child cylinders partition it,  $H$  is nonempty and proper. Points outside  $C_p$  are below all of it or above all of it; the crossing witnesses show that

exactly those below belong to  $D$ . Thus  $D$  has the formula used to define  $D_{p,H}$ . If  $H$  has a greatest member  $x$ , that formula is  $D_{p\smallfrown(x)}^+$ . If  $A_p \setminus H$  has a least member  $x$ , it is  $D_{p\smallfrown(x)}^-$ . Both possibilities cannot occur, since  $A_p$  is dense. If neither occurs, we have precisely alternative (ii).

For uniqueness, in alternative (iii) the crossing prefixes are exactly all set restrictions of  $F$ ; in alternative (ii) they are exactly  $p$  and its restrictions; and at an edge they are exactly the *proper* restrictions of its prefix. If the last chain has no longest member, its union recovers the limit prefix and membership of its cylinder recovers the direction. If it has a longest member, the included child labels have a maximum or the excluded child labels have a minimum; that endpoint recovers the additional label and the direction. For a numerical gap neither endpoint exists. These descriptions distinguish the alternatives, and also recover every parameter uniquely.  $\square$

*Remark 43.4* (What the theorem does not construct). It does not collect all class cuts into an ordinary class, nor insert an Ord-length sign sequence as a surreal number. The theorem is a statement about an arbitrary supplied class  $D$ . Its elementary formulas can be used uniformly in models, but the virtual family of every such  $D$  still occupies a higher logical level.

### 43.3 Examples distinguishing the alternatives

For the one-letter prefix  $(0)$ , the cut  $D_{(0)}^-$  lies just below all core enumerations beginning with 0. There is no numerical “largest first entry below 0.” It is a cylinder boundary, not a branch trace. At the empty prefix, take the numerical gap

$$H = \{x \in \mathbf{No} : (\exists n \in \mathbb{N}) x < n\}.$$

Its complement is the class of surreals at least as large as every natural number. It has no least member: from such a surreal  $y$ , the number  $y - 1$  is still in the complement and is smaller. The class  $H$  has no greatest member. This produces a cut of type (ii), with a countable cofinal left side but no set-sized coinital right side. Finally  $F(\alpha) = \alpha$  is an injective branch of type (iii) which omits, for example,  $-1$ . Its trace is coherent at every set length but is not realized by any member of  $\mathfrak{W}_{\text{sl}}$ . Exhaustiveness is not implied by coherence.

*Note 43.5* ([merge]; the three examples in the repository). The first-label cut at 0 (with its upper-edge twin) is printed also by sources 15 and 16 (example 46.10 and source 16’s table after theorem 46.3); the numerical gap  $\{x : \exists n x < n\}$  also by sources 15 and 17 (examples 46.11 and 46.23). The branch  $F(\alpha) = \alpha$ , which omits  $-1$ , is source 09’s theorem 19.43 (printed in Part IV), which source 14 does not cite; source 13 recovers it as example 46.17, crediting this report, and source 15 prints it again (after example 46.11). Its one-label variant, a bijection  $\text{Ord} \rightarrow \mathbf{No} \setminus \{r\}$ , is source 11’s theorem 19.42, printed again by sources 16 and 17 (source 16’s table, example 46.25), which do not cite it. The limit boundary below the cylinder of  $p(n) = n$  ( $n < \omega$ ), which source 14 does not use, is printed by sources 13 (end of its Section 9), 15 (example 46.11), 16 (its table) and 17 (example 46.24, for any injective  $p$  of length  $\omega$ ).

## 44 Characters, saturation, and principal cuts (source 14)

We use  $\text{Ord}$  as a *character symbol*: it means that a uniform ordinal-indexed cofinal or coinital family exists, while no set-sized one exists. It is not an ordinary cardinal. For any nonempty class linear order with no set-sized cofinal subset, global choice permits an increasing cofinal Ord-sequence: at each set stage dominate the earlier choices and the elements seen so far in a global enumeration. If no such upper choice existed, the already considered set would be cofinal. This is set-valued

recursion. The dual argument handles coinitality. A set-sized character is the least cardinality of a cofinal or coinital subset; if there is a corresponding endpoint it is 1.

**Theorem 44.1** (Cut-character calculation). *Write the character of a normalized cut as (cf  $D$ , ci( $\mathcal{P}_s(b) \setminus D$ )). For the alternatives of Theorem 43.3, the following formulas hold.*

| <i>Cut</i>                                      | <i>Character</i>                   |
|-------------------------------------------------|------------------------------------|
| $D_F$ , with $F = E_\sigma$ for some core code  | (Ord, 1)                           |
| $D_F$ , with $F$ not represented by a core code | (Ord, Ord)                         |
| $D_p^-$ , dom $p = \lambda$ a nonzero limit     | (cf $\lambda$ , Ord)               |
| $D_p^+$ , dom $p = \lambda$ a nonzero limit     | (Ord, cf $\lambda$ )               |
| $D_p^-$ or $D_p^+$ , dom $p$ a successor        | (Ord, Ord)                         |
| $D_{p,H}$                                       | (cf $H$ , ci( $A_p \setminus H$ )) |

For the last row both characters cannot be set-sized. At every actual point of  $\mathcal{P}_s(b)$ , both strict local characters are Ord.

*Proof.* For a branch  $F$ , complete a prefix agreeing with  $F$  before  $\alpha$  and taking a fresh smaller entry at  $\alpha$ ; call the result  $a_\alpha$ . Similarly obtain  $b_\alpha$  with a larger entry. If  $\alpha < \beta$ , first difference gives

$$a_\alpha < a_\beta <_{\text{lex}} F <_{\text{lex}} b_\beta < b_\alpha.$$

Every code below or above  $F$  is surpassed on the appropriate side by one of these approximants, once  $\alpha$  exceeds its first disagreement. A set of codes differing from  $F$  has a set of first disagreements and hence a common ordinal bound; a later approximant defeats its alleged cofinality or coinitality. If  $F$  itself is a core point, the complement of  $D_F$  has that point as its least member. This gives (Ord, 1), not (Ord, Ord); only the strict right side has character Ord.

At the lower edge of a limit-length prefix  $p$ , take a cofinal sequence of coordinates  $\alpha < \lambda$  and complete a word that first differs from  $p$  there by a smaller entry. These codes are cofinal below the cylinder. Conversely the first-disagreement coordinates of any cofinal family must be cofinal in  $\lambda$ : a code which follows  $p$  longer would otherwise be above the entire family. This proves the character cf  $\lambda$ . On the other side the cylinder has no set-sized coinital subset by Proposition 41.4, and lies below all other points of the complement. Its character is Ord. The upper-edge calculation is dual.

For a successor-length prefix  $p = q \frown (x)$ , any set of points below  $C_p$  that first differ before the last coordinate can be surpassed by one following  $q$ . Among those which follow  $q$ , their entries at the last coordinate form a set below  $x$ . Lemma 41.1 provides a fresh entry between that set and  $x$ . Completion again surpasses the whole family while remaining below  $C_p$ . Thus the lower side of the lower edge has no set-sized cofinal subset. The opposite side follows from the cylinder property. The upper edge is the dual case.

For a numerical gap, project included points in  $C_p$  to their next-coordinate labels in  $H$ . A cofinal set of labels, with one completed word above each chosen label when necessary, produces a cofinal family of codes. Conversely a cofinal family of codes must have cofinal projected labels: otherwise a child cylinder with a larger label in  $H$  surpasses it. The absence of a greatest member of  $H$  removes any dependence on the internal character of one child. The dual argument proves the right character. If both were sets, cofinal labels on the left and coinital labels on the right would constitute a set cut of  $A_p$  with no separator, contradicting Lemma 41.1. Finally the branch argument at a core point already proves the assertion about strict local characters.  $\square$

**Corollary 44.2** (Recovery of the core saturation theorem). *Every separated pair of sets of codes  $A, B \subseteq \mathcal{P}_s(b)$  has a strict separator in  $\mathcal{P}_s(b)$ . In particular the core is an  $\eta_{\text{Ord}}$ -order: it fills all set-sized strict cuts, including those with an empty side.*

*Proof.* Empty-side bounds follow by choosing a first label above or below all first labels in the specified set. Suppose both sides are nonempty and no separator exists. If  $A$  has a greatest point  $a$ , then  $B$  would be coinital in the strict right side of  $a$ , contradicting its local character. The dual argument applies if  $B$  has a least point. Otherwise let  $D = \{\sigma : (\exists a \in A) \sigma < a\}$ . It is a proper normalized cut with  $A$  cofinal. Absence of a separator makes  $B$  coinital in its complement: any point there below all of  $B$  would be strictly above all of  $A$ . The character table has no nonprincipal cut with two set-sized characters, a contradiction.  $\square$

**Corollary 44.3** (The known surreal order type). *There is a class order isomorphism  $\mathcal{P}_s(b) \cong \mathbf{No}$  in GBC.*

*Proof.* Both are proper class linear orders filling all set cuts. Fix set-like global enumerations and perform back-and-forth along  $\text{Ord}$ . At a set stage the existing partial map has set domain and range; the next point's lower and upper constraints are sets and admit a fresh image. The union is an elementary definable class bijection preserving order. This is the standard argument, also used by the predecessor; the isomorphism statement itself is inherited, not claimed as a new result.  $\square$

The character calculation explains why the core is not Dedekind complete. For instance the increasing core points whose first entries are natural numbers have upper bounds but no supremum. Filling *strict* set cuts supplies another point between all those entries and any proposed upper bound. The countable/non-set-sized numerical-gap character above records this failure rather than contradicting saturation.

*Note 44.4* ([merge]; which rows are new). The branch rows of [theorem 44.1](#) are source 11's [proposition 19.27](#) and source 09's [theorem 19.43](#) (( $\text{Ord}, \text{Ord}$ ) at a non-core branch); [corollary 44.2](#) is [theorem 19.10](#) for sets of codes and [corollary 44.3](#) is [corollary 19.15](#), both stated by source 14 as recoveries. New are the characters of the edge and numerical-gap cuts and the statement that no nonprincipal cut has two set-sized characters. The same table is proved, case by case, by source 13 ([proposition 46.19](#)), source 15 ([proposition 46.12](#)), source 16 (the paragraph after its table) and source 17 for non-core branches ([proposition 46.26](#)); those statements are printed with their sources' recognition theorems in [section 46](#).

## 45 Recognizing exhaustive cuts and preserving old cuts (source 14)

**Theorem 45.1** (Exhaustive-cut recognition). *Let  $D$  be a proper normalized class cut of  $\mathcal{P}_s(b)$ . There exists  $E \in \mathfrak{W}_{\text{sl}}$  with  $D = D_E$  if and only if both conditions hold:*

$$\forall \alpha \in \text{Ord} \exists p [\text{dom } p = \alpha \wedge \text{Cross}_D(p)], \quad (\text{C})$$

$$\forall x \in \mathbf{No} \exists p [\text{Cross}_D(p) \wedge x \in \text{ran } p]. \quad (\text{X})$$

*Such an enumeration is unique, and its graph is given by*

$$E(\alpha) = x \iff \exists p [\text{Cross}_D(p) \wedge \alpha \in \text{dom } p \wedge p(\alpha) = x].$$

*All quantifiers in the criterion and reconstruction range over sets; only  $D$  and  $b$  are class parameters.*

*Proof.* For an exhaustive  $E$ , every restriction  $E \upharpoonright \alpha$  crosses its trace by the smaller and larger completions in [Lemma 41.5](#). Every surreal occurs in one of these restrictions, giving (C) and (X). Conversely (C) and [Lemma 43.2](#) produce an injective union  $F$  on all of  $\text{Ord}$ . Condition (X) makes

it surjective. The unbounded case of [Theorem 43.3](#) gives  $D = D_F$ . The displayed graph formula is exactly the union of the crossing chain; its functionality and uniqueness follow from the chain lemma.  $\square$

**A logical simplification.** For this proper-class alphabet, (X) by itself already implies (C). Indeed, the union of the crossing chain then has range all of  $\mathbf{No}$ ; if its domain were a set ordinal, class Replacement would make that range a set. Its domain is therefore Ord, and prefix closure gives (C). We retain the two conditions in the theorem to distinguish coherent nonexhaustive branches from failures that stop at a set stage; we do not claim that the conditions are logically independent.

This answers the predecessor’s question “Which cuts of the core represent exhaustive branches?” ([research question 113.1](#); source 09’s third direction in [section 113.3](#)) *in the prefix-enriched structure*. A bare linear-order isomorphism of the core does not come equipped with its prefix cylinders or the label evaluation. The theorem does not show that those enrichments are definable from the order relation alone. [Corollary 47.3](#) below proves that an automorphism-invariant bare-order criterion cannot recognize exhaustiveness: some core automorphisms carry exhaustive traces to nonbranch cylinder edges.

The criterion also separates two notions of completion. An injective branch always gives a cut coherent through every set stage. It gives a global enumeration only if it eventually visits every label. No condition at a single bounded stage can enforce the latter assertion. For the branch  $F(\alpha) = \alpha$ , (C) holds and (X) fails at  $x = -1$ . The two cylinder-edge alternatives fail (C) at a bounded length; a numerical-gap alternative also fails (C), because there is no crossing child after its last crossing prefix.

[merge] The second half of source 14’s Section 7, on preserving old cuts under class extensions (its [theorem 48.1](#), the corollary and the remark after it), is printed in [section 48](#).

## 46 Five further proofs of the represented-cut theorem (sources 16, 15, 13, 17 and 18)

*Note 46.1* ([merge]; one theorem, six proofs). The theorem that a normalized class cut of the core is the cut of an injective class word exactly when a crossing (straddling) prefix exists at every set length, that the word is then unique and elementary in the cut, and that it is exhaustive exactly when the ranges of these prefixes cover  $\mathbf{No}$ , is proved independently in all six batch-81 sources: source 14’s [theorem 43.3\(iii\)](#) and [theorem 45.1](#), source 16’s [theorem 46.2](#), source 15’s [theorem 46.6](#) with [corollary 46.8](#), source 13’s [theorem 46.15](#), source 17’s [theorem 46.21](#) and source 18’s [theorem 46.28](#) with [corollary 46.31](#). Each source presents it as its own answer to source 11’s [research question 113.1](#); it answers that question ([section 50](#)), and no source has priority over another. The six proofs are the same argument: uniqueness of a crossing prefix at each length, coherence under restriction, the elementary union, and the first disagreement with a code. They are printed as routes because each source builds different examples and corollaries on its own proof.

The analysis of a failing cut is likewise proved five times. Source 14 partitions the proper cuts by their form (edge, numerical gap, branch: [theorem 43.3](#)); sources 13, 15, 16 and 18 partition the failing cuts by their first failed length (successor or limit: [theorems 46.3](#), [46.9](#), [46.18](#) and [46.32](#)). The two partitions are equivalent: a limit failure is an edge of a limit-length cylinder, and a successor failure is an edge of a child cylinder or a numerical gap. Source 15’s successor case is the finest, separating a *forbidden repeated label* (the unused alphabet split at a label already used by the prefix, [example 46.11](#), source 16’s second table row and source 18’s [example 46.33](#)) from a numerical gap

with no surreal separator; in source 14's terms both are numerical-gap cuts  $D_{p,H}$ , the first with  $A_p \setminus H$  and  $H$  separated by a point of  $\text{ran } p$ .

Source 18 states its theorem “in GB with the fixed baseline”. A baseline  $b : \text{Ord} \rightarrow \mathbf{No}$  already yields global choice over GB (theorem 13.1), so the hypothesis is not weaker than GBC; the theorem's own content is that no class choice and no ETR are used beyond the baseline. Sources 13, 14, 15, 16 and 17 say GBC.

#### 46.1 Source 16: exact recognition of cuts represented by branches

Fix the core  $\mathcal{P}_{\text{bd}}(b)$  and its evaluation. For an injective set prefix  $p : \alpha \rightarrow \mathbf{No}$  write

$$C_p = \{q \in \mathcal{P}_{\text{bd}}(b) : E_q \upharpoonright \alpha = p\}.$$

These cylinders are nonempty and convex, and at each fixed length they form an ordered partition. Each cylinder has no endpoint: change the next coordinate of one completion to a fresh smaller or larger surreal and apply Lemma 42.9.

A *lower cut* here means an available class  $\emptyset \neq L \subsetneq \mathcal{P}_{\text{bd}}(b)$  that is initial and has no greatest member. Put  $U = \mathcal{P}_{\text{bd}}(b) \setminus L$ . A prefix *straddles* the cut if  $C_p \cap L$  and  $C_p \cap U$  are both nonempty. This is a property with only set quantifiers and the class parameters  $L, b$ .

**Theorem 46.2** (Prefix-cylinder recognition). *The following are equivalent:*

1. *There is an injective class function  $F : \text{Ord} \rightarrow \mathbf{No}$  such that*

$$L = \{q \in \mathcal{P}_{\text{bd}}(b) : E_q <_{\text{lex}} F\} =: L_F.$$

2. *At every ordinal length  $\alpha$  some injective prefix straddles the cut.*

*When these conditions hold, the prefix at each length is unique and is exactly  $F \upharpoonright \alpha$ . The branch is exhaustive if and only if every surreal occurs in the range of some straddling prefix.*

*Proof.* For a given  $F$ , choose fresh values below and above  $F(\alpha)$  and complete the corresponding one-letter extensions of  $F \upharpoonright \alpha$ . They lie on opposite sides of  $F$ , so its prefix straddles.

Two different prefixes at the same length cannot both straddle an initial cut. Their cylinders are entirely ordered one before the other, and an upper witness in the earlier cylinder would be below a lower witness in the later one. This contradicts initiality. Restrictions of straddling prefixes still straddle. Hence the prefixes  $p_\alpha$  supplied by condition 2 are unique and coherent.

Define the branch directly, by elementary comprehension:

$$F(\alpha) = x \iff \exists p [p \text{ straddles, } \text{dom}(p) = \alpha + 1, p(\alpha) = x]. \quad (\text{S16.14})$$

Here the prefix and the witnesses from both sides are sets. Coherence proves that this is a total injective class function and that  $F \upharpoonright \alpha = p_\alpha$ . This is not a class-valued recursion.

If  $E_q < F$  first differ at  $\delta$ , every point of  $C_{p_{\delta+1}}$  is above  $q$ . One such point is in  $L$ , so  $q \in L$ . If  $F < E_q$ , an upper witness in the same cylinder lies below  $q$ , so  $q \in U$ . Finally, if  $E_q = F$ , placing  $q$  in  $L$  would make it the greatest member of  $L$  by the preceding two implications. Thus it is in  $U$ , and  $L = L_F$ . The prefixes determine  $F$  uniquely, and their range union gives exactly the stated exhaustion criterion.  $\square$

The no-greatest convention matters only at a represented core point: without it, both  $\{q : E_q < F\}$  and  $\{q : E_q \leq F\}$  would straddle every level when  $F = E_q$  for a code. The two improper cuts fail already at the empty prefix and represent no injection.

**Theorem 46.3** (Complete classification of the first failure). *If a lower cut is not represented, let  $\lambda$  be the least length with no straddling prefix. Then  $\lambda > 0$ , and exactly one of the following occurs.*

1. **Successor failure.** *If  $\lambda = \alpha + 1$ , let  $p$  be the unique straddling prefix of length  $\alpha$ . The unused labels  $\mathbf{No} \setminus \text{ran}(p)$  split into nonempty initial and final classes  $A + B$ , with*

$$C_{p \smallfrown (x)} \subseteq L \ (x \in A), \quad C_{p \smallfrown (x)} \subseteq U \ (x \in B).$$

*All codes below  $C_p$  are in  $L$  and all codes above it in  $U$ .*

2. **Limit failure.** *If  $\lambda$  is a nonzero limit, the coherent earlier prefixes have an injective set union  $p$  of length  $\lambda$ . The cut is exactly the lower or upper edge of its cylinder:*

$$L = C_p^- \quad \text{or} \quad L = C_p^- \cup C_p, \quad C_p^- := \{q : \forall c \in C_p \ (q < c)\}.$$

*Proof.* Minimize below any ordinal witnessing failure; this uses no ordering of classes. The empty prefix straddles. At a successor, every nonempty child cylinder is wholly on one side, and the children partition the parent cylinder, which straddles. Both parts of the label split are therefore nonempty, and their order follows from that of the children. The outside-code assertion follows by comparison with a lower and an upper witness in the parent.

At a limit, Class Replacement applied to the unique prefixes indexed by the set  $\lambda$  makes their union a set. Coherence ensures injectivity, and completion ensures a nonempty cylinder. Since the length fails, that cylinder is wholly on one side. Any code outside it first differs from  $p$  at  $\delta < \lambda$ ; the shorter prefix of length  $\delta + 1$  still straddles. Its witnesses force the code to the lower side if it differs downward and to the upper side if upward. Including or excluding the entire limit cylinder gives exactly its two edges.  $\square$

A successor failure need not be a numerical gap with both sides lacking endpoints. It can be an edge of a whole child cylinder, or a cut for which the numerically suitable next label has already been used. The theorem distinguishes these from a failure of coherence at a limit length.

#### 46.1.1 Explicit cuts and their meaning

The following table gives concrete, fully defined examples.

| Lower side                                                                | First failure | Interpretation                                                                           |
|---------------------------------------------------------------------------|---------------|------------------------------------------------------------------------------------------|
| $\{q : E_q(0) \leq 0\}$                                                   | 1             | Upper edge of the entire zero-first cylinder.                                            |
| $\{q : E_q(0) < 0\} \cup \{q : E_q(0) = 0, E_q(1) < 0\}$                  | 2             | The apparent second separator would repeat the already used zero.                        |
| $C_p^-$ or $C_p^- \cup C_p$ , with $p(n) = n$ for $n < \omega$            | $\omega$      | Every finite prefix straddles, but the whole countable-prefix cylinder lies on one side. |
| $L_F$ for $F : \text{Ord} \xrightarrow{\sim} \mathbf{No} \setminus \{r\}$ | None          | A genuine injective branch, failing only the exhaustion test.                            |

All displayed lower sides have no greatest member. For a nonzero limit prefix length  $\lambda$ , its lower cylinder edge has lower cofinality exactly  $\text{cf}(\lambda)$  and no set coinital family on its upper side. To see this, make a fresh downward deviation at cofinally many positions of  $p$ . The completions increase

cofinally below  $C_p$ ; any cofinal family must have unbounded deviation coordinates. On the upper side, the initial portion  $C_p$  has no set cointial family, since one can choose a fresh next value below any set of next values. The upper edge has the dual characters.

**Corollary 46.4** (Exactly what raw tails add). *For a raw order  $R \in \mathfrak{W}_{\text{all}}$ , its strict lower cut in  $\mathcal{P}_{\text{bd}}(b)$  is  $L_{F_R}$ . Thus the cut image of all raw orders consists exactly of the cuts passing the straddling test. Over the cut of  $F$ , the fiber is the convex order  $\mathcal{W}(\mathbf{No} \setminus \text{ran } F)$ . Neither successor nor limit first-failure cuts are filled by any raw class well-order.*

*Proof.* A bounded-support enumeration unequal to  $F_R$  first disagrees at a set ordinal, before any non-set-like tail begins. Its comparison with  $R$  is therefore its comparison with  $F_R$ . Equality is possible only when  $F_R$  is exhaustive, in which case it determines  $R$ . Conversely every injection occurs as a first core, by (S16.12). Distinct cores give different cuts by Theorem 46.2, proving exactly the asserted image and fibers.  $\square$

This resolves the earlier report’s represented-cut question using the prefix tree with its numerical labels. It does not claim that the tree is recoverable from the bare order on  $\mathcal{P}_{\text{bd}}(b)$ . Since  $\mathcal{P}_{\text{bd}}(b) \cong \mathbf{No}$ , forgetting those additional predicates can lose precisely the information used by the recognition test.

*Note 46.5* ([merge]; on source 16’s last paragraph). Source 16’s sentence that this “resolves the earlier report’s represented-cut question” is true of the theorem, which all six batch-81 sources prove (note 46.1). Its corollary 46.4 is the statement about raw orders that sources 13, 15, 17 and 18 make in corollary 46.16, corollary 46.8, proposition 46.27 and corollary 46.30; the fibre description in it is source 12’s proposition 15.3, and the image of all raw orders, exactly the cuts passing the straddling test, is the new part. Part IX prints source 14’s trace-fibre theorem (theorem 54.6).

## 46.2 Source 15: a prefix criterion for all represented core cuts

[merge] Source 15’s Section 7, from its Subsection 7.2 (Subsection 7.1, the class of codes, is printed in section 42.3; Subsection 7.5, the automorphism theorem, in section 47).

### 46.2.1 The persistent-cylinder theorem

A normalized class cut of  $\mathcal{P}_{\text{bd}}(b)$  is a nonempty proper initial subclass  $L$  with no greatest member; write  $R = \mathcal{P}_{\text{bd}}(b) \setminus L$ . The upper side may have a least element. A cylinder *crosses* the cut if it meets both sides. For an injective class word  $F : \text{Ord} \rightarrow \mathbf{No}$ , put

$$L_F = \{d \in \mathcal{P}_{\text{bd}}(b) : E_d <_{\text{lex}} F\}.$$

The comparison is defined at the first ordinal difference, unless the functions agree, in which case the strict inequality is false.

**Theorem 46.6** (Exact criterion for representation). *Extension proved in source 15. In GBC, for a normalized class cut  $L$  the following are equivalent:*

1.  $L = L_F$  for an injective class word  $F : \text{Ord} \rightarrow \mathbf{No}$ ;
2. for every ordinal  $\alpha$ , some cylinder  $C_p$  with  $\text{dom}(p) = \alpha$  crosses the cut.

*The representing word is unique. Its restrictions are exactly the unique crossing prefixes. Its construction uses elementary comprehension, not ETR.*

*Proof.* At most one cylinder at a given level crosses. If  $C_p < C_q$  both crossed, a point of  $R$  in  $C_p$  would precede a point of  $L$  in  $C_q$ , contradicting initiality. A restriction of a crossing prefix also crosses. Thus the unique prefixes  $p_\alpha$  in (2) are coherent.

Define  $F(\alpha) = x$  when the crossing prefix of length  $\alpha + 1$  has last value  $x$ . This is an elementary formula: prefixes and codes are sets, and crossing is expressed by two existential set quantifiers with the cut and evaluation as class parameters. Coherence shows that  $F \upharpoonright \alpha = p_\alpha$ ; injectivity holds on every such restriction and hence globally.

If  $E_d \neq F$ , let  $\delta$  be the first difference. The cylinder  $C_{p_{\delta+1}}$  crosses the cut. If  $E_d(\delta) < F(\delta)$ , the whole cylinder is above  $d$ , and its lower-side member forces  $d \in L$ . If  $E_d(\delta) > F(\delta)$ , its upper-side member lies below  $d$ , forcing  $d \in R$ . If  $E_d = F$ , the code  $d$  cannot lie in  $L$ , since it would then be its greatest member. This proves (1).

Conversely, at every  $\alpha$  choose fresh labels  $a < F(\alpha) < c$ , neither in  $\text{ran}(F \upharpoonright \alpha)$ . Completions of  $(F \upharpoonright \alpha) \cap a$  and  $(F \upharpoonright \alpha) \cap c$  lie on opposite sides of  $F$ . Thus  $C_{F \upharpoonright \alpha}$  crosses. These same perturbations show that  $L_F$  is nonempty, proper, and has no greatest member. Uniqueness follows from recovery of every prefix.  $\square$

*Remark 46.7* (The normalization is necessary). Without the no-greatest condition, persistence determines a unique  $F$  but allows either side of a principal point:

$$L_F \subseteq L \subseteq L_F \cup \{d : E_d = F\}.$$

Only a word already represented by a core code permits the two choices. Both  $\{d : E_d < F\}$  and  $\{d : E_d \leq F\}$  cross every level, but the second has a greatest member. Terminal cuts below have neither endpoint.

**Corollary 46.8** (Exhaustiveness and the kernel of the raw cut map). *A persistent cut is represented by a set-like global well-order exactly when*

$$\forall x \in \mathbf{No} \ \exists \alpha \quad x \in \text{ran}(p_\alpha).$$

*Every persistent cut is represented by an arbitrary raw class well-order. Two raw orders determine the same strict lower cut on  $\mathcal{P}_{\text{bd}}(b)$  exactly when their initial words  $F_R$  agree. The common fibre is precisely  $\mathcal{W}(\mathbf{No} \setminus \text{ran}(F_R))$ , interpreted at the appropriate size level.*

*Proof.* The displayed condition says exactly that the recovered word is onto. Every injective word has a raw completion by source 15's Proposition 4.2 (prefix convexity and initial-word fibres; [merge] proposition 51.10; it is proposition 15.3). A raw order and its initial word compare with a core evaluation at the same first ordinal disagreement. If a core evaluation equals that word, its exhaustiveness forces the raw order to have no residual tail. Thus its lower cut is  $L_{F_R}$ . Apply uniqueness in the theorem and the fibre description of the same proposition.  $\square$

This answers the prior report's represented-cut question by a necessary and sufficient condition on all set-length prefix levels. Missing labels are not a failure of persistence. They distinguish the exhaustive words inside the persistent branches. Any ordering information after the first proper block is invisible to comparisons with the bounded-support core.

#### 46.2.2 An exhaustive description of first failure

**Theorem 46.9** (Terminal-cut classification). *Extension proved in source 15. If a normalized class cut fails the criterion, let  $\theta > 0$  be the least length without a crossing cylinder. Exactly one of the following descriptions applies.*

1. **Successor failure.** If  $\theta = \alpha + 1$ , there is a unique crossing prefix  $p : \alpha \rightarrow \mathbf{No}$  and a nonempty initial/final partition

$$A + B = \mathbf{No} \setminus \text{ran}(p), \quad A < B,$$

such that each child  $C_{p \frown x}$  lies wholly in  $L$  for  $x \in A$  and wholly in  $R$  for  $x \in B$ . The four mutually exclusive forms are: an upper boundary of a child cylinder when  $A$  has a greatest element; a lower boundary when  $B$  has a least element; a unique forbidden repeated label separating  $A$  and  $B$  when neither endpoint exists but a surreal separator exists; or a numerical class gap with no surreal separator.

2. **Limit failure.** If  $\theta$  is limit, the coherent union  $p = \bigcup_{\alpha < \theta} p_\alpha$  is an injective set word. The cut is exactly the lower or upper boundary of its nonempty cylinder:

$$L = \{d : E_d \upharpoonright \theta < p\} \quad \text{or} \quad L = \{d : E_d \upharpoonright \theta \leq p\}.$$

*Proof.* The empty cylinder crosses, so  $\theta \neq 0$ . At a successor, child cylinders partition the crossing parent and none crosses. Each is nonempty, giving the asserted partition of allowed labels. Both parts are nonempty because the parent crosses. Their order follows from the order of the cylinders and initiality of  $L$ . All codes below the parent lie in  $L$ , and all those above it lie in  $R$ .

The numerical residual alphabet is dense by the fresh-separator lemma (source 15's Lemma 3.1, lemma 51.2; lemma 5.2), so  $A$  cannot have a greatest element while  $B$  has a least one. If neither endpoint exists and  $s$  strictly separates them,  $s$  cannot be an allowed label: membership in  $A$  or  $B$  would contradict strict separation. Hence  $s \in \text{ran}(p)$ . Two different separators would enclose a fresh allowed label, which is impossible. This proves all four subcases.

At a limit, replacement over the set ordinal  $\theta$  collects the coherent prefixes, and their union is an injective set word. Its cylinder is nonempty by prefix completion but does not cross. A code outside it differs from  $p$  at a coordinate  $\delta < \theta$ ; the crossing cylinder of length  $\delta + 1$  then fixes its side. The only remaining choice is which side contains all of  $C_p$ , giving precisely the two formulas. There is no incoherent-branch case: uniqueness at the earlier levels already ruled it out.  $\square$

**Example 46.10** (A cut not filled even by arbitrary class well-orders). The initial class  $L = \{d : E_d(0) < 0\}$  has no greatest member. Its empty cylinder crosses, but each length-one cylinder lies on one side. It is the lower boundary of  $C_{(0)}$ . Therefore no injective Ord-word and no raw class well-order represents this cut. The upper boundary  $\{d : E_d(0) \leq 0\}$  is likewise unrepresented.

**Example 46.11** (Repeated label, numerical gap, and limit boundary). The cut defined by

$$E_d(0) < 0 \quad \text{or} \quad (E_d(0) = 0 \wedge E_d(1) < 0)$$

first fails at length two: the putative continuation of  $(0)$  would repeat 0. For a numerical-gap example, use  $A = \{x : \exists n \in \omega \ x < n\}$  and its complementary final class of positive infinite surreals, and put  $d \in L$  when  $E_d(0) \in A$ . No surreal strictly separates these label classes; neither relevant endpoint exists. Finally, if  $p(n) = n$  for  $n < \omega$ , the lower and upper boundaries of  $C_p$  first fail at length  $\omega$  even though every finite prefix still crosses.

For a persistent but nonexhaustive example, take  $F(\alpha) = \alpha$ . Every prefix level crosses, but the range omits the negative surreals. Appending a well-order of the omitted range gives many raw completions with exactly the same lower core cut. If  $F$  instead omits just one label, it has one raw completion of type  $\text{Ord} + 1$ . These are sharply different from the terminal cuts in Example 46.10.

### 46.2.3 Local characters of terminal cuts

Here a “set cofinal family” is an actual set of codes cofinal in an ordinary class side of a cut. We say explicitly when none exists; Ord is not being used as a set cardinal.

**Proposition 46.12** (Cofinality read from first failure). *At a first limit failure  $\theta$ , the lower-boundary case has  $\text{cf}(L) = \text{cf}(\theta)$ , while  $R$  has no set coinitial family. The upper-boundary case has the dual properties. At a successor failure with label partition  $A + B$ , if  $A$  has no greatest label,  $L$  has exactly the same least set cofinality as  $A$ , or no set cofinality if  $A$  has none. If  $A$  has a greatest label,  $L$  has no set cofinal family. The dual statements hold for  $B$  and  $R$ .*

*Proof.* At a limit, choose cofinally many coordinates  $\beta < \theta$  and complete prefixes agreeing with  $p$  before  $\beta$  but smaller at  $\beta$ . These form an increasing cofinal family on the lower side. Any cofinal family must have first-divergence coordinates unbounded in  $\theta$ , since a later lower perturbation dominates every family with bounded divergence coordinates. This proves equality. The upper side begins with the whole cylinder  $C_p$ , which has no set coinitial family; all remaining upper-side points are above it.

At a successor with no greatest label in  $A$ , a cofinal set of labels can be lifted to completions, and conversely the next labels of any cofinal family eventually inside the parent cylinder must be cofinal in  $A$ . If  $A$  has a greatest label, its final child cylinder has no set cofinal family and is final on the lower side. The dual argument proves the remaining assertions.  $\square$

No gap of  $\mathcal{P}_{\text{bd}}(b)$  can have both a set cofinal lower side and a set coinitial upper side: the core’s set-cut filling theorem would put a point between such two sets. The character calculation is compatible with this restriction, while identifying many genuinely different class cuts.

### 46.2.4 What a completion would have to mean

The normalized class cuts of  $\mathcal{P}_{\text{bd}}(b)$ , ordered by inclusion, give the natural Dedekind-cut interpretation at the next size level. For a uniform family of such cuts whose union is nonempty and proper, the union is again a normalized class cut: its defining membership formula quantifies over set indices. This is a precise available-family completeness statement, not a same-level class containing all its subclasses.

The map from raw orders to these cuts collapses exactly the residual fibres of [Corollary 46.8](#). Therefore adjoining all raw orders is neither a faithful Dedekind completion of the core nor a realization of every core cut. It both retains multiplicity over persistent cuts and omits all terminal cuts. Any order embedding into a dense completion that fixes the core would have to identify distinct raw orders lying in one fibre, which is impossible. Arbitrary embeddings that move the core are a different question.

## 46.3 Source 13: exact reconstruction of cuts from prefix cylinders

We now address the earlier report’s question asking for a necessary and sufficient cylinder criterion for represented cuts ([research question 113.1](#)). The criterion is relative to the chosen core and prefix system; [Section 47.4](#) will show why it is not a statement about the pure linear order alone.

### 46.3.1 Normalization and crossing

**Definition 46.13.** A *normalized proper cut* of  $\mathcal{P}_s(b)$  is a pair of ordinary classes  $(L, U)$  such that  $L \sqcup U = \mathcal{P}_s(b)$ , both sides are nonempty, every member of  $L$  precedes every member of  $U$ , and  $L$  has no greatest member. The upper side may have a least member.

An injective set prefix  $p$  crosses this cut when

$$\mathcal{P}_s(b)_p \cap L \neq \emptyset, \quad \mathcal{P}_s(b)_p \cap U \neq \emptyset.$$

The normalization is essential. Immediately below and immediately above a code  $d$ , two different cuts would otherwise reconstruct the same branch  $E_d$ . We choose the lower trace convention, so the cut at  $d$  puts  $d$  in the upper side.

**Lemma 46.14** (Uniqueness and coherence of crossing prefixes). *At a fixed ordinal length there is at most one crossing prefix. Restrictions of a crossing prefix cross the same cut. Consequently crossing prefixes of different lengths are coherent.*

*Proof.* Distinct same-length prefixes first differ at a coordinate, placing one entire cylinder below the other. If both cylinders crossed, an upper-side point in the first would precede a lower-side point in the second, impossible. Restriction enlarges a cylinder, so preserves crossing. Apply same-length uniqueness to the restriction of a longer crossing prefix.  $\square$

For  $F \in \mathfrak{J}$ , its lower trace is the class

$$\text{tr}(F) = \{d \in \mathcal{P}_s(b) : E_d < F\}.$$

All comparisons use a least set-ordinal disagreement, except equality, which simply excludes a code from the lower trace.

**Theorem 46.15** (Exact branch representation). *In GBC, a normalized proper cut  $(L, U)$  of  $\mathcal{P}_s(b)$  is the lower trace of a unique  $F \in \mathfrak{J}$  if and only if*

$$\text{for every ordinal } \alpha \text{ there exists a crossing prefix of length } \alpha. \quad (\text{S13.1})$$

*The represented word is exhaustive, hence belongs to  $\mathfrak{W}_{\text{sl}}$ , if and only if it also satisfies*

$$\text{for every } x \in \mathbf{No} \text{ some crossing prefix has } x \text{ in its range.} \quad (\text{S13.2})$$

*Proof.* Suppose first that  $L = \text{tr}(F)$ . For each ordinal  $\alpha$ , the prefix  $F \upharpoonright \alpha$  has code completions below and above  $F$ , by choosing a fresh next value on the desired side. Thus it crosses. It is the unique crossing prefix of that length. Equation (S13.2) is then precisely surjectivity of  $F$ .

Conversely, let  $p_\alpha$  be the unique crossing prefix of length  $\alpha$ . Coherence gives  $p_\alpha = p_\beta \upharpoonright \alpha$  whenever  $\alpha < \beta$ . Define

$$F(\alpha) = p_{\alpha+1}(\alpha).$$

This is an elementary class definition quantifying over the set code  $p_{\alpha+1}$ . It does not ask for a class-valued choice or a class-valued recursive sequence of prefixes. Every two coordinates belong to one longer injective prefix, so  $F$  is injective.

We check the trace equality. If  $E_d < F$ , let  $\xi$  be the first disagreement and choose a crossing prefix of length greater than  $\xi$ . Every code in its cylinder is above  $d$ . One of those codes is in  $L$ , so downward closure gives  $d \in L$ . If  $E_d > F$ , the symmetric argument with an upper-side code gives  $d \in U$ .

The only possible remaining case is  $E_d = F$ . Every other lower-side code has smaller evaluation, by the two arguments just given. If  $d$  were in  $L$ , it would therefore be its greatest member, contradicting normalization. Thus  $L = \text{tr}(F)$ . Distinct words have a code strictly between them by Corollary 42.5, so their traces are distinct. Finally, the union of the prefix ranges is exactly  $\text{ran}(F)$ , which proves the exhaustion criterion.  $\square$

### 46.3.2 What raw well-orders add, and what they cannot add

**Corollary 46.16** (Trace image and fibers of raw orders). *For  $R \in \mathfrak{W}_{\text{all}}$ , define  $L_R = \{d \in \mathcal{P}_s(b) : E_d < R\}$ . The normalized proper cuts represented in this way are exactly those satisfying (S13.1). For such a cut the unique reconstructed word is  $F_R$ . Its raw realization fiber is precisely the order of all well-orders of  $\mathbf{No} \setminus \text{ran}(F_R)$ . The fiber contains a set-like realization exactly when the coverage condition holds, and then it is a singleton.*

*Proof.* Every comparison with a code is decided inside the ordinal head unless the code equals the entire raw order; equality can occur only when the head is exhaustive. Hence  $L_R = \text{tr}(F_R)$ . Conversely, append a well-order of the omitted range to the branch reconstructed by Theorem 46.15. Source 13's Proposition 6.2 ("Canonical head; prior structural lemma", [merge] proposition 51.8; it is theorem 15.1 and proposition 15.3) gives every realization and proves the fiber statement.  $\square$

If the omitted range has  $n$  elements, there are exactly  $n!$  raw realizations. A single omitted label gives one additional point of type  $\text{Ord} + 1$ ; two omitted labels give two adjacent realizations of type  $\text{Ord} + 2$ . These examples were already constructed in the earlier report. The new criterion determines the complete trace image: adding arbitrary non-set-like tails still does not fill a cut that fails the all-level crossing test.

**Example 46.17** (A branch that fails only exhaustion). Let  $F(\alpha) = \alpha$ , viewed as the all-plus surreal of length  $\alpha$ . Its lower trace crosses every prefix length, but its prefixes never contain  $-1$ . It has raw realizations obtained by well-ordering the nonordinal surreals after its head, and no realization in  $\mathfrak{W}_{\text{sl}}$ . This recovers the earlier omitted-range example through the exact criterion rather than through a single selected gap.

## 46.4 Source 13: a complete first-failure classification

The representation theorem reduces the problem to a question about crossing prefixes. The next theorem describes every way the test can fail. In particular, failure at a limit is not an unexplained compactness assumption: it has an exact geometric form.

**Theorem 46.18** (Branch, horizontal cut, or limit boundary). *Let  $(L, U)$  be a normalized proper cut of  $\mathcal{P}_s(b)$ . Exactly one of the following descriptions applies.*

- (i) *There is a crossing prefix at every ordinal length. The cut is the trace of a unique injective class word.*
- (ii) *There is a least failed length  $\lambda = \beta + 1$ . Let  $p$  be the crossing prefix of length  $\beta$ . There is a nonempty cut  $A < B$  partitioning  $Y = \mathbf{No} \setminus \text{ran}(p)$  such that, within  $\mathcal{P}_s(b)_p$ ,*

$$L \cap \mathcal{P}_s(b)_p = \bigcup_{x \in A} \mathcal{P}_s(b)_{p \smallfrown x}, \quad U \cap \mathcal{P}_s(b)_p = \bigcup_{x \in B} \mathcal{P}_s(b)_{p \smallfrown x}.$$

*Thus the cut separates whole next-letter cylinders. We call it horizontal at  $p$ .*

- (iii) *There is a least failed length  $\lambda$  that is a nonzero limit. The union  $p$  of the shorter crossing prefixes has length  $\lambda$ , and the cut is exactly the lower or upper boundary of  $\mathcal{P}_s(b)_p$ .*

*All descriptions are expressible with ordinary class parameters in GBC.*

*Proof.* The empty prefix crosses every proper cut. If some length fails, the class of failed ordinals has a least member  $\lambda > 0$ .

For  $\lambda = \beta + 1$ , uniqueness gives the crossing  $p$  of length  $\beta$ . Every child cylinder is nonempty by prefix completion, but none crosses the cut. Each is therefore entirely on one side. Put  $x \in A$  or  $x \in B$  according to that side. These are ordinary classes: the predicate “every code in this child is in  $L$ ” quantifies only over set codes. Their union is  $Y$ , they are disjoint, and the label order of the children shows  $A < B$ . Both sides are nonempty because the parent crosses. Every code outside the parent lies below all of it or above all of it, so its placement in the cut is forced.

For limit  $\lambda$ , coherence gives an injective set word  $p = \bigcup_{\alpha < \lambda} p_\alpha$ . Its cylinder is nonempty but cannot cross. If a code does not extend  $p$ , it first disagrees at some  $\xi < \lambda$ . A shorter crossing prefix of length greater than  $\xi$  forces its side: a lower disagreement puts it in  $L$ , and an upper disagreement puts it in  $U$ . Thus every code below  $\mathcal{P}_s(b)_p$  is in  $L$ , and every code above it is in  $U$ . The entire  $\mathcal{P}_s(b)_p$  lies on one side, giving precisely one of its two boundaries.

If there is no failed set ordinal, [Theorem 46.15](#) applies. The three cases are disjoint by their first failed length.  $\square$

There is no fourth case called “failure at Ord”. An injective branch that omits labels still crosses every set level; its failure is exhaustion, not prefix existence. Treating Ord as one more set stage would conflate the two tests.

#### 46.4.1 One-sided characters of the three cases

For a class order, say that a side has character Ord when it has no set-sized cofinal (respectively coinital) family but does have a uniform increasing (respectively decreasing) Ord-indexed family. This is a notation for a pair of properties, not a set cardinal. When a set-sized family suffices, use the usual least cofinal cardinal; an endpoint has character 1.

Every ordinary class order without a set-cofinal subset has an Ord-indexed increasing cofinal sequence in GBC: enumerate its points by the global well-order and at each stage choose a point above both the earlier set of choices and the next enumerated point. Absence of a set-cofinal subset guarantees this choice. The dual construction handles coinitality.

**Proposition 46.19** (Characters at first failure). *The cut descriptions have the following character consequences.*

- (i) *A branch trace has character (Ord, Ord) when its word is not a code evaluation. If  $F = E_d$ , its normalized trace has character (Ord, 1); the punctured upper side again has character Ord.*
- (ii) *A lower boundary of a limit-length cylinder  $\mathcal{P}_s(b)_p$ , of length  $\lambda$ , has character (cf  $\lambda$ , Ord). Its upper boundary has character (Ord, cf  $\lambda$ ).*
- (iii) *For a horizontal cut associated with  $A < B$ , the lower character is cf( $A$ ) if  $A$  has no greatest label, and is Ord if  $A$  has a greatest label. The upper character is ci( $B$ ) if  $B$  has no least label, and is Ord if it has a least label.*

*Proof.* The branch statement is [Lemma 42.6](#), with the possible equal code placed in the upper side.

At a lower limit boundary, choose prefixes agreeing with  $p$  up to  $\xi$  and then taking a fresh lower letter. Completions at lengths  $\xi$  cofinal in  $\lambda$  are cofinal below the whole cylinder. Conversely, fewer than cf  $\lambda$  many codes below it have their first-disagreement coordinates bounded below  $\lambda$ , so a later such completion lies above them all. The right side has  $\mathcal{P}_s(b)_p$  as a coinital subclass, and that cylinder has no set-coinital family by [Corollary 42.5](#). The upper-boundary proof is dual.

For a horizontal cut whose lower label side has no greatest member, choose one code in each child along a cofinal family of labels. This family is cofinal among all lower codes. Conversely, projecting a cofinal family of lower codes in the parent onto its next labels is cofinal in  $A$ . Codes

below the parent cannot improve this bound. If  $A$  has a greatest label  $a$ , the whole terminal child  $\mathcal{P}_s(b)_{p \smallfrown a}$  is cofinal on the lower side. Its character is  $\text{Ord}$ , not 1. The upper assertion is the reversed argument.  $\square$

#### 46.4.2 Equal characters do not imply representability

**Example 46.20** (A horizontal  $(\text{Ord}, \text{Ord})$  cut). Let  $s : \text{Ord} \rightarrow \{-, +\}$  be the proper-class sign string whose sign is  $+$  when the finite remainder of its ordinal index is even and  $-$  when it is odd. Both signs occur cofinally. This is *not* a surreal number.

Compare each set-length surreal sign sequence with  $s$  at its first difference, regarding its termination as 0. Every surreal differs from  $s$  by the time of its termination. Define

$$A = \{x \in \mathbf{No} : x < s\}, \quad B = \{x \in \mathbf{No} : s < x\}.$$

These are nonempty classes partitioning the label order. Neither side has an endpoint or a set-sized cofinal or coinital family. Indeed, the birthdays of any proposed set family are bounded by some  $\gamma$ . Truncating  $s$  at a later  $+$  position gives a larger lower label than all lower members of the family; truncating at a later  $-$  position gives a smaller upper label. The corresponding ordinal sequences of truncations supply cofinal and coinital class families.

Now partition the core by its first label:

$$L = \{d : E_d(0) \in A\}, \quad U = \{d : E_d(0) \in B\}.$$

This cut has character  $(\text{Ord}, \text{Ord})$  but no crossing prefix of length 1. It is horizontal at the root, and is not the trace of any injective class word or of any raw class well-order.

Thus neither saturation below set size nor the ordered pair of local characters identifies the represented cuts. The labeled prefix criterion contains strictly more information.

#### 46.4.3 An explicit limit-boundary example

Let  $p(n) = n$  for  $n < \omega$ . The cut just below  $\mathcal{P}_s(b)_p$  is crossed by every finite initial prefix of  $p$ , but not by any prefix of length  $\omega$ . At each finite level, some lower code leaves the ordinal prefix later, while an upper code extends all of  $p$ . The cut has character  $(\omega, \text{Ord})$  and is not represented by a raw global well-order. Its obstruction is a set-length limit boundary rather than an omitted proper-class range. This is the distinction that an informal “keep taking longer prefixes” argument would overlook.

### 46.5 Source 17: recognizing exactly which core cuts are global enumerations

The preceding source results place  $\mathfrak{W}_{\text{sl}}$  in a larger collection of cuts of  $\mathcal{P}_s(b)$ , but do not by themselves identify its image. We now give a necessary-and-sufficient test in terms of the displayed prefix cylinders. This addresses source question [swo:n16.1](#) ([research question 113.1](#)) and its parallel in source 09 (its third direction in [section 113.3](#)). It is a *labelled-tree* recognition theorem; a pure-order recognition theorem would be stronger and, as shown below, cannot hold in the naive invariant form.

### 46.5.1 The straddling test

For an injective set prefix  $p : \alpha \rightarrow \mathbf{No}$ , define the ordinary class

$$C_p = \{c \in \mathcal{P}_s(b) : E_c \upharpoonright \alpha = p\}.$$

Let  $L$  be a proper nonempty lower subclass of  $\mathcal{P}_s(b)$  with no greatest element, and put  $U = \mathcal{P}_s(b) \setminus L$ . We allow  $U$  to have a least element. Thus the convention is the *open lower cut*, including the one immediately before an actual core point. Say that  $p$  straddles  $L$  when  $C_p$  meets both  $L$  and  $U$ .

**Theorem 46.21** (Recognition of injective branches). *The following conditions are equivalent.*

1. *There is an injective class word  $f : \text{Ord} \rightarrow \mathbf{No}$  such that*

$$L = L_f := \{c \in \mathcal{P}_s(b) : E_c <_{\text{lex}} f\}.$$

2. *For every set ordinal  $\alpha$ , there is a straddling injective prefix of length  $\alpha$ .*

*When these conditions hold, both the straddling prefix at each length and the word  $f$  are unique. Moreover  $f$  is surjective if and only if*

$$\forall x \in \mathbf{No} \exists p (p \text{ straddles } L \wedge x \in \text{ran } p). \quad (\text{S17.8})$$

*The reconstruction uses elementary class comprehension over GBC, not ETR.*

*Proof.* Distinct cylinders of the same length are disjoint convex blocks in lexicographic order. At most one can meet both sides of a cut: if an earlier block met  $U$ , every later block would be in  $U$ .

Suppose first that  $f$  is given. For any  $\alpha$ , take its prefix  $p = f \upharpoonright \alpha$ . A fresh smaller next label than  $f(\alpha)$ , and a fresh larger one, yield core completions respectively below and above  $f$ . Thus  $p$  straddles. These completions also show that  $L_f$  has no greatest element and is proper and nonempty.

Conversely, let  $p_\alpha$  denote the unique straddling prefix at length  $\alpha$ . Restrictions of straddling prefixes straddle, so uniqueness implies  $p_\beta \upharpoonright \alpha = p_\alpha$  for  $\alpha < \beta$ . Define a class graph by

$$f(\alpha) = x \iff \exists p (p \text{ is a straddling prefix of length } \alpha + 1 \wedge p(\alpha) = x).$$

The quantifier over  $p$  ranges over sets. Straddling itself quantifies over the set codes in  $\mathcal{P}_s(b)$ , with  $L$  and  $b$  as class parameters. Thus this is elementary comprehension. Coherence makes  $f$  a total function; its set restrictions are injective, so it is injective.

If  $E_c \neq f$ , let  $\delta$  be their first disagreement. The cylinder of  $p_{\delta+1}$  straddles. If  $E_c(\delta) < f(\delta)$ , then  $c$  is below every code in that cylinder, including a code in  $L$ , so  $c \in L$ . The reversed inequality places  $c$  in  $U$ . If  $E_c = f$ , putting  $c$  in  $L$  would make it the greatest member of  $L$ , already excluded. Hence  $L = L_f$  exactly, including the principal-cut case. Two different words would be separated by a core code, so the representing word is unique. Finally  $\text{ran } f$  is the union of the ranges of its straddling prefixes; this proves the coverage criterion.  $\square$

*Remark 46.22* (Why every ordinal length and the endpoint convention matter). Checking only successor extensions along finite histories is inadequate. A cut can track a coherent prefix through all finite levels and then lie at the boundary of its length- $\omega$  cylinder. There is then no straddling cylinder at that limit. In contrast, [Theorem 46.21](#) requires a straddler at *every* set ordinal. Also, a closed principal lower cut would have the same straddling prefixes as the corresponding open one. The hypothesis that  $L$  has no greatest element removes that ambiguity.

### 46.5.2 Three independent failures

**Example 46.23** (A coordinate cut that does not follow a branch). Let  $A \subseteq \mathbf{No}$  consist of those  $x$  with  $x < n$  for some natural number  $n$ , and let  $B = \mathbf{No} \setminus A$ . Both are nonempty,  $A$  has no largest element, and  $B$  has no least element: a positive infinite member of  $B$  has a smaller positive infinite half. Partition core codes by whether their first label lies in  $A$  or  $B$ . The root cylinder straddles, but no length-one cylinder does. This is a genuine cut of the core, but not comparison with an injective Ord-word.

**Example 46.24** (A limit boundary that defeats finite-depth testing). Fix an injective prefix  $p : \omega \rightarrow \mathbf{No}$ . Take the cut immediately before  $C_p$ . At every finite length  $n$ , the cylinder for  $p \upharpoonright n$  meets both cut sides, because a fresh lower label at a later finite coordinate gives a code strictly below  $C_p$ . At length  $\omega$ , the entire cylinder lies on the upper side and no cylinder straddles. This is precisely the limit obstruction in the set-sized cut trichotomy, now at an ordinary class of set codes.

**Example 46.25** (A coherent branch which is not exhaustive). Fix  $r_0 \in \mathbf{No}$  and a bijection  $f : \text{Ord} \rightarrow \mathbf{No} \setminus \{r_0\}$ . The cut  $L_f$  passes the straddling test at every ordinal length, but fails (S17.8) for  $r_0$ . It is not represented by any member of  $\mathfrak{W}_{\text{sl}}$ , since the representing injective word is unique.

These examples separate numerical-cut failure, limit coherence, and exhaustiveness. The test is not merely the assertion that a representation exists restated in different notation: its quantifiers over prefixes and core witnesses are over *sets*, and the representing proper-class function is recovered by one elementary formula.

**Proposition 46.26** (Characters of branch cuts outside the core). *If  $f \in \mathfrak{J}$  has no code in  $\mathcal{P}_s(b)$ , both sides of its core cut have no set-sized cofinal or coinitial subset, respectively. Both admit uniform Ord-indexed approximation families. This is often abbreviated by saying that the cut has character  $(\text{Ord}, \text{Ord})$ ; that notation does not make Ord into a cardinal or set.*

*Proof.* For each  $\alpha$ , extend  $f \upharpoonright \alpha$  by a smaller or larger fresh label and complete in the core, making the choices uniformly using global choice. As  $\alpha$  increases, these codes approach the cut from their respective sides. For any set of codes below  $f$ , Class Replacement bounds all their first disagreements with  $f$  by a set ordinal. A later lower approximation lies above them all. The upper argument is identical. There is no equality case because  $f$  has no core code.  $\square$

### 46.5.3 What the same cut remembers about unrestricted orders

For  $f \in \mathfrak{J}$ , put  $D_f = \mathbf{No} \setminus \text{ran } f$ . Append to the well-order listed by  $f$  any class well-order of  $D_f$ , choosing one using global choice when necessary. The result is a raw class well-order of  $\mathbf{No}$ . Every appended label has a proper class of predecessors; the initial set-like part is exactly  $f$ .

**Proposition 46.27** (Raw lifts and loss of residual information). *All raw well-orders with canonical initial enumeration  $f$  induce the same comparison cut  $L_f$  on  $\mathcal{P}_s(b)$ . Their convex fibre is the lexicographic order of all well-orders of  $D_f$ . Consequently the fibre is a singleton when  $|D_f| = 0$  or 1, and has  $n!$  members when  $|D_f| = n < \omega$ . For larger complements it retains the full residual well-order problem.*

*Proof.* Unless a core enumeration equals  $f$ , its comparison is decided at a set ordinal before any appended label. Equality is possible only when  $f$  is exhaustive, in which case no tail remains. Restriction to  $D_f$  and concatenation with the fixed initial order are inverse order-preserving operations. The source proves this convex-fibre description for all raw orders (proposition 15.3); the argument here identifies its interaction with the reconstructed cut.  $\square$

Thus recognition of an injective branch determines the raw order's first Ord-part but not its residual order. The core is dense in  $\mathfrak{W}_{\text{sl}}$  and  $\mathfrak{J}$ , not in the interiors of these nontrivial raw fibres.

#### 46.6 Source 18: exactly which class cuts of a core are represented

Fix a baseline bijection  $b : \text{Ord} \rightarrow \mathbf{No}$  and let  $\mathcal{P}_s(b)$  be its ordinary class of normalized bounded-support permutation codes. Write  $E_c$  for the enumeration evaluated from a code  $c \in \mathcal{P}_s(b)$ . All such evaluations are supplied by one class relation. For an injective set prefix  $p : \delta \rightarrow \mathbf{No}$ , put

$$C_p = \{c \in \mathcal{P}_s(b) : E_c \upharpoonright \delta = p\}.$$

The core-completion lemma ensures that every such cylinder is nonempty. It is convex. At a fixed length  $\delta$ , these cylinders partition  $\mathcal{P}_s(b)$  and are linearly ordered without overlap.

Throughout this section, a cut is an ordinary class  $L \subseteq \mathcal{P}_s(b)$  that is nonempty, proper, initial, and has no greatest element. This convention uses the strict lower side of a represented point. In particular, it excludes the closed principal cut at a code. Say that  $p$  *straddles*  $L$  if

$$C_p \cap L \neq \emptyset, \quad C_p \setminus L \neq \emptyset.$$

This is an elementary predicate of the set  $p$ , with class parameters  $b, L$ . Its witnesses are set codes, not arbitrary classes.

**Theorem 46.28** (The prefix criterion for represented class cuts). *In GB with the fixed baseline above, the following are equivalent.*

1. *There is an injective class function  $f : \text{Ord} \rightarrow \mathbf{No}$  such that*

$$L = \{c \in \mathcal{P}_s(b) : E_c <_{\text{lex}} f\}.$$

2. *For every ordinal  $\delta$  there is an injective prefix  $p : \delta \rightarrow \mathbf{No}$  that straddles  $L$ .*

*When they hold,  $f$  is unique. At every length  $\delta$ , the unique straddling prefix is  $f \upharpoonright \delta$ . The function  $f$  is defined by an elementary formula from  $b, L$ ; no class choice or ETR is needed to assemble it.*

*Proof.* At most one prefix of a given length can straddle. Indeed, if the cylinder of  $p$  lies below that of  $q$ , an element outside  $L$  in the first cylinder lies below an element of  $L$  in the second, contradicting initiality.

Assume the second condition and denote the unique prefix at length  $\delta$  by  $p_\delta$ . If  $\gamma < \delta$ , the restriction  $p_\delta \upharpoonright \gamma$  also straddles, since its cylinder contains the straddling cylinder of  $p_\delta$ . Uniqueness gives

$$p_\delta \upharpoonright \gamma = p_\gamma.$$

Define

$$f(\alpha) = p_{\alpha+1}(\alpha).$$

The graph is elementary because each  $p_\delta$  is a uniquely specified set. Coherence proves that this is an injective class function and that  $f \upharpoonright \delta = p_\delta$ .

Take a core code  $c$  with  $E_c \neq f$ , and let  $\alpha$  be the first coordinate of disagreement. If  $E_c(\alpha) < f(\alpha)$ , then  $c$  lies below every code in  $C_{p_{\alpha+1}}$ . That cylinder meets  $L$ , so  $c \in L$  by initiality. If  $E_c(\alpha) > f(\alpha)$ , then  $c$  lies above every code in the same cylinder. Its member outside  $L$  shows that  $c \notin L$ . Finally, if  $E_c = f$  and  $c \in L$ , the absence of a greatest element of  $L$  supplies  $d \in L$  with  $E_d > f$ , contradicting the previous case. Hence the displayed cut identity holds in every case.

Conversely, let  $L$  be the strict lower cut of an injective class word  $f$ . For any ordinal  $\delta$ , its prefix  $p = f \upharpoonright \delta$  is a set. Choose fresh surreal labels

$$u < f(\delta) < v, \quad u, v \notin \text{ran}(p).$$

Such labels exist because a set cannot exhaust either numerical interval next to a given surreal. Complete  $p$  followed by  $u$ , and  $p$  followed by  $v$ , to core enumerations. Both completions belong to  $C_p$ , and they lie respectively below and above  $f$ . Thus every prefix straddles. Its uniqueness at each length also proves the uniqueness of  $f$ .  $\square$

For completeness, the strict lower cut of every injective class word is indeed nonempty, proper, and without a greatest element. The first two assertions follow by choosing a smaller or larger first label. If  $E_c < f$  first differs at  $\alpha$ , complete  $f \upharpoonright (\alpha + 1)$  with a fresh next label smaller than  $f(\alpha + 1)$ . The resulting core row lies strictly between  $E_c$  and  $f$ .

*Remark 46.29* (Why the strict-cut convention matters). If  $f = E_c$  is itself a core row, both its strict lower cut and its closed lower cut have a straddling cylinder at every length. The closed cut has greatest element  $c$ . The no-greatest-element hypothesis is therefore necessary for the stated strict-cut criterion; it is not an incidental regularity assumption.

#### 46.6.1 Set-like representation and all raw representations

For a raw class well-order  $R$  of  $\mathbf{No}$ , let  $F_R : \text{Ord} \rightarrow \mathbf{No}$  be the unique enumeration of its canonical initial set-like part. It is injective, and the remaining labels, if any, occur after its entire ordinal-class prefix. The earlier common-prefix theorem shows that a core row and  $R$  are compared at their first ordinal disagreement with  $F_R$ , unless they are identical.

**Corollary 46.30** (Surjectivity is the exact remaining obstruction). *A cut  $L$  is represented by a raw class well-order of  $\mathbf{No}$  if and only if it satisfies the prefix criterion of [Theorem 46.28](#). Let  $f$  be the unique class word recovered from such a cut. Then:*

1.  *$L$  is represented by a set-like global well-order if and only if  $f$  is surjective onto  $\mathbf{No}$ .*
2. *All its raw representatives are exactly the well-orders obtained by putting the sequence  $f$  first and then well-ordering  $Y_f = \mathbf{No} \setminus \text{ran}(f)$ .*
3. *These representatives form the previously described convex fiber isomorphic, in the typed uniform sense, to  $\mathcal{W}(Y_f)$ .*

*Proof.* For any raw representative  $R$ , its cut on the core is the strict lower cut of  $F_R$ . [Theorem 46.28](#) therefore applies and gives  $f = F_R$ . Conversely, append the restriction of the baseline well-order to  $Y_f$  after  $f$ . The range of  $f$  is proper, and its points have precisely set-many earlier  $f$ -values; every appended point has the whole proper range before it. Thus the canonical initial function is exactly  $f$ , and the resulting raw order has cut  $L$ .

A set-like representative has no residual labels, so its canonical function is a bijection. Conversely a bijective  $f$  directly defines a set-like representative. Uniqueness of the recovered class word excludes a different surjective word representing the same cut. The last two statements are the canonical-fiber description.  $\square$

Thus allowing arbitrary raw well-orders fills the omitted-range branch cuts, but it still does not fill every class cut of the core. The first-failure theorem below identifies exactly where an unsuccessful prefix criterion breaks down.

**Corollary 46.31** (Elementary recognition in uniform families). *Relative to the baseline, raw representability of a cut is an elementary property of its class parameter. Set-like representability is also elementary: in addition to a straddling prefix at every length, require*

$$\forall x \in \mathbf{No} \ \exists \delta \in \text{Ord} \ \exists p[p : \delta \rightarrow \mathbf{No} \text{ straddles } L \wedge x \in \text{ran}(p)].$$

*Consequently a uniformly class-indexed family of cuts has an elementary class of raw-represented indices, an elementary class of set-like-represented indices, and a uniform relation recovering the injective words of all raw-represented members.*

*Proof.* All displayed variables are sets. The coverage condition is equivalent to surjectivity of the uniquely recovered word. Insert the family index into the same formulas and apply elementary class comprehension. The input cut remains a class parameter; this does not provide set codes for all cuts or all class words.  $\square$

#### 46.6.2 The first failure: a numerical split or a limit boundary

**Theorem 46.32** (First-failure classification). *Suppose  $L$  fails the prefix criterion, and let  $\delta$  be the least length with no straddling prefix. Then  $\delta > 0$  and exactly one of the following descriptions applies.*

1. **Successor failure.** *If  $\delta = \eta + 1$ , let  $p$  be the unique straddling prefix of length  $\eta$ . The unused alphabet  $Y = \mathbf{No} \setminus \text{ran}(p)$  has a nontrivial class cut  $Y = A \sqcup B$ , with  $A < B$ , such that*

$$C_{p \smallfrown \langle x \rangle} \subseteq \begin{cases} L, & x \in A, \\ \mathcal{P}_s(b) \setminus L, & x \in B. \end{cases}$$

*Outside  $C_p$ , the codes below that cylinder lie in  $L$  and those above it do not.*

2. **Limit failure.** *If  $\delta$  is a limit ordinal, the shorter unique straddling prefixes have a coherent union  $p : \delta \rightarrow \mathbf{No}$ , which is an injective set prefix. Its nonempty cylinder lies wholly in  $L$  or wholly outside  $L$ . The cut is respectively the upper or lower boundary of that cylinder: codes strictly below the cylinder belong to  $L$ , and codes strictly above it do not.*

*Proof.* The empty prefix straddles because  $L$  and its complement are nonempty, so  $\delta > 0$ . Unique shorter straddling prefixes are coherent by the proof of [Theorem 46.28](#).

In the successor case, every next-letter cylinder is nonempty and fails to straddle, so it lies wholly on one side. The two sides of the parent cylinder supply a letter of each kind. Initiality orders the resulting classes  $A < B$ . The straddling parent also forces every code below it into  $L$  and every code above it outside  $L$ .

In the limit case, Class Replacement on the set ordinal  $\delta$  collects the uniquely defined shorter prefixes into a set, so their union  $p$  is a set. Its cylinder is nonempty by core completion, and does not straddle by the defining failure at  $\delta$ . A code outside it first differs from  $p$  at some  $\alpha < \delta$ . The straddling cylinder at length  $\alpha + 1 < \delta$  then decides its side exactly as in the main proof. All codes below the length- $\delta$  cylinder lie in  $L$ , all those above it lie outside, and the entire cylinder itself lies on one side.  $\square$

The successor split is a class cut in the *unused* numerical alphabet. It can be principal at a remaining label, can occur at a label deleted by the prefix, or can be an unfilled class cut of the surreal numerical order. Surreal set-cut interpolation does not imply that an arbitrary class cut has a surreal boundary. The limit case records the independent possibility of reaching an entire set prefix while the cut lies at one of its cylinder's boundaries. Neither failure type is represented even by a raw class well-order, by [Corollary 46.30](#).

**Example 46.33** (A deleted-label cut caused by repetition). Fix  $x \in \mathbf{No}$  and put

$$L_x = \{c \in \mathcal{P}_s(b) : E_c(0) < x \text{ or } (E_c(0) = x \text{ and } E_c(1) < x)\}.$$

This is a nonempty proper initial class without a greatest element. The unique straddling prefix of length 1 is  $\langle x \rangle$ . There is no straddling prefix of length 2: its first entry other than  $x$  already decides the side, and when its first entry is  $x$ , its second entry must be different from  $x$  by injectivity. The first failure is therefore at length 2, where the unused alphabet is split at the deleted label  $x$ .

The cut is not represented by any injective ordinal-class word, and hence by no raw class well-order of  $\mathbf{No}$ . A would-be word would have to begin with  $x, x$ . This is an explicit omitted class cut distinct from the omitted-range branch cuts: enlarging the order from set-like to unrestricted raw well-orders does not repair it. If repeated labels are allowed in class words, however, the constant word  $x, x, x, \dots$  represents this cut. Every injective core row differs from that word by coordinate 1 at the latest.

*Remark 46.34* (Class character does not decide representability). Both sides of  $L_x$  have no set-sized cofinal or coinital witness, respectively, although they have uniform witnesses indexed by  $\text{Ord}$ . To see this, complete the prefixes

$$\left\langle x, x - \frac{1}{\alpha + 1} \right\rangle, \quad \left\langle x, x + \frac{1}{\alpha + 1} \right\rangle \quad (\alpha \in \text{Ord})$$

uniformly to core rows. Since ordinals are cofinal in the numerical surreal order, the first family is cofinal in  $L_x$  and the second is coinital in its complement. Any proposed set-sized witness can be improved at its second coordinate by surreal set interpolation. Thus this unrepresented cut has the same  $(\text{Ord}, \text{Ord})$  class character as omitted-range branch cuts that do have raw representatives. This notation records the stated existence and nonexistence of uniform witnesses; it does not assign a set cardinal to a proper class.

### 46.6.3 Foundational accounting

All cylinders, cuts, and recovered graphs in this section are ordinary classes of sets. Prefixes are set functions; core rows are accessed through set codes. Uniqueness assembles coherent prefixes without a class-choice principle. Replacement is used only on set-sized domains, including the union at a limit failure. The argument never constructs a class containing all class words, never invokes a truth predicate for arbitrary formulas, and never uses ETR. The fixed baseline already supplies the choice strength needed for the previously proved completion and extension lemmas.

## 47 Automorphisms of the core (source 14; sources 17, 15 and 13)

[merge] Four sources show that the bare order of the core, or of the full order of global enumerations, does not remember what the recognition theorem uses. Source 14 classifies the automorphism orbits of class cuts by their characters (complete invariant) and derives that exhaustiveness is not invariant; source 17 gives an exact criterion for an automorphism of the core to extend to the global enumerations, the non-extension theorem and the positive family of numerical relabellings; source 15 gives a weaker form of source 14's corollary; source 13 proves a different theorem, that an automorphism of the full order  $\mathfrak{W}_{s1}$  can move a cylinder to a non-cylinder. Source 14 is printed first.

### 47.1 Source 14: automorphism orbits and the limits of bare-order recognition

The prefix classification has a complementary classification in the language of order alone. It is coarser: different prefix-boundary types can belong to the same orbit under class order automorphisms.

**Lemma 47.1** (Set homogeneity of the core). *Every increasing bijection between two set-sized suborders of  $\mathcal{P}_s(b)$  extends to a class order automorphism of  $\mathcal{P}_s(b)$ .*

*Proof.* Begin with the given partial map and carry out the back-and-forth construction used in [Corollary 44.3](#). At any set stage its domain and range are sets, even though they may already contain the entire initial partial map. The lower and upper images of a new point form a set cut. A strict separator automatically avoids all previously used image points, since each of those is on one of the two sides. The inverse step is symmetric. Taking the coherent union gives a surjective class order embedding extending the original map.  $\square$

**Theorem 47.2** (Complete character invariant for cut orbits). *Two proper normalized class cuts of  $\mathcal{P}_s(b)$  lie in the same orbit under class order automorphisms if and only if they have the same character pair. The possible pairs are exactly*

$$(\rho, \text{Ord}), \quad (\text{Ord}, \rho), \quad (\text{Ord}, 1), \quad (\text{Ord}, \text{Ord}),$$

where  $\rho$  ranges over the infinite regular set cardinals.

*Proof.* A class automorphism and its inverse carry sets to sets and preserve cofinality and coinitality, so equality of characters is necessary. A normalized lower cut has no maximum, so any set-sized cofinality is an infinite regular cardinal. The upper complement either has a least point, with character 1, has infinite regular set coinitality, or has character Ord. Both characters cannot be set-sized by the core set-cut property. These observations exhaust the displayed possibilities. They all occur: lower and upper edges of a prefix of length  $\rho$  realize the first two, a core point realizes the third, and a successor-prefix cylinder edge realizes the fourth.

Suppose first that  $D, D'$  have the same set-sized left cofinality  $\rho$ . Choose strictly increasing cofinal sequences of type  $\rho$  in them. Matching the sequences gives a set partial isomorphism. [Lemma 47.1](#) extends it to an automorphism. Since a normalized lower set is the strict downward closure of any cofinal sequence with no last member, that automorphism carries  $D$  onto  $D'$ . For equal right coinitalities use coinital sequences in their complements and the same argument with upward closures. This includes right character 1, where one simply matches the two least points of the complements.

It remains to consider two cuts with character (Ord, Ord). Each of their four sides is itself a proper class  $\eta_{\text{Ord}}$ -order. For example a set cut inside  $D$  with a nonempty upper side is filled by core saturation, with the interpolant still below an element of  $D$ ; a set with no upper constraints has an upper bound inside  $D$  because  $D$  has no set-sized cofinal subset. Lower bounds remain available from the ambient core. The corresponding argument for the complement uses its absence of a set-sized coinital subset. None of these sides has an endpoint. Back-and-forth therefore gives one class isomorphism  $D \rightarrow D'$  and another between their complements. Their union is an order automorphism of the core, since all points on a lower side precede all points on its upper side.  $\square$

**Corollary 47.3** (Exhaustiveness is not a bare-order invariant). *There are a global exhaustive enumeration  $E$  and a class order automorphism  $g$  of  $\mathcal{P}_s(b)$  such that  $g[D_E]$  is not the trace of any unrestricted class well-order on  $\mathbf{No}$ . In particular, exhaustive representability and even branch representability cannot be recognized by a criterion invariant under all class automorphisms of the bare core order.*

*Proof.* Let  $E$  swap every consecutive ordinal pair of the baseline:

$$E(2 \cdot \alpha) = b(2 \cdot \alpha + 1), \quad E(2 \cdot \alpha + 1) = b(2 \cdot \alpha).$$

It is exhaustive, but it is not represented by a core code, because it moves a proper class of coordinates. Hence  $D_E$  has character (Ord, Ord). The lower edge of the one-letter cylinder  $C_{(b(0))}$  has the same character. The orbit theorem supplies  $g$  carrying the former cut to the latter. A cylinder edge is not a branch trace by [Theorem 43.3](#), and is not a raw-order trace by source 14's [Theorem 10.2](#) (trace fibres; [\[merge\] theorem 54.6](#), and [proposition 15.3](#) for the fibre description). This proves the assertion.  $\square$

Thus the reference to named cylinders in the recognition theorem is not merely a technical limitation of its proof. A genuine symmetry of the bare linear order can destroy the property being recognized. Principal exhaustive cuts are distinguished by their right character 1, but non-core exhaustive cuts are not distinguished from other (Ord, Ord) boundaries. The stabilizer of the exhaustive-cut collection inside the full automorphism group is therefore a proper subgroup, deserving its own study.

*Note 47.4* ([\[merge\]](#); overlaps). [Lemma 47.1](#) is the set-homogeneity of an order filling all set cuts ([theorem 5.17](#), source 09's remark on set-sized partial isomorphisms in its direction 4). [Corollary 47.3](#) and source 17's [theorem 47.7](#) use the same exhaustive enumeration (the baseline with every consecutive pair swapped); source 14 sends its cut to a cylinder edge, source 17 to the cut of a nonexhaustive injective word, and source 15's [theorem 47.10](#) to a first-label cut, so all three show that neither represented cuts nor exhaustive cuts are invariant under automorphisms of the bare core. Source 15's proof that each side of such a cut is a copy of **No** is the argument of source 17's [lemma 47.6](#) and of the last paragraph of the proof of [theorem 47.2](#).

## 47.2 Source 17: automorphisms, an exact extension test and a negative result

Let  $\mathcal{R}_b(L)$  be the predicate saying that  $L$  is a proper nonempty open lower cut of  $\mathcal{P}_s(b)$  which satisfies both the straddling and coverage conditions of [Theorem 46.21](#). Thus  $\mathcal{R}_b$  describes exactly the cuts  $L_E$  with  $E \in \mathfrak{W}_{sl}$ . It is a predicate on individual class parameters, not an ordinary class of cuts.

For a class order-automorphism  $h : \mathcal{P}_s(b) \rightarrow \mathcal{P}_s(b)$ , its action on cuts is  $h_*L = h[L]$ . An extension of  $h$  to  $\mathfrak{W}_{sl}$  means a uniform operator sending each global enumeration to a global enumeration, preserving comparisons and having a uniform inverse, whose action on core enumerations is  $h$ . This convention states the higher-order typing of the assertion.

**Theorem 47.5** (Extension criterion). *A class order-automorphism  $h$  of  $\mathcal{P}_s(b)$  extends to an automorphism of  $\mathfrak{W}_{sl}$  if and only if*

$$\mathcal{R}_b(L) \iff \mathcal{R}_b(h_*L) \quad \text{for every admissible lower class cut } L. \quad (\text{S17.9})$$

*When it exists, the extension is unique and is reconstructed uniformly by [Theorem 46.21](#). No new class-valued recursion is required.*

*Proof.* If  $H$  extends  $h$ , order preservation gives

$$L_{H(E)} = h_*L_E.$$

Applying the same fact to  $H^{-1}$  proves preservation of the represented cut predicate in both directions.

Conversely assume (S17.9). For each  $E$ , form  $L_E$ , take its image under  $h$ , and reconstruct its unique exhaustive word by Theorem 46.21. Call this word  $H(E)$ . The entire construction is elementary from  $E, h, b$ . Distinct rows have distinct cuts, and  $E < F$  if and only if  $L_E \subsetneq L_F$ , because the core is dense between them. Hence  $H$  preserves and reflects order. The same recipe using  $h^{-1}$  is its inverse. For a code  $c$ , the image of the strict lower segment below  $c$  is the strict lower segment below  $h(c)$ , so  $H$  agrees with  $h$  on the core. Finally an extension's value is determined by its comparisons with every core code, proving uniqueness.  $\square$

The criterion gives a precise role to the represented-cut predicate. It is not automatic that an abstract automorphism of the dense core preserves it. In fact it can fail in a strong way.

**Lemma 47.6** (Homogeneity of large two-sided core gaps). *Let  $(L, U)$  be a gap of  $\mathcal{P}_s(b)$  such that  $L$  has no set-sized cofinal subset and  $U$  no set-sized coinital subset. Each of the class orders  $L$  and  $U$  is isomorphic to  $\mathbf{No}$ . Any two such gaps are conjugate by a class order-automorphism of  $\mathcal{P}_s(b)$ .*

*Proof.* Consider a separated pair of sets  $A < B$  in  $L$ . If  $B$  is nonempty, Theorem 42.13 gives a core interpolant below every member of  $B$ , hence lying in  $L$ . If  $B$  is empty, the absence of a set-sized cofinal subset of  $L$  supplies a member of  $L$  strictly above all of  $A$ ; this includes the case  $A = \emptyset$  after choosing any member. Therefore  $L$  has the full set-cut interpolation property. It is proper: a set  $L$  would be a set-sized cofinal subset of itself. The dual proof gives the same property and properness for  $U$ .

The class back-and-forth proof of Corollary 42.14 now yields  $L \cong \mathbf{No} \cong U$ . Given two gaps, choose order-isomorphisms between their lower sides and between their upper sides. The union of these two class maps is an order-automorphism of the core carrying the first gap to the second. This uses only two class maps at a time, not an exhaustive choice of maps for a higher collection of gaps.  $\square$

**Theorem 47.7** (Some core automorphisms do not extend). *In GBC there is a class order-automorphism of  $\mathcal{P}_s(b)$  which does not extend to an automorphism of  $\mathfrak{W}_{sl}$ . More precisely, there is one taking the cut of an exhaustive enumeration to the cut of a nonexhaustive injective word.*

*Proof.* Construct an exhaustive enumeration  $E$  by transposing the two entries in every successive pair of positions of  $b$ . It differs from  $b$  on a proper class of positions, so it has no core code. Choose also a bijection  $F : \text{Ord} \rightarrow \mathbf{No} \setminus \{r_0\}$  for one fixed label  $r_0$ . It cannot have a core code because it is not exhaustive.

By Proposition 46.26, both  $L_E$  and  $L_F$  are genuine two-sided core gaps with no small cofinal or coinital side. Lemma 47.6 supplies an automorphism  $h$  with  $h_*L_E = L_F$ . The first cut satisfies  $\mathcal{R}_b$ , whereas the second fails coverage. Theorem 47.5 rules out an extension. Alternatively, any proposed image  $H(E) \in \mathfrak{W}_{sl}$  would have cut  $L_F$ , whose unique representing injection is the nonexhaustive word  $F$ , a contradiction.  $\square$

**Corollary 47.8** (A limit to pure-order recognition). *Exhaustiveness of a branch cut is not invariant under all automorphisms of the bare class order  $\mathcal{P}_s(b)$ . In particular it cannot be characterized by a parameter-free, automorphism-invariant property of that order and its cuts alone. The two-sided character  $(\text{Ord}, \text{Ord})$  does not suffice.*

This does not preclude recognition using the baseline, labelled prefix tree, or suitable additional predicates. Theorem 46.21 provides exactly such a positive result. Nor does it rule out more subtle reconstruction after adding a distinguished represented-cut predicate. It shows why order-isomorphism of dense cores, by itself, cannot be used to extend maps of the entire higher-order comparison.

### 47.2.1 A natural positive family

**Proposition 47.9** (Relabelling by numerical automorphisms). *If  $\varphi : \mathbf{No} \rightarrow \mathbf{No}$  is an increasing class bijection, then  $E \mapsto \varphi \circ E$  is an automorphism of  $\mathfrak{W}_{\text{sl}}$ , and transporting relations by  $\varphi$  is an automorphism of the unrestricted comparison  $\mathfrak{W}_{\text{all}}$ . It carries the core associated with  $b$  onto the core associated with  $\varphi \circ b$ .*

*Proof.* The first differing labels are transformed by an increasing bijection, so their comparison is unchanged. Surjectivity, injectivity, and the class well-order property are preserved under relabelling. Finally  $\varphi \circ (b \circ \hat{\sigma}) = (\varphi \circ b) \circ \hat{\sigma}$ , with the same set support code.  $\square$

This is a sufficient family of extendible maps, not a classification of all of them. Arbitrary permutations of the label class need not preserve lexicographic order. A general isomorphism between two cores whose baselines differ on a proper class of positions need not extend either; [Theorem 47.5](#) identifies the additional condition that must be checked.

### 47.3 Source 15: the bare order does not determine represented cuts

**Theorem 47.10** (An automorphism destroys prefix representability). *Extension proved in source 15. In GBC, there is a class order automorphism of  $\mathcal{P}_{\text{bd}}(b)$  taking a cut represented by an injective Ord-word to a cut represented by no such word, and therefore by no raw class well-order.*

*Proof.* Take a nonexhaustive word  $F$ . Neither side of  $(L_F, R_F)$  has a set cofinality toward the cut: a set of first-disagreement coordinates can be bounded, and a perturbation agreeing with  $F$  beyond that bound improves every proposed bound. Each side consequently fills all its own set cuts. For a cut with constraints on both sides, use the core interpolation theorem between bounding points in that side. For an empty bounding side, use the absence of a set cofinal or cointial family toward the removed boundary, together with the unboundedness away from it. Thus each side is a copy of  $\mathbf{No}$ .

The class order  $\mathbf{No} + \mathbf{No}$  also fills every set cut. If constraints straddle the summands, choose a point in the first summand above the set of lower constraints; cases with both bounds in one summand reduce to that summand. The cases of constraints extending into the second summand are handled there. Class uniqueness gives  $\mathbf{No} + \mathbf{No} \cong \mathbf{No}$ . Hence there is a numerical partition  $\mathbf{No} = A + B$  with both sides isomorphic to  $\mathbf{No}$ .

Let  $L' = \{d : E_d(0) \in A\}$  and  $R' = \{d : E_d(0) \in B\}$ . This cut has no crossing cylinder at length one, so it is unrepresented. Neither side has a set cofinality toward the cut, as is seen already in its first labels. The preceding interpolation argument shows that  $L'$  and  $R'$  are also copies of  $\mathbf{No}$ . Choose class isomorphisms  $L_F \rightarrow L'$  and  $R_F \rightarrow R'$  and take their union. It is the required automorphism. All these maps have sets as inputs and outputs.  $\square$

Thus even knowing the abstract class order  $\mathcal{P}_{\text{bd}}(b) \cong \mathbf{No}$  is insufficient to identify the enumeration cuts. One must retain predicates for the cylinders, the evaluation map, or equivalent structure. This supplies a negative answer to a natural reconstruction question raised in the prior report. The theorem does not claim that every automorphism of the core extends to the higher collection of all global enumerations.

[merge] Source 15 states [theorem 47.10](#) without naming its foundation; its proof chooses class isomorphisms of the sides of two cuts with  $\mathbf{No}$ , so it is a theorem of GBC, and the words “In GBC” are added at the merge. Its Proposition 4.2 ([proposition 51.10](#)) needs GBC for the same reason. Its closing sentence, a “negative answer to a natural reconstruction question raised in the prior report”, answers [research question 113.4](#) in part only ([section 50](#)).

#### 47.4 Source 13: the pure order does not recover the prefix cylinders

The earlier report asks whether prefix structure can be recovered from the pure order ([research question 113.4](#)). We give a negative answer for the family of all set-prefix cylinders, using only a finite change in how information is grouped.

**Lemma 47.11** (Finite tuples as a surreal class order). *For each positive integer  $n$ , the class  $P_n$  of injective  $n$ -tuples of surreals, ordered lexicographically, is isomorphic to  $\mathbf{No}$ .*

*Proof.* First, finite lexicographic powers  $\mathbf{No}^n$  fill every set cut. At the first coordinate, the lower and upper projected values satisfy all cross weak inequalities. If no cross value is shared, choose a strict separator for that coordinate and fill the remaining coordinates arbitrarily. If a value is shared, it is the unique common one; keep that coordinate and use the active rows in the remaining coordinates. Continuing this way cannot reach two identical opposing tuples, because the original cut was strict. This proves the set-cut property. [Lemma 42.2](#) gives  $\mathbf{No}^n \cong \mathbf{No}$ .

There is a uniform order isomorphism  $\mathbf{No}^n \rightarrow P_n$ : at coordinate  $i$ , map the input value increasingly into the complement of the previously output finite set, using  $h_S$ . Recover the input by the inverse complement map coordinate by coordinate. First disagreements are preserved. Compose the two isomorphisms.  $\square$

Fix an order isomorphism  $k : \mathbf{No} \rightarrow P_2$ . Write  $k(x) = (u_x, v_x)$ , where  $u_x \neq v_x$ . There is a uniform increasing bijection

$$g_x : \mathbf{No} \setminus \{x\} \longrightarrow \mathbf{No} \setminus \{u_x, v_x\}, \quad g_x = h_{\{u_x, v_x\}} \circ h_{\{x\}}^{-1}.$$

**Theorem 47.12** (Cylinder non-rigidity). *In GBC there is a uniform order automorphism of  $\mathfrak{W}_{\text{sl}}$  that maps some prefix cylinder to a class of enumerations that is not any prefix cylinder. Thus the family of all prefix cylinders is not invariant under automorphisms of the pure linear order.*

*Proof.* Define  $H(E)$  by replacing the first label  $x = E(0)$  with the pair  $(u_x, v_x)$ , and translating the remaining labels by  $g_x$ :

$$H(E)(0) = u_x, \quad H(E)(1) = v_x, \quad H(E)(2 + \alpha) = g_x(E(1 + \alpha)).$$

This is a class bijection onto  $\mathbf{No}$ . The first two output labels determine  $x$  by  $k^{-1}$ ; the inverse of  $g_x$  recovers the tail. Therefore  $H$  is a bijection on the virtual domain. Different first input labels are compared by the order isomorphism  $k$ , and equal first labels leave an increasing tail transformation. Hence  $H$  is an order automorphism, with

$$H(C_{(x)}) = C_{k(x)}.$$

Fix a label  $u$ . Then

$$H^{-1}(C_{(u)}) = \bigcup_{x \in A_u} C_{(x)}, \quad A_u = \{x : \text{the first coordinate of } k(x) \text{ is } u\}.$$

The class  $A_u$  contains more than one label, because  $P_2$  contains  $(u, v)$  for every  $v \neq u$ . It is nonempty and proper, since pairs with another first coordinate also exist. The displayed inverse image therefore contains enumerations with different first labels, but is not the whole domain. It cannot be a nonempty-prefix cylinder, all of whose members have the same first label, and it cannot be the empty-prefix cylinder, which is the whole domain. Apply the automorphism  $H^{-1}$  to  $C_{(u)}$ .  $\square$

#### 47.4.1 What the counterexample does not say

The theorem rules out a parameter-free order-theoretic characterization whose members are exactly the prefix cylinders. It also rules out recovering their original tree canonically from the pure linear order. It does not say that no useful interval structure is recoverable, that every order automorphism arises by block recoding, or that the chosen core  $\mathcal{P}_s(b)$  is preserved by  $H$ .

In particular, the expanded structure containing the core, its set-support filtration, birthday data, or an explicit prefix predicate may have a much smaller automorphism group. The cut criterion of [Theorem 46.15](#) is correctly a criterion in such an expanded prefix presentation. Its non-invariance under forgetting that presentation is a substantive feature, not a foundational flaw.

#### 47.4.2 Finite block depth is not intrinsic either

Using  $P_n$  instead of  $P_2$  replaces one first label by any fixed positive finite number of distinct labels, with a complement isomorphism applied to the tail. The same construction gives an order automorphism that sends first-level cylinders to selected  $n$ th-level cylinders. Thus even finite prefix depth has no absolute meaning in the pure order, despite being indispensable to a particular lexicographic presentation.

[merge] Source 13's opening sentence refers to [research question 113.4](#), which its theorem answers in part. [Lemma 47.11](#) uses the family  $h_S$  of [lemma 42.2](#).

### 48 Class extensions (source 14; source 17)

[merge] Sources 14 and 17 prove the same theorem: for two class realizations with the same sets and a common baseline, an old core cut is the cut of a global enumeration in the larger realization exactly when it already is in the smaller one, and the enumeration is then old. The proof is the elementarity of the recognition criterion. Source 17 adds that every proper class extension adds a new global enumeration and a new represented cut ([theorem 48.4](#)). Source 14's text, from the second half of its Section 7, is printed first.

**Theorem 48.1** (No new realization of an old trace cut). *Suppose  $(M, \mathcal{C})$  and  $(M, \mathcal{D})$  are models of GBC with the same set structure,  $\mathcal{C} \subseteq \mathcal{D}$ , and a common baseline enumeration  $b \in \mathcal{C}$ . If a proper normalized core cut  $D$  belongs to  $\mathcal{C}$ , then*

$$(M, \mathcal{C}) \models \exists E \in \mathfrak{W}_{\text{sl}} (D = D_E) \iff (M, \mathcal{D}) \models \exists E \in \mathfrak{W}_{\text{sl}} (D = D_E).$$

*Moreover, when it exists, the realizing enumeration in the larger model is already a class of the smaller model.*

*Proof.* The canonical support codes, the cylinders, and their membership relations are defined from the same sets and  $b$ . Every formula in (C), (X), and the reconstruction formula has set quantifiers and the old class parameters  $D, b$  only. Its truth is therefore the same in the two structures. If the larger model contains a realizing enumeration, the recognition theorem gives (C) and (X) there and hence in the smaller model. Elementary comprehension in the smaller model constructs the displayed graph from  $D, b$ . It is the same graph as the larger model's enumeration by uniqueness. The converse is immediate.  $\square$

**Corollary 48.2.** *An enumeration newly available after such a class extension has a trace cut not belonging to the old class collection. An old nonexhaustive branch cut, cylinder edge, or numerical-gap cut is not turned into the trace of a global enumeration by enlarging only the class part.*

*Remark 48.3* (Scope of absoluteness). The theorem holds because realizability of this particular kind of cut has an elementary, uniquely reconstructing criterion. It is not an assertion that all class-existence questions are absolute, that the virtual enumeration order is unchanged, or that arbitrary internal well-foundedness is externally absolute. The set structure and the baseline must remain fixed. New classes can, and in suitable realizations do, supply new enumerations and new cuts simultaneously.

#### 48.1 Source 17: what changes when the available classes change?

Let  $(M, \mathcal{X}) \subseteq (M, \mathcal{Y})$  be two transitive two-sorted models of GBC with the same sets and  $\mathcal{X} \subseteq \mathcal{Y}$ . Assume the baseline  $b$  belongs to  $\mathcal{X}$ . The assertions below can also be stated internally as preservation statements for a specified same-set extension; the transitive formulation avoids irrelevant ambiguities about external well-foundedness.

**Theorem 48.4** (New enumerations are exactly new represented core cuts). *The set-code carrier  $\mathcal{P}_s(b)$ , its order relation, and its labelled set-prefix cylinders are unchanged between the two models. For any  $E \in \mathfrak{M}_{sl}^{\mathcal{Y}}$ ,*

$$E \in \mathcal{X} \iff L_E \in \mathcal{X}.$$

*Consequently every genuinely larger class realization  $\mathcal{X} \subsetneq \mathcal{Y}$  adds a global enumeration and a represented cut of the unchanged core.*

*Proof.* Support codes and prefixes are sets, and the two models have exactly the same sets. Their evaluations use the same baseline class. All relations in the definition of a cylinder are therefore the same.

If  $E \in \mathcal{X}$ , elementary comprehension in the smaller model gives  $L_E \in \mathcal{X}$ . Conversely, suppose  $L_E \in \mathcal{X}$ . At every ordinal length, the assertion that a set prefix straddles this cut has the same truth value in the two models: its witnesses are set codes and its quantifiers range over their common sets. Thus the smaller model can reconstruct the unique branch by the elementary formula in [Theorem 46.21](#). Its graph must be  $E$ , so  $E \in \mathcal{X}$ . Coverage is also an elementary assertion with the same set domain.

For the final assertion, choose  $A \in \mathcal{Y} \setminus \mathcal{X}$ . A global well-order already in  $\mathcal{X}$  gives a class bijection  $g : \text{Ord}^M \rightarrow M$ . The pullback  $D = g^{-1}[A]$  is a subclass of  $\text{Ord}^M$  in  $\mathcal{Y}$  and not in  $\mathcal{X}$ , since  $A$  is recovered from it by the same old  $g$ . Encode  $D$  by listing each sorted baseline pair in increasing or decreasing order according as its index is absent from or present in  $D$ . This yields  $E_D \in \mathfrak{M}_{sl}^{\mathcal{Y}}$ . Pair orientation recovers  $D$ , so  $E_D$  is not in  $\mathcal{X}$ . Its core cut is new by the first part of the theorem.  $\square$

For pre-existing global enumerations, their comparisons and their surjectivity are unchanged. A bijection from the common ordinal class still induces a well-order: any nonempty subclass of its index class has a least ordinal, witnessed below any one of its members. Thus the old set-like comparison sits inside the new one with its order intact, even though the represented-cut collection strictly expands.

This result answers a precise part of the source's class-realization question. It does not reconstruct the entire class collection from the *unlabelled external order type* of its admitted enumerations. The proof uses the baseline and its fixed decoder. That stronger reconstruction problem remains open here.

## 49 Support-restricted suborders and the exact reserve (source 14; source 17)

[merge] Source 14 measures how much support an interpolant needs; source 17 measures how much support beyond the forced positions a completion of a partial injection needs. Source 14's Section 9 is printed first, then source 17's Section 7.

### 49.1 Source 14: a sharp hierarchy of support-restricted orders

Fix an infinite set cardinal  $\kappa$  and define

$$\mathcal{P}_{<\kappa}(b) = \{\sigma \in \mathcal{P}_s(b) : |\text{supp}(\sigma)| < \kappa\}.$$

For an infinite regular cardinal  $\theta$ , an  $\eta_\theta$ -order is a linear order in which every separated pair  $A < B$  with  $|A \cup B| < \theta$  has a strict separator, including when one side is empty. This convention makes  $\eta_\omega$  mean dense without endpoints. The class-sized orders here need not have cardinality  $\theta$ .

The predecessor distinguishes finite support from arbitrary set support ([proposition 19.31](#); Section 19 of this report at the pin). We now give an exact intermediate hierarchy, including singular thresholds. The key is to compress the support of a separator without preserving its irrelevant later coordinates.

**Lemma 49.1** (Small-support extension of a partial injection). *Let  $f : D \rightarrow \text{Ord}$  be a set injection. It extends to a class permutation of  $\text{Ord}$  with finite support if  $D$  is finite, and with support of cardinality at most  $|D|$  if  $D$  is infinite. One may require that any specified set of already prescribed fixed positions, disjoint from  $D \cup f[D]$ , stay fixed.*

*Proof.* Put  $T_0 = D \cup f[D]$ . For finite  $D$ , the complements  $T_0 \setminus D$  and  $T_0 \setminus f[D]$  have the same finite cardinality. Choose a bijection between them and combine it with  $f$ ; fix everything outside  $T_0$ . For infinite  $D$  of cardinality  $\nu$ , adjoin a fresh set  $B$  of  $\nu$  ordinals disjoint from  $T_0$  and from the specified fixed positions. With  $T = T_0 \cup B$ , both  $T \setminus D$  and  $T \setminus f[D]$  have cardinality  $\nu$ . A bijection between them extends  $f$  to a permutation of  $T$ , again extended by the identity. The resulting support has cardinality at most  $\nu$ .  $\square$

**Lemma 49.2** (Support compression). *Let  $A, B$  be separated sets of core codes and let*

$$S = \bigcup \{\text{supp}(\sigma) : \sigma \in A \cup B\}.$$

*There is a strict separator whose support is finite if  $S$  is finite, and has cardinality at most  $|S|$  if  $S$  is infinite.*

*Proof.* By [Corollary 44.2](#), choose a separator  $Q \in \mathcal{P}_s(b)$ . If its support is contained in  $S$ , nothing remains to prove. Otherwise let

$$\gamma = \min(\text{supp}(Q) \setminus S).$$

Every input permutation fixes  $\gamma$ , while  $\hat{Q}$  moves it. Thus the first disagreement between  $E_Q$  and every input enumeration occurs no later than  $\gamma$ . Any permutation agreeing with  $\hat{Q}$  through  $\gamma$  will preserve all those comparisons.

Let  $D = \{\alpha \leq \gamma : \hat{Q}(\alpha) \neq \alpha\}$ . By minimality of  $\gamma$ ,  $D \subseteq S \cup \{\gamma\}$ . Keep the partial injection  $\hat{Q} \upharpoonright D$ . None of its images is a prescribed fixed position  $\beta \leq \gamma$  outside  $D$ : otherwise  $\hat{Q}(\beta) = \beta = \hat{Q}(\alpha)$  for a distinct  $\alpha \in D$ , contradicting injectivity. Apply [Lemma 49.1](#) while retaining those fixed positions. For infinite  $D$  its buffer can explicitly be chosen above  $\gamma$ . The resulting permutation agrees with  $\hat{Q}$  through  $\gamma$ , hence is still a strict separator. Its support is finite when  $S$  is finite, and is at most  $|S|$  when  $S$  is infinite, since  $|D| \leq |S \cup \{\gamma\}|$ .  $\square$

**Theorem 49.3** (Exact support saturation and an attained obstruction). *For every infinite set cardinal  $\kappa$ , put  $r = \text{cf } \kappa$ . Then  $\mathcal{P}_{<\kappa}(b)$  is an  $\eta_r$ -order but not an  $\eta_{r+}$ -order. More precisely, there are increasing  $(l_i)_{i<r}$  and decreasing  $(u_i)_{i<r}$  in  $\mathcal{P}_{<\kappa}(b)$  such that  $l_i < u_j$  for all  $i, j$ , and every core separator moves at least  $\kappa$  coordinates. A separator of support cardinality exactly  $\kappa$  exists in  $\mathcal{P}_s(b)$ .*

*Proof.* For the positive assertion take  $A, B \subseteq \mathcal{P}_{<\kappa}(b)$  with  $|A \cup B| < r$ . Fewer than  $\text{cf } \kappa$  sets, each of cardinality  $< \kappa$ , have union of cardinality  $< \kappa$ . Their union of supports therefore satisfies  $|S| < \kappa$ . Support compression gives an interpolant with support  $< \kappa$ . For  $\kappa = \omega$  both the family and all its supports are finite, so the finite clause applies.

For sharpness choose strictly increasing ordinals  $(\lambda_i)_{i<r}$  cofinal in  $\kappa$ . Consider the injective prefix

$$p : \kappa \rightarrow \mathbf{No}, \quad p(\alpha) = b(\alpha + 1).$$

Every infinite initial cardinal is a limit ordinal, so this formula uses coordinates below  $\kappa$ . It moves every coordinate of its domain relative to  $b$ . For each  $i$ , choose fresh labels

$$a_i < p(\lambda_i) < c_i, \quad a_i, c_i \notin \text{ran}(p \upharpoonright \lambda_i),$$

and extend the two prefixes

$$(p \upharpoonright \lambda_i) \frown (a_i), \quad (p \upharpoonright \lambda_i) \frown (c_i)$$

to enumerations with codes  $l_i, u_i$ . Their partial ordinal maps have domains of cardinality  $|\lambda_i + 1| < \kappa$ ; by Lemma 49.1 they can be completed with support  $< \kappa$ , even when a chosen label has a very large baseline index. Set choice suffices to make the  $r$  choices simultaneously.

For  $i < j$ , comparison at  $\lambda_i$  gives  $l_i < l_j$  and  $u_j < u_i$ . The same first-coordinate argument gives  $l_i < u_j$  for every  $i, j$ . Suppose any global enumeration  $E$  separated the two families and first differed from  $p$  at some  $\alpha < \kappa$ . Choose  $i$  with  $\lambda_i > \alpha$ . Both  $E_{l_i}$  and  $E_{u_i}$  agree with  $p$  through  $\alpha$ . According to its differing value there,  $E$  would lie below both or above both, a contradiction. Hence any separator satisfies  $E \upharpoonright \kappa = p$ . Relative to  $b$  it must move all  $\kappa$  coordinates of that prefix. In particular no member of  $\mathcal{P}_{<\kappa}(b)$  separates the families.

Finally extend  $p$  itself by Lemma 49.1. Its domain has cardinality  $\kappa$ , so the extension has support at most  $\kappa$ ; the forced moves show the support is exactly  $\kappa$ . It separates the two families by comparison at  $\lambda_i$ . The obstruction has combined cardinality  $r$ , hence violates  $\eta_{r+}$ , and its minimum support cost is attained.  $\square$

#### 49.1.1 Consequences and examples

For a regular  $\kappa$  the answer is exactly  $\eta_\kappa$  but not  $\eta_{\kappa+}$ . In particular finite support is dense without endpoints but can fail a countable cut; countable support fills every countable strict cut but can fail a cut of size  $\omega_1$ . For  $\kappa = \aleph_\omega$ , the cofinality is  $\omega$ , so support of every cardinality below  $\aleph_\omega$  still does not guarantee countable-cut filling. The same construction takes supports cofinal in the threshold and forces their full union at the limit.

This sharpness statement is stronger than merely exhibiting some gap: it quantifies how much extra support any solution must use. It also explains why replacing a singular support bound by its cardinal size in a saturation argument is invalid. The closure property used in the positive direction is closure under unions of fewer than  $\text{cf } \kappa$  supports, not fewer than  $\kappa$  supports.

**Proposition 49.4** (Universality without high saturation). *Every  $\mathcal{P}_{<\kappa}(b)$  contains an order-isomorphic copy of  $\mathbf{No}$ , already among the permutations with support at most two. Thus, in GBC, it contains every ordinary class linear order up to embedding. Nevertheless no fixed  $\mathcal{P}_{<\kappa}(b)$  is isomorphic to  $\mathbf{No}$ , and it is not dense in  $\mathfrak{W}_{\text{sl}}$ .*

*Proof.* For  $x \in \mathbf{No}$ , transpose the baseline positions 0 and  $b^{-1}(x)$ , using the identity if these coincide. Call the code  $t_x$ . Then  $E_{t_x}(0) = x$ , so  $x < y$  implies  $t_x < t_y$ . The familiar class universality of  $\mathbf{No}$  follows by inserting points of any ordinary class linear order, in a fixed set-like global enumeration, between the images of their earlier lower and upper neighbors; every stage has only set many constraints. Composing gives the asserted embeddings.

**Theorem 49.3** supplies a set cut not filled by  $\mathcal{P}_{<\kappa}(b)$ , whereas  $\mathbf{No}$  fills all set cuts, so the two orders are not isomorphic. For ambient nondensity, use the prefix  $p$  of length  $\kappa$  in that theorem. Choose two distinct fresh next labels and complete both prefixes to core enumerations. Every enumeration between them shares  $p$  and hence moves at least  $\kappa$  baseline coordinates. The nonempty open interval they determine misses  $\mathcal{P}_{<\kappa}(b)$  entirely.  $\square$

*Remark 49.5* (Cardinality versus location of support). The theorem restricts  $|\text{supp } \sigma|$ , not the ordinal height of the support. A transposition with an arbitrarily late baseline coordinate still has support two. Replacing the cardinality condition by  $\text{supp } \sigma \subseteq \gamma$  for one fixed ordinal  $\gamma$  gives a set-sized permutation space with quite different universality. These two filtrations should never share an undifferentiated “bounded” label.

*Note 49.6* ([merge]; the finite case is source 08’s). At  $\kappa = \omega$ , **theorem 49.3** is source 08’s **proposition 19.31** (printed in Part IV), with the same witness prefix  $p(n) = b(n+1)$  and the same fresh labels; source 14 cites the finite-support subsection but not the proposition. New in source 14 are the positive half ( $\mathcal{P}_{<\kappa}(b)$  is  $\eta_r$ ), the threshold at every infinite  $\kappa$ , including singular  $\kappa$ , and the attained support cost  $\kappa$  of a separator. **Proposition 49.4** extends source 08’s remark that the finite-support codes contain a copy of  $\mathbf{No}$  (**note 19.9**).

## 49.2 Source 17: the optimal extra support needed to extend a partial injection

The source extends a prescribed prefix inside a sufficiently large cardinal block. That argument is safe but leaves a more elementary optimization question: how many *additional moved positions* are actually necessary? The following answer applies to arbitrary set-sized partial injections, not just prefixes.

**Theorem 49.7** (Exact reserve cardinal). *Let  $A \subseteq \text{Ord}$  be a set and let  $h : A \rightarrow \text{Ord}$  be injective. Define*

$$D = \{\xi \in A : h(\xi) \neq \xi\}, \quad R = h[D], \quad S = D \cup R, \quad u = |R \setminus D|, \quad v = |D \setminus R|.$$

*Among class permutations  $\pi : \text{Ord} \rightarrow \text{Ord}$  with set support which extend  $h$ , the minimum possible value of  $|\text{supp}(\pi) \setminus S|$  is*

$$\tau(h) = \begin{cases} 0, & u = v, \\ \max(\aleph_0, u, v), & u \neq v. \end{cases} \quad (\text{S17.6})$$

*Moreover every point of  $S$  must move. An extension attaining the bound can be constructed by a bijection between two explicitly specified sets. The theorem uses only set choice and elementary operations with the class of ordinals; with a fixed global choice parameter the construction can be made uniform.*

*Proof.* The fixed points  $A \setminus D$  are disjoint from  $R$ , by injectivity of  $h$ . Every  $d \in D$  must move. If  $r \in R \setminus D$ , it already has a preimage  $d \neq r$  under the prescribed map, so an extending permutation cannot fix  $r$ . Thus every point of  $S$  must move.

Suppose  $\pi$  is an extension and put  $T = \text{supp}(\pi) \setminus S$ . No point of  $T$  is in  $A \setminus D$ , whose values are prescribed to be fixed. The support of a permutation is invariant under the permutation and

its inverse. After the prescribed bijection  $h : D \rightarrow R$  has been removed,  $\pi$  must therefore give a bijection

$$(R \setminus D) \cup T \longrightarrow (D \setminus R) \cup T. \quad (\text{S17.7})$$

In particular  $u + |T| = v + |T|$ . If  $u \neq v$  are finite, finite cancellation rules out finite  $T$ , and  $\aleph_0$  suffices. If at least one of  $u, v$  is infinite, unequal cardinals can be equalized by addition of  $|T|$  only when  $|T| \geq \max(u, v)$ . This follows from the formula for addition of infinite cardinals as their maximum. These observations prove the lower bound in (S17.6).

Conversely, choose a fresh set of ordinals  $T$  of cardinality  $\tau(h)$ , disjoint from  $A \cup R$ , and choose a bijection in (S17.7). Combine it with  $h : D \rightarrow R$ , and take the identity outside  $S \cup T$ . The result is a permutation extending  $h$ , with support contained in  $S \cup T$ . All points of  $S$  move, as proved above. If  $\tau(h) > 0$ , the lower bound forces exactly  $\tau(h)$  further points to move; if  $\tau(h) = 0$ , no reserve was used. This proves attainment, including cases where the chosen bijection happens to fix some points of  $T$ .  $\square$

**Example 49.8** (Why a finite reserve can never repair a one-sided shift). Prescribe  $h(n) = n + 1$  for every  $n < \omega$ . Then  $D = \omega$ ,  $R = \omega \setminus \{0\}$ , and  $(u, v) = (0, 1)$ . No permutation on  $\omega$  extends  $h$ . More strongly, no extension can use only finitely many additional moved positions outside  $\omega$ . Exactly countably many are necessary and sufficient. One concrete completion chooses fresh  $t_0, t_1, \dots$ , sends  $t_0$  to 0, and sends  $t_{n+1}$  to  $t_n$ ; all other ordinals are fixed.

**Example 49.9** (Finite partial injections require no reserve). When  $D$  is finite,  $|D| = |R|$  implies  $|R \setminus D| = |D \setminus R|$ . Hence every finite partial injection extends to a permutation supported exactly on  $D \cup R$ . The distinction between this fact and the preceding infinite example is precisely the failure of finite cancellation for infinite sets; finite testing alone cannot find the infinite obstruction.

**Corollary 49.10** (Application to prescribed surreal prefixes). *Fix a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . If  $p : \alpha \rightarrow \mathbf{No}$  is an injective set prefix, apply Theorem 49.7 to  $h = b^{-1} \circ p$ . The resulting  $b \circ \pi$  extends  $p$  and agrees with  $b$  outside a set. Formula (S17.6) gives the exact minimum number of moved coordinates beyond the necessarily moved set  $D \cup h[D]$ .*

This is a cardinal optimum relative to a given partial injection and baseline. It does not assert a minimum *ordinal* support bound, a minimum birthday of a code, or a canonical extension independent of choice. Those are different optimization problems. The source’s larger-cardinal completion remains a useful simple implementation; the reserve formula says exactly when its extra room is genuinely necessary.

*Note 49.11* ([merge]; the reserve theorem in this report). Theorem 49.7 sharpens source 09’s remark 19.7: the example  $n \mapsto n + 1$  there is source 17’s example 49.8, and the theorem says exactly when the larger cardinal of lemma 19.4 is needed and how many extra positions suffice. The two support theorems are consistent: lemma 49.1 bounds the support of an extension of a set injection  $f : D \rightarrow \text{Ord}$  by  $|D|$  when  $D$  is infinite and keeps it finite when  $D$  is finite, while theorem 49.7 computes the least number of moved positions outside the forced set: 0 for finite partial injections (example 49.9), and otherwise 0 or  $\max(\aleph_0, u, v) \leq |D|$ . Source 17’s question table maps the reserve theorem to source 11’s research question 113.6; that question asks for birthday bounds, and the theorem bears instead on source 09’s direction “Sharp birthday and support bounds” and source 08’s question 13 (section 50).

## 50 What this Part answers

[merge] Dated notes, 3 October 2026, in the form of [section 33](#); where the question index of [section 113](#) (dated 2 October 2026) says otherwise, these notes supersede it.

- (a) *Source 11's research question 113.1 and source 09's direction "Which cuts of the core represent exhaustive branches?"* ([section 113.3](#)): **answered**, in the labelled-tree form the question asks for. A normalized class cut of the core is the cut of an injective class word exactly when a crossing prefix exists at every set length; the word is unique and elementary in the cut; it is exhaustive exactly when the crossing prefixes cover **No** ([theorem 45.1](#); six proofs, [note 46.1](#)). Every other proper cut is a cylinder edge or a numerical gap after a set prefix, with unique data ([theorem 43.3](#)); the missing labels, the forbidden repeated labels and the cuts escaping every coherent branch that [research question 113.1's](#) commentary asks to separate are exactly the coverage failure, source 15's repeated-label case and the edge and gap cuts. A recognition from the bare order is impossible (item (c)).
- (b) *Source 08's question 8, higher-size cuts and completion* ([section 113.4](#)): answered for the class cuts of the core relative to its prefix presentation: the trichotomy and characters ([theorems 43.3](#) and [44.1](#)), the image of the raw orders ([corollary 46.4](#)), and source 15's remark that adjoining the raw orders is neither a Dedekind completion of the core nor a realization of every core cut ([section 46.2](#)). Cuts given by higher collections of classes stay open.
- (c) *Source 11's research question 113.4, source 09's direction "Automorphisms beyond set-sized partial maps" and source 08's question 6*: answered in part, negatively. The automorphism orbits of class cuts of the core are exactly the four character classes ([theorem 47.2](#)); neither represented nor exhaustive cuts are invariant under automorphisms of the bare core ([corollary 47.3](#) and [theorems 47.7](#) and [47.10](#)); the prefix cylinders of  $\mathfrak{W}_{\text{sl}}$  are not invariant under automorphisms of  $\mathfrak{W}_{\text{sl}}$ , nor is finite prefix depth ([theorem 47.12](#)). An automorphism of the core extends to  $\mathfrak{W}_{\text{sl}}$  exactly when it preserves represented cuts ([theorem 47.5](#)). Open: the stabilizer of the exhaustive cuts, and which extra predicates make the reconstruction unique (source 14's and source 17's own questions).
- (d) *Source 11's research question 113.5, baselines*: its suggested restricted first case is settled: a baseline change by an increasing class bijection of **No** is an automorphism of  $\mathfrak{W}_{\text{sl}}$  and of  $\mathfrak{W}_{\text{all}}$  carrying one core onto the other ([proposition 47.9](#), source 08's remark in its question 6). The general case is open.
- (e) *Source 11's research question 113.8, source 12's research question 113.18 and source 08's question 12, class realizations*: answered in part. Over a fixed set structure and baseline, the represented-cut status of an old core cut is absolute, its enumeration is old, and every proper extension of the class part adds a global enumeration and a represented cut ([theorems 48.1](#) and [48.4](#)). What the unlabelled external order type remembers is open here (Part IX prints source 18's countable models, [section 58](#), and [section 60](#) (e) records what they answer).
- (f) *Source 09's direction "Sharp birthday and support bounds" and source 08's question 13*: answered in part for support. The least support cardinal of an interpolant in  $\mathcal{P}_{<\kappa}(b)$  is governed by  $\text{cf } \kappa$  ([theorem 49.3](#)), and the least reserve of a completion of a partial injection is 0 or  $\max(\aleph_0, u, v)$  ([theorem 49.7](#)). Ordinal support bounds, birthday bounds and the forced-prefix length remain open, as source 17 says.
- (g) *Source 11's research question 113.6* is not affected by the reserve theorem ([note 49.11](#)).

[merge] Dated note, 3 October 2026 (batch 83). Items (c)–(f) are answered further by Parts XIII and XIV: unlabelled cylinders do not recognize exhaustiveness while equality of labels across

extension edges does, the admitted labelled enumerations recover a class realization, and the least ordinal support is computed (sections 105 and 112; section 113.25 (e), (h), (i)).

## Part IX

# Unrestricted class well-orders: canonical blocks, condensation, products, comprehension and models

[merge] (3 October 2026.) The fourth and last Part of the batch-81 addition (section 1.8; notation in section 1.3.1). Part III (part III) compared arbitrary class well-orders of **No** directly, extracted the canonical initial set-like part of each, and asked how far that extraction can be iterated (research question 113.3); Part V (part V) compared the two global orders in larger universes. This Part prints what sources 13–18 prove beyond those Parts, and every remaining section of theirs on foundations, universes and formalization:

- their restatements of the order facts and of the direct comparison of class well-orders (section 51), all re-proofs of Parts I and III;
- the canonical decomposition of a class well-order into proper blocks of type **Ord** and one optional final set block, and the theorem that every class well-order is a block-index order (section 52), proved by sources 15, 16 and 18;
- explicit condensation histories of every class length and what they say about recursion strength (section 53, source 15);
- the maximal finite components of the unrestricted order and the trace fibres of the core (section 54, sources 17 and 14);
- asymmetric products (section 55, source 13);
- binary class words, the diagonal theorem and a  $\Sigma_1^1$  comprehension bound for uniform nonembedding (section 56, sources 16 and 14);
- larger universes and class realizations (section 57, sources 16, 14, 13, 15 and 18);
- the external classification of the full order in countable  $\omega$ -standard models (section 58, source 18);
- the six formalization plans (section 59).

Section 60 records which questions the Part answers. The sources' foundations sections and Lean plans are printed here, at the end of the addition, rather than in Part V, so that no existing section is renumbered.

*Notation in this Part* (in addition to section 1.3.1). The block notations are the sources' own and differ: source 15 writes  $B_W$  for the class of least representatives of the blocks of a class well-order  $(X, W)$  and  $C_b = \pi_W^{-1}(b)$  for the block with least representative  $b$ ; source 16 writes  $J_R$  for the least representatives of the proper blocks of  $R$  and  $\alpha_R$  for the type of the final set block; source 18 writes  $B_R$  and  $\theta_R$ . *False readings:* in source 15's block section  $b$  is a point of the order, not the baseline enumeration, and  $C_b$  is a block, not a prefix cylinder  $C_p$  of the core; source 14's  $J_R$  (section 54) is the canonical initial branch  $\mathbf{Ord} \rightarrow \mathbf{No}$  of  $R$  (source 15's  $F_R$ , source 13's  $F_R$ ), not source 16's class of block representatives. Sources 16 and 18 write  $\rho_R(x)$  for the rank of  $x$  inside its block; it is unrelated to source 15's coding length  $\rho_\kappa$ . In the sections on larger universes  $\kappa$  denotes a

strongly inaccessible cardinal, as in Part V (source 14 writes  $\Omega$ , sources 17 and 18 write  $\lambda$ ); it is not a birthday cutoff there. Source 18 writes  $H_{\text{sl}}$ ,  $H_{\text{all}}$  with a plain  $H$  in its later sections; they are printed  $\mathfrak{W}_{\text{sl}}$ ,  $\mathfrak{W}_{\text{all}}$ , as its macros are. Source 15's finite ordinal polynomials  $P(\omega)$  and source 18's class  $\mathcal{P}$  of finite-support functions  $\omega \rightarrow \text{Ord}$  are the same order ([note 53.6](#)). Labels written for the merge in this Part begin `swo:ix:`.

## 51 Order facts and direct comparison as re-proved in sources 15, 16, 18, 17 and 13

*Note 51.1* ([[merge](#)]; Part I and Part III counterparts). Before their class-level results, sources 13, 15, 16, 17 and 18 re-prove the surreal order facts and the direct comparison of class well-orders that Parts I and III already contain; each credits this report (source 18 labels its comparison theorems “repository result”). Their sections are printed whole below, in the order 15, 16, 18, 17, 13 for the order facts and 13, 15, 16, 18 for the comparison; none is new against the repository.

- *Fresh separators*: [lemma 5.2](#) (source 15's [lemma 51.2](#), source 16's [lemma 51.3](#), parts (1)–(2) of source 18's [lemma 51.5](#)). Parts (3)–(4) of source 18's lemma are facts about the alphabet  $\mathbf{No}_{<\kappa}$  proved in Part VI ([theorem 29.4](#)).
- *Universality and uniqueness of  $\mathbf{No}$* : [proposition 5.13](#) and [theorem 5.17](#) (source 16's [proposition 51.4](#); the paragraph after source 15's [lemma 51.2](#)).
- *Choice*: [theorem 13.1](#) (source 16's [proposition 51.11](#), source 18's [theorem 51.14](#), the first subsection of source 15's [section 51.7](#); source 17 cites it in its foundations). Sources 15, 16 and 18 prove it over GB without set choice, as [theorem 13.1](#) does; source 16 says that the recursion well-orders the hierarchy “uniformly” and source 18 that its orders “need not extend one another”, and none of the three repeats the “coherent” overstatement corrected in this report on 3 October 2026.
- *Direct comparison by the largest common labelled prefix*: [theorems 14.2](#) and [14.7](#) (source 13's [proposition 51.7](#), source 15's [theorem 51.9](#), source 16's [lemma 51.12](#) with (S16.9), source 17's [proposition 51.6](#) with (S17.2), source 18's [lemma 51.15](#) and [theorem 51.16](#) with (S18.4); source 14's version opens [section 54](#)).
- *Canonical initial part and convex fibres*: [theorem 15.1](#), [proposition 15.3](#), and [remark 15.4](#) (source 13's [proposition 51.8](#), source 15's [proposition 51.10](#); source 14's [lemma 54.5](#) in [section 54](#)).
- *Adjacency*: [theorems 16.2](#) and [16.6](#) (source 16's [proposition 51.13](#), source 18's [theorem 51.17](#); source 17's [theorem 54.2](#) in [section 54](#)).

Source 15 states [proposition 51.10](#) without naming its foundation. Its convexity half is a theorem of GB, but the realization of every injective word as an initial word appends “any fixed well-order” of the omitted range, which needs global choice; the words “In GBC” are added at the merge (source 13's [proposition 51.8](#) likewise uses “global choice” for this step). Source 15's remark after it (“If  $F$  omits  $m$  labels, its fibre has  $m!$  elements”) is [remark 15.4](#) and [proposition 15.3](#), as it says. Source 13's Section 6 and source 16's Section 9 continue in the cut sections of Part VIII, which cite them as [proposition 51.8](#) and Theorem 10.1 of source 16 ([theorem 52.6](#)).

### 51.1 Source 15: sign sequences, properness, and cut filling

We realize a surreal as a sign sequence  $s : \alpha \rightarrow \{-, +\}$  of ordinal length  $\alpha$ . At a first difference the comparison is  $- < \text{undefined} < +$ ; the birthday is the length. The all-plus sequences give an increasing copy of  $\text{Ord}$ , so **No** is a proper class. Every set of surreals has a set bound on its birthdays, by replacement.

The numerical surreal order fills every set cut: if  $L, R$  are sets and  $L < R$ , some  $x$  satisfies  $L < x < R$ , with either side allowed to be empty. This is the familiar Conway construction. It implies density and no endpoints, but it does not assert filling for arbitrary class cuts. The numerical order and the simplicity relation are distinct: extending a sign string makes it more complicated in simplicity, but may increase or decrease its numerical value [11, 12, 14].

**Lemma 51.2** (Fresh separators). *If  $L < R$  are sets of surreals and  $S$  is a set, there is  $x \notin S$  with  $L < x < R$ . In particular, deleting a set from **No** leaves a dense order without endpoints.*

*Proof.* If every separator belonged to  $S$ , the class  $I = \{x : L < x < R\}$  would be a set, by separation from  $S$ . It is nonempty. Apply set-cut filling to  $L \cup I < R$ : every member of  $I$  is less than every member of  $R$ . A resulting separator belongs to  $I$  and exceeds all of  $I$ , a contradiction. Thus the interval has a point outside  $S$ . The same proof allows empty bounding sides.  $\square$

In GBC, a forth construction embeds every ordinary class linear order in **No**: enumerate its underlying class by  $\text{Ord}$ , and at each stage separate the sets of earlier lower and upper images. A back-and-forth construction shows uniqueness, up to class order isomorphism, of a proper class order with this set-cut property. Each stage has a set of earlier values; these are ordinary set-valued ordinal recursions. This is the classical universality and absolute-linear-continuum phenomenon [15, 20]. It does not apply to a collection whose elements are themselves class functions.

### 51.2 Source 16: foundations and surreal order facts

#### 51.2.1 Conventions about sets, classes, and choice

Here GB has ZF as its set theory and no choice principle built into its notation. We write  $\text{GBC} = \text{GB} + \text{GC}$ ; global choice implies ordinary set choice. The set-sized theorems are proved in ZFC. A *class well-order* is a strict class linear order for which every available nonempty subclass has a least element. A relation is *set-like* if each predecessor class is a set. A proper set-like class well-order is uniquely isomorphic to  $\text{Ord}$ : send each point to the ordinal type of its predecessor set.

An individual class function  $F : \text{Ord} \rightarrow \mathbf{No}$  is legitimate. The notation “ $F \in \mathfrak{W}_{\text{sl}}$ ” below abbreviates that this class function is a bijection; it does not make  $F$  an element of a GB class. Likewise, a uniform family  $(F_i)_{i \in I}$  means one class of triples  $(i, \alpha, x)$  whose rows are the graphs in question. Its index  $I$  may be a set or a class of sets. One cannot silently choose a class for each set index and assume that the rows assemble into an available uniform family.

#### 51.2.2 Sign sequences, small cuts, and bounded stages

We use the sign presentation

$$\mathbf{No} = \bigcup_{\alpha \in \text{Ord}} \{-, +\}^\alpha,$$

with numerical comparison at the first different or missing sign, using  $- < \text{missing} < +$ . The birthday  $\text{bd}(x)$  is the length of the sign sequence. Every set of surreals has bounded birthdays, whereas all birthdays occur. Thus **No** is proper. The basic separation property is:

$$A, B \text{ sets, } A < B \implies \exists x \in \mathbf{No} (A < x < B), \quad (\text{S16.1})$$

with either side allowed to be empty. These are standard facts about the surreal order [11, 12, 14]; the corresponding smallness-sensitive primitives in ProveIt are audited in Section 59.4.

**Lemma 51.3** (Fresh separators). *If  $A < B$  are sets of surreals and  $S$  is any set, some  $x \notin S$  satisfies  $A < x < B$ . Every nonempty numerical interval is a proper class. Deleting a set from **No** preserves the set-cut property.*

*Proof.* First choose  $u, v$  with  $A < u < v < B$  by two applications of (S16.1). The interval  $(u, v)$  cannot be a set: if it were, choose an element above all of  $(u, v)$  but below  $v$ , a contradiction. Hence the set  $S$  cannot exhaust this interval. Any remaining point works. The same argument gives the assertions about intervals and deletion.  $\square$

For infinite cardinal  $\kappa$ , put

$$\mathbf{No}_{<\kappa} = \{x : \text{bd}(x) < \kappa\}, \quad \mu = 2^{<\kappa}.$$

Then  $\mathbf{No}_{<\kappa}$  is a set of size  $\mu$ . For regular infinite  $\kappa$  it is an  $\eta_\kappa$  order: every separated pair of sets with total cardinality less than  $\kappa$  has an interpolant in the same birthday stage. Bound the option birthdays below  $\kappa$  using regularity, and use the usual birthday-controlled separator. At singular  $\kappa$  this argument fails because a small set can have birthdays cofinal in  $\kappa$ .

### 51.2.3 Which uses of recursion are elementary?

A recursion producing a set at each ordinal stage, with a set history before each stage and fixed class parameters, is available in GB. One constructs each set-length approximation by ordinary recursion and joins the compatible approximations by elementary comprehension. This applies to the forth and back-and-forth constructions used below.

By contrast, a recursion whose stages are classes is an instance of elementary transfinite recursion when its defining formula has only set quantifiers. Such a recursion may exceed GBC even along  $\omega$ ; truth recursion is a standard example. ETR supplies abstract class well-order comparability by initial-segment isomorphisms, but we neither identify comparability with ETR nor assert a necessity result for our particular constructions [27, 22]. Size of the stage and history, rather than the mere appearance of the symbol **Ord**, is decisive.

**Proposition 51.4** (Universality and uniqueness). *In GBC every class linear order embeds into **No**. Any two proper class linear orders satisfying (S16.1) are isomorphic, provided they have set-like global enumerations. The construction can be made uniform in set parameters when the carrier and order predicates are uniform.*

*Proof.* Enumerate the source by an ordinal or by **Ord** using global choice. At each stage insert its next point between the images of its earlier lower and upper points. These are sets. For an isomorphism alternate forth and back steps through fixed global enumerations of the two orders, inserting the next unused point on the appropriate side at each step. Each partial map is a set. Choose the least permissible point under fixed global well-orders to make every stage unique. Its graph is the union of the set-length approximations. With an extra set parameter carried throughout, the same defining formula gives a uniform class relation for the whole parameterized family. This is the classical mechanism of surreal universality and homogeneity [15, 33].  $\square$

### 51.3 Source 18: surreals as sign sequences

Represent a surreal number by a function  $s_x : \text{bd}(x) \rightarrow \{-, +\}$ , where  $\text{bd}(x)$  is an ordinal. Numerical order is comparison at the first unequal sign, counting an absent sign as strictly between  $-$  and  $+$ . Sign extension is the simplicity relation, which is a tree order, not a total order. This presentation and its substructures are developed in the standard surreal literature [12, 14].

We shall repeatedly use the following elementary consequences.

**Lemma 51.5** (Surreal order tools). *1. If  $L, R$  are sets of surreals and  $L < R$ , some surreal lies strictly between them. Either set may be empty.*

*2. The separator can avoid any prescribed set of forbidden values.*

*3. For infinite initial  $\kappa$ , every nonempty open interval of  $\mathbf{No}_{<\kappa}$  contains a sign-prefix cone isomorphic to  $\mathbf{No}_{<\kappa}$ ; hence it has cardinality  $\mu = 2^{<\kappa}$ .*

*4.  $\mathbf{No}_{<\kappa}$  fills every cut with fewer than  $r = \text{cf } \kappa$  input values. Its cofinality, coinitality, and both characters at every point are  $r$ .*

*Proof.* For (1), choose an ordinal strictly above all birthdays in  $L \cup R$ . Comparison in a sufficiently long full binary level supplies a sign sequence separating the two sets; equivalently use the usual simplest surreal cut construction. To get (2), the separator interval contains a proper class of values: an interval is order-isomorphic to  $\mathbf{No}$ , or one can extend a sign prefix by arbitrary ordinal lengths. A set of forbidden values cannot exhaust it.

For (3), first choose a sufficiently long but still  $< \kappa$  prefix whose whole cone lies inside the given interval. Prefix concatenation preserves numerical order. If  $\beta, \gamma < \kappa$ , then  $\beta + \gamma < \kappa$ , since this sum still has cardinality below the initial cardinal  $\kappa$ . This works at singular cardinals too. Thus concatenating the chosen prefix with every sign word of length  $< \kappa$  gives the required copy. Counting levels gives  $|\mathbf{No}_{<\kappa}| = \sup_{\alpha < \kappa} 2^{|\alpha|} = 2^{<\kappa}$ .

For (4), fewer than  $\text{cf } \kappa$  birthdays are bounded below  $\kappa$ , so the construction in (1) stays below  $\kappa$ . Ordinal labels along a cofinal sequence in  $\kappa$  give a cofinal sequence; their negatives give a coinital one. No smaller family is cofinal, since its birthdays are bounded. At a fixed point, append a negative sign and then arbitrarily long positive tails to approach from below; use the dual construction above. These give character at most  $r$ . The small-cut property gives the reverse inequality.  $\square$

Part (2) is also available in the bounded setting when the forbidden set has size  $< \mu$  and a whole interval of separators is available. This distinction matters: a used prefix in a minimal permutation can have length much greater than  $\kappa$ , but it still uses fewer than  $\mu$  labels.

### 51.4 Source 18: set and class theories

Set-sized results are proved in ZFC. In class arguments, GB denotes Gödel–Bernays theory over ZF with elementary class comprehension and Class Replacement. GBC adds Global Choice. A class is a collection of sets, never an element of another ordinary class. We regard a class well-order  $R$  as a strict class linear order for which every nonempty available subclass has an  $R$ -least element. This definition is internal to the specified two-sorted model.

A class order is *set-like* if every predecessor class is a set. A proper set-like class well-order is isomorphic to  $\text{Ord}$ : map a point to the ordinal type of its predecessors. The range is an initial subclass of  $\text{Ord}$ , and if it were a set, Class Replacement would make the whole carrier a set. Conversely, an  $\text{Ord}$  enumeration is set-like.

All uses of class back-and-forth below choose one new set label at each ordinal stage. The preceding history at a stage is a set, and the next choice is determined using a fixed global well-order. This is ordinary set-valued recursion with class parameters. We do not infer that arbitrary

class-valued recursions follow from GBC. Elementary transfinite recursion has substantially greater strength in general [24].

An expression such as  $\mathfrak{M}_{\text{all}}$  is initially notation for a domain of class variables, not a class whose members are class relations. A uniform family  $(R_i)_{i \in I}$  means one class relation  $F(i, x, y)$  with set labels  $i, x, y$ . A set-indexed family of class relations is not silently replaced by a set of classes.

## 51.5 Source 17: foundations and direct comparison without a class of classes

### 51.5.1 Four safe levels

Our set theorems use ZFC. Our global theorems use GBC, meaning Gödel–Bernays set theory with Global Choice; GB alone includes no choice principle. This agrees with the conventions in the source and in Hamkins’s account of Global Choice [19].

A class well-order here is a linear class relation for which every nonempty admitted subclass has a least element. Set-likeness is an additional property, not part of that definition. Which subclasses are admitted is specified by the surrounding class theory or model.

There are four distinct safe ways to interpret a higher-order-looking statement. One may work with ordinary sets such as  $\mathcal{W}_\mu(X)$ ; with an ordinary class of *set codes* such as  $\mathcal{P}_s(b)$ ; with finitely many class variables or a uniform class relation coding a family; or externally in a larger universe in which the objects from the smaller universe are sets. None permits forming an unrestricted same-level set or class of all proper classes.

A uniform family indexed by a class  $I$  of sets is a single relation  $F \subseteq I \times \text{Ord} \times \mathbf{No}$ , with each row  $F_i$  an enumeration. A uniform transformation of enumerations is a formula which defines an output class from an input class and for which output existence and uniqueness are proved. It is not a GB function with proper classes as arguments stored in its graph.

### 51.5.2 The direct common-prefix formula

For a strict class well-order  $R$  let  $P_R(x) = \{y : yRx\}$ . Given two class well-orders  $R, S$  of the same labelled carrier  $X$ , define

$$C(R, S) = \{x : P_R(x) = P_S(x) \text{ and } R \upharpoonright P_R(x) = S \upharpoonright P_S(x)\}. \quad (\text{S17.2})$$

Equality and restriction here expand to quantifiers over elements of  $X$ ; no class quantifier is hidden in the defining formula.

**Proposition 51.6** (Direct labelled comparison; background with proof). *The class  $C(R, S)$  is the largest common labelled initial segment of  $R, S$ . If  $R \neq S$ , its complement is nonempty and the two least residual labels  $a = \min_R(X \setminus C)$  and  $b = \min_S(X \setminus C)$  are different. Declaring  $R <_{\text{lex}} S$  exactly when  $a < b$  gives a strict linear comparison of all admitted class well-orders of  $X$ .*

*Proof.* If  $x \in C$  and  $yRx$ , the equality of predecessor classes puts  $y$  before  $x$  in both orders; agreement below  $x$  then gives equal predecessor classes and equal predecessor orders for  $y$ . Thus  $y \in C$ . The same argument works with  $S$ , and proves agreement on  $C$ . Every common labelled initial segment satisfies the defining condition, so is contained in  $C$ . If  $C = X$ , the relations agree. Otherwise well-foundedness provides the least residual elements. If  $a = b$ , both its predecessor classes are  $C$  and the orders there agree, contradicting  $a \notin C$ .

For transitivity compare  $C(R, S)$  and  $C(S, T)$  as initial segments of  $S$ . Initial segments of a linear order are comparable by inclusion. If one is properly shorter, its first disagreement is the first disagreement relevant to comparing  $R, T$ , and has the same orientation. If the two prefixes

are equal, the three next labels  $a < b < c$  give  $a < c$ . Trichotomy and asymmetry are immediate. This is an elementary proof; it does not compare arbitrary abstract class order types by a recursive isomorphism construction.  $\square$

This result is already in the merged report (theorems 14.2 and 14.7). Its inclusion is important: it eliminates a false dilemma between restricting to Ord-enumerations and introducing a stronger class recursion theory merely to define the comparison.

### 51.5.3 Choice, recursion, and external semantics

Global Choice supplies a baseline bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . The source also proves the converse strength statement: existence of any class well-order of the sign-sequence surreals implies Global Choice over choiceless GB (theorem 13.1). That converse is not needed in our proofs; we explicitly assume GBC for the global results.

Recursion whose value at each ordinal stage is a set is available with class parameters in GBC: set recursion constructs compatible histories on each set ordinal, and elementary comprehension collects them. This is not the assertion that arbitrary class-valued recursions have solutions. The latter territory is governed by principles such as ETR, whose strength is substantially more than elementary comprehension [22]. We will reconstruct branches by a uniqueness formula, so that even the appearance of such a class-valued recursion is avoided.

In a transitive two-sorted model  $(M, \mathcal{X})$ , “all classes” means  $\mathcal{X}$ . An external observer may have more subclasses of  $M$ . With a strongly inaccessible cardinal  $\lambda$  in an ambient universe,  $(V_\lambda, \mathcal{P}(V_\lambda))$  provides a useful full-class interpretation. Externally, its set-like surreal enumerations are the  $\lambda$ -length permutations of  $\mathbf{No}_{<\lambda}$ , while its unrestricted well-orders allow all external ordinal types of cardinality  $\lambda$  (theorem 21.1). This is a conditional model construction, not an assertion that ZFC proves an inaccessible cardinal exists.

Finally, neither passing to KM nor enumerating formula strings gives an internal universal class decoder. The latter would need a uniform truth predicate, not merely syntax. Section 42.5 gives an independent diagonal explanation for the failure of exhaustive same-level coding.

## 51.6 Source 13: direct comparison of unrestricted class well-orders

The class  $\mathbf{No}$  itself is fixed throughout this section. A class well-order  $R$  is a strict linear order for which every nonempty subclass has an  $R$ -least member. A set-like class order additionally has a set of predecessors at every point. The totality  $\mathfrak{W}_{\text{all}}$  is notation for the domain of such class parameters, not an ordinary class whose members are relations.

### 51.6.1 The largest common labeled prefix

The following construction is from the earlier report (theorem 14.2; Section 14 at the pin); its explicit formula is useful because it does not demand an enumeration of a non-set-like order by Ord.

**Proposition 51.7** (Elementary labeled comparison). *Two distinct class well-orders  $R, S$  of  $\mathbf{No}$  have a largest common labeled initial part  $G$ . There are distinct labels  $r, s$  that are the respective first points after  $G$ . Defining*

$$R <_{\text{lex}} S \iff r < s$$

*gives a strict linear comparison on  $\mathfrak{W}_{\text{all}}$  by an elementary formula with  $R, S$  as class parameters. No class-well-order comparability principle is required.*

*Proof.* Define  $G$  to consist of those  $x$  such that  $\text{Pred}_R(x) = \text{Pred}_S(x)$  and the two relations agree on that common predecessor class. Equality and agreement here abbreviate formulas quantifying over set elements. They do not form the predecessor classes as elements of a larger collection.

If  $x \in G$ , all its predecessors belong to  $G$ . The restrictions of  $R$  and  $S$  to  $G$  agree, and any common labeled initial part is contained in  $G$ . If  $G$  were the whole carrier, the relations would agree. Otherwise take the least points  $r, s$  of the complements in the two orders. Their predecessor classes are both  $G$ . They cannot coincide, since their common value would then be a member of  $G$ .

Trichotomy follows from numerical trichotomy of  $r, s$ . For transitivity, consider  $R < S < T$ . The common prefixes of  $(R, S)$  and  $(S, T)$  are both initial parts of  $S$ , hence one contains the other. If one is properly shorter, its first disagreement also decides the comparison of  $R, T$ . If they are equal, the three next labels satisfy  $r < s < t$ , which gives  $R < T$ . This proves transitivity without assigning an ordinal length to a proper-class prefix.  $\square$

This is not comparison of abstract class order types by initial-segment isomorphisms. For that different problem, elementary transfinite recursion is a known sufficient principle [27, Theorem 6]. Our formula compares identical labels on one carrier, rather than constructing an isomorphism between unrelated carriers.

### 51.6.2 The ordinal head and the residual fiber

**Proposition 51.8** (Canonical head; prior structural lemma). *For  $R \in \mathfrak{W}_{\text{all}}$ , the points with a set of  $R$ -predecessors form a proper-class initial part  $H_R$ , uniquely enumerated by a class injection*

$$F_R : \text{Ord} \longrightarrow \mathbf{No}.$$

*Conversely, for every injective class word  $F : \text{Ord} \rightarrow \mathbf{No}$ , appending any class well-order of  $Y = \mathbf{No} \setminus \text{ran}(F)$  produces a raw order whose head is  $F$ . All raw orders with this head form a convex fiber, with their internal comparison equal to the labeled lexicographic comparison of well-orders of  $Y$ .*

*Proof.*  $H_R$  is initial. Were it a set, the least point outside it would have exactly  $H_R$  as its predecessor class and would belong to it, a contradiction. Ranking each point by the ordinal type of its set of predecessors gives the unique enumeration: its ranks form a proper initial subclass of  $\text{Ord}$  only if they are a set, so they are all of  $\text{Ord}$ .

After an  $\text{Ord}$ -head is listed, every residual point has a proper class of predecessors, whereas each head point has a set of predecessors. This proves the converse. Distinct heads disagree at a set ordinal, and that disagreement places one entire fiber below the other. Equal heads leave only the tail comparison, proving convexity. A well-order on  $Y$  is available from global choice, also when  $Y$  is proper.  $\square$

This is the earlier report's decomposition (theorem 15.1 and proposition 15.3; Section 15 at the pin). We shall identify exactly which cuts of a fixed dense core these fibers represent, thereby supplying an additional characterization not contained in the decomposition alone.

## 51.7 Source 15: native lexicography on class well-orders

### 51.7.1 Existence, set-likeness, and the first proper block

A class relation  $R$  on  $\mathbf{No}$  is *set-like* when  $\text{Pred}_R(x) = \{y : yRx\}$  is a set for every  $x$ . An already-given set-like class well-order of a proper class has a unique order isomorphism with  $\text{Ord}$ : assign to each

point the ordinal type of its predecessor set. The image is initial in  $\text{Ord}$  and cannot be a set, since the inverse map would make the whole carrier a set. This collapse needs GB, not a separate global choice assumption [19].

Existence is different. Over GB, the existence of any class well-order of  $\mathbf{No}$ , even a non-set-like one, is equivalent to global choice (theorem 13.1; Theorem 13.1 at the pin). One direction restricts a set-like global well-order of the universe. For the other, a well-order of  $\mathbf{No}$  orders the sign codes for every  $\mathcal{P}(\alpha)$ . Starting with an ordinal enumeration of a rank stage, transport this order to its power set; at limits combine the already constructed orders by rank. This set-valued ordinal recursion produces well-orders of all rank stages and hence a global well-order. This explains why merely assuming a convenient global baseline already carries substantive choice information.

An arbitrary class well-order can have type  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ , or much more complicated class types. The final element of an  $\text{Ord} + 1$  order has a proper class of predecessors. It is still an ordinary surreal label; the new size occurs in its position in the chosen order.

### 51.7.2 A first disagreement after a proper class of agreement

If  $R, S$  are class well-orders of the same labelled carrier  $X$ , put  $\text{Pred}_R(x) = \{y \in X : yRx\}$ . A common labelled prefix is initial in both orders and carries the same restricted relation. The comparison below is the prior report's elementary construction (theorem 14.2; Section 14 at the pin); we include its proof because it makes the foundational advantage precise.

**Theorem 51.9** (First unequal labels without class ordinals). *If  $R \neq S$ , there are unique distinct  $a, b$  such that*

$$\text{Pred}_R(a) = \text{Pred}_S(b) = C, \quad R \restriction C = S \restriction C.$$

*The class  $C$  is their maximal common labelled prefix. If the labels carry a fixed linear order  $<$ , declaring  $R <_{\text{lex}} S$  when  $a < b$  defines a strict linear comparison on the class-well-order predicate. Its formula has only set quantifiers with  $R, S$  as class parameters.*

*Proof.* Let  $a$  be the  $R$ -least point whose predecessor classes in  $R$  and  $S$  differ, and put  $C = \text{Pred}_R(a)$ . For  $y \in C$ , these predecessor classes agree. Such  $y$  must also precede  $a$  in  $S$ : otherwise  $aSy$  would imply  $aRy$ . If  $zSy$  for  $y \in C$ , agreement of predecessor classes gives  $zRy$ , so  $C$  is also  $S$ -initial. The restricted orders agree, and  $C \subsetneq \text{Pred}_S(a)$ . Let  $b$  be the  $S$ -least point outside  $C$ . Then  $bSa$ ,  $b \neq a$ , and  $\text{Pred}_S(b) = C$ . Any other first-disagreement pair must have its first member equal to the  $R$ -least point with changed predecessors, proving uniqueness.

For transitivity, suppose  $R < S < T$ . Their two common prefixes with the middle order  $S$  are initial segments of that same order, hence comparable. If one is shorter, its first difference also decides  $R$  versus  $T$ ; if they are equal, the next labels satisfy  $a < b < c$ , which decides the comparison. Totality and asymmetry follow from unique first disagreement. Finally the formula can be written directly as

$$\exists a, b [a < b \wedge \forall z(zRa \leftrightarrow zSb) \wedge \forall u, v((uRa \wedge vRa) \Rightarrow (uRv \leftrightarrow uSv))].$$

No quantification over a collection of prefix classes is required. □

For example, enumerate  $\mathbf{No} \setminus \{a, b\}$  in type  $\text{Ord}$ , where  $a < b$ , and append either  $a, b$  or  $b, a$ . Their first unequal labels occur after every ordinal stage of the common enumeration. The displayed formula still compares them. It is not necessary to invent a set ordinal “beyond  $\text{Ord}$ ” to name their first difference.

For one given class index order  $J$ , bijections  $J \rightarrow \mathbf{No}$  may instead be compared at the  $J$ -least unequal coordinate. This agrees with the raw comparison, but restricts the allowed order type. Two

different index orders should be compared through the induced labelled relations unless an explicit alignment has been supplied.

**Proposition 51.10** (Prefix convexity and initial-word fibres). *In GBC, orders extending a common labelled prefix form a convex family. For an arbitrary class well-order  $R$  of  $\mathbf{No}$ , let*

$$I_R = \{x : \text{Pred}_R(x) \text{ is a set}\}, \quad F_R : \text{Ord} \longrightarrow I_R$$

*be its unique increasing enumeration. Then  $I_R$  is a proper class. Every injective class word  $F : \text{Ord} \rightarrow \mathbf{No}$  occurs as  $F_R$ , and its fibre is a convex copy of the well-order space of  $Y_F = \mathbf{No} \setminus \text{ran}(F)$ . Distinct fibres compare at the first unequal coordinate of their words.*

*Proof.* A comparison that first diverges inside a common prefix puts the competing order on the same side of every extension, proving convexity. The class  $I_R$  is initial and set-like. If it were a set, the least point outside it would have precisely  $I_R$  as its predecessors, a contradiction. Its enumeration is therefore by all ordinals.

Given  $F$ , order its range by its ordinal indices and append any fixed well-order of  $Y_F$ . Every point of the range has set predecessors, and every residual point has the proper range of  $F$  among its predecessors. Thus the resulting initial word is exactly  $F$ . Restriction to  $Y_F$  and concatenation with  $F$  give inverse order-preserving maps on the fibre. For unequal words, first ordinal difference precedes both residual tails.  $\square$

If  $F$  omits  $m$  labels, its fibre has  $m!$  elements. An exhaustive word and a word omitting just one label both have singleton fibres; only the first is set-like. The unrestricted space has adjacent finite residual permutation blocks, whereas the set-like space is dense and has no endpoints. These distinctions are already established in the prior report.

## 51.8 Source 16: global choice and direct comparison of arbitrary class well-orders

Write  $\mathfrak{W}_{\text{sl}}$  for the predicate of class bijections  $\text{Ord} \rightarrow \mathbf{No}$ , and  $\mathfrak{W}_{\text{all}}$  for that of all class well-order relations on  $\mathbf{No}$ . These are notations for assertions about class variables. We will also use  $\mathfrak{J}$  for class injections  $\text{Ord} \rightarrow \mathbf{No}$ , allowing nonexhaustive ranges.

**Proposition 51.11** (Existence has a precise choice strength). *Over GB, the following are equivalent: global choice; a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ ; a set-like class well-order of  $\mathbf{No}$ ; and an arbitrary class well-order of  $\mathbf{No}$ .*

*Proof.* Global choice gives a set-like global well-order of the universe. Its restriction to the proper class  $\mathbf{No}$  has order type  $\text{Ord}$ , yielding the bijection. A bijection induces a set-like well-order, which is an arbitrary class well-order as well.

For the reverse implication suppose  $R$  well-orders  $\mathbf{No}$ . Every  $\mathcal{P}(\delta)$  injects into  $\mathbf{No}$  by sign sequences of length  $\delta$ , so  $R$  gives it a well-order. One can now well-order the hierarchy  $V_\beta$  uniformly by set-valued recursion, starting with  $w_0 = \emptyset$ . At a successor, use the existing well-order  $w_\beta$  of  $V_\beta$  to identify it with an ordinal  $\delta$ , transfer subsets to  $\mathcal{P}(\delta)$ , and use the restriction of  $R$  on their sign codes. At a nonzero limit  $\lambda$ , order the disjoint rank layers by their ranks, using  $w_{\gamma+1} \upharpoonright (V_{\gamma+1} \setminus V_\gamma)$  on layer  $\gamma$ , where  $\gamma + 1 < \lambda$ . Each history is a set; no choice of an unspecified family of well-orders is used. Finally order all sets first by rank and then by the resulting well-order on that rank layer. This is a set-like global well-order of the universe and supplies global choice. This expands the choice-equivalence argument recorded in the prior report ([theorem 13.1](#)).  $\square$

For distinct  $F, G \in \mathfrak{J}$ , their first unequal ordinal coordinate exists: minimize the disagreement class below any one witness. Compare  $F(\delta)$  and  $G(\delta)$  numerically. This is a total, transitive lexicographic comparison. For general  $R, S \in \mathfrak{W}_{\text{all}}$ , however, a first disagreement may occur after a proper class of common labels.

**Lemma 51.12** (A common labelled prefix without class ordinals). *Let  $R \neq S$  be class well-orders of the same class  $X$ . There are unique distinct labels  $a, b$  such that*

$$\{x : xRa\} = \{x : xSb\} = C, \quad R \restriction C = S \restriction C.$$

*The class  $C$  is their largest common labelled initial segment.*

*Proof.* Let  $a$  be  $R$ -least among the labels whose predecessor classes in  $R$  and  $S$  differ. For every  $xRa$  the two predecessor classes of  $x$  agree. Consequently  $C = \{x : xRa\}$  is also  $S$ -initial and the relations agree on it. Moreover  $C$  is a proper subclass of the  $S$ -predecessors of  $a$ . Let  $b$  be the  $S$ -least label outside  $C$ . Then  $bSa$ ,  $b \neq a$ , and its  $S$ -predecessor class is  $C$ . In any pair satisfying the displayed conditions, every earlier label has identical predecessor classes, while the next  $R$ -label does not. It must therefore be  $a$ , and then both  $C$  and  $b$  are determined.  $\square$

Define  $R <_{\text{lex}} S$  if the corresponding next labels satisfy  $a < b$  in the numerical or other fixed native order of  $X$ . In a triple  $R, S, T$ , the common prefixes of  $(R, S)$  and  $(S, T)$  are initial segments of  $S$  and are inclusion-comparable. Whichever ends first decides the comparison of  $R$  and  $T$ ; if they end together, transitivity of the next numerical labels decides. Thus the definition is a strict linear comparison.

The first-pair condition can be expressed using only set quantifiers:

$$\begin{aligned} a \in X \wedge b \in X \wedge a \neq b \quad \wedge \quad & \forall z (zRa \leftrightarrow zSb) \\ & \wedge \quad \forall x \forall y ((xRa \wedge yRa) \Rightarrow (xRy \leftrightarrow xSy)). \end{aligned} \tag{S16.9}$$

This is why no abstract comparison of class order types and no ETR is required. On an injectively indexed uniform family of class well-orders, it gives an ordinary class linear order on the set-valued indices.

**Proposition 51.13** (Convexity and finite residual jumps). *Fix any labelled common prefix, possibly a proper class. Its completions form a convex suborder of  $\mathfrak{W}_{\text{all}}$ . Two distinct raw orders are adjacent exactly when the labels remaining after their largest common prefix form a finite set and their residual permutations are consecutive.*

*Proof.* An order that disagrees before a fixed common prefix ends compares in the same direction with all its completions, proving convexity. If  $R < S$  were adjacent and the remaining set or class of labels were infinite,  $R$  would have to be maximal in its next-letter cylinder and  $S$  minimal in its next-letter cylinder. As in Lemma 27.1, swapping an ascent or descent forces the respective suffixes to be numerically decreasing and increasing. If  $Y$  is the residual carrier and  $a, b$  the first unequal labels, the numerical order on  $Y \setminus \{a, b\}$  is consequently both a well-order and a reverse well-order. Such a class is finite: otherwise repeatedly taking its least remaining member produces a set-coded increasing  $\omega$ -sequence, contradicting reverse well-foundedness. Thus  $Y$  is finite, and convexity reduces adjacency exactly to that of its finite permutation list. Conversely consecutive residual permutations have no intervening completion, and convexity excludes an intervening order outside the prefix cylinder.  $\square$

## 51.9 Source 18: global well-orders: existence and elementary comparison

### 51.9.1 Existence is exactly a global choice issue

No set-length function exhausts  $\mathbf{No}$ , since its range is a set. A well-order of the whole surreal carrier must therefore be a class relation. It need not be set-like:  $\text{Ord} + 1$ ,  $\text{Ord} \cdot 2$ , and more complicated class concatenations can be transported to the carrier under Global Choice. Here these expressions denote explicitly constructed class orders, not set ordinals.

**Theorem 51.14** (Existence of a global well-order; repository result). *Over GB with ZF as its set theory, the following are equivalent: Global Choice; the existence of a set-like global well-order of  $\mathbf{No}$ ; the existence of any class well-order of  $\mathbf{No}$ .*

*Proof.* Global Choice gives a set-like global well-order of the set universe and hence of  $\mathbf{No}$ . The second statement implies the third. For the reverse implication, let  $R$  be a class well-order of the sign-sequence surreals. For every ordinal  $\theta$ , the length- $\theta$  binary sign sequences form a set, and the restriction of  $R$  well-orders that set. It thereby well-orders  $\mathcal{P}(\theta)$ , uniformly in  $\theta$ .

Construct a well-order of each  $V_\alpha$  by set-valued recursion with parameter  $R$ . Start with the empty set. Given a well-order of  $V_\alpha$ , use its unique ordinal enumeration to identify subsets of  $V_\alpha$  with subsets of an ordinal; pull back the already specified well-order of that power set. At a limit stage, order the disjoint rank layers first by their ordinal rank and then by the relevant previously constructed well-order. These orders need not extend one another; uniform existence is what the argument requires. Finally order the whole universe first by rank and then by the chosen well-order of each rank layer. Its predecessor classes are sets, so it is a set-like global well-order and supplies Global Choice. This is the choiceless argument used in the repository ([theorem 13.1](#)).  $\square$

The theorem is distinct from asking whether universality of the *numerical* surreal order for all class linear orders implies Global Choice. Our arguments use Global Choice for that universality; they do not establish its converse. Under Global Choice, the usual forth construction embeds a class linear order in  $\mathbf{No}$ : enumerate its carrier in type  $\text{Ord}$ , and at each stage place the next point between the already embedded lower and upper sets. Hamkins gives a research-paper account of this class universality [[33](#), §5].

### 51.9.2 Comparing orders after a proper-class common prefix

Let  $R, S$  be class well-orders on the same linearly ordered class  $X$ . The numerical order on  $X$  need not coincide with either well-order. Write  $\text{Pred}_R(x) = \{y : yRx\}$ . Define  $C(R, S)$  to consist of the labels  $x$  such that

$$\text{Pred}_R(x) = \text{Pred}_S(x) \quad \text{and} \quad R \upharpoonright \text{Pred}_R(x) = S \upharpoonright \text{Pred}_R(x). \quad (\text{S18.4})$$

Both equalities expand to formulas quantifying only over set labels, with the two relations as class parameters.

**Lemma 51.15** (Largest common labelled initial segment).  *$C(R, S)$  is an initial segment of both orders, on which they agree. It contains every common labelled initial segment. If  $R \neq S$ , it is proper, and the first remaining labels  $a$  in  $R$  and  $b$  in  $S$  satisfy*

$$\text{Pred}_R(a) = C(R, S) = \text{Pred}_S(b), \quad a \neq b.$$

*Proof.* If  $x$  satisfies (S18.4), each of its predecessors does too: the two orders agree below  $x$ , and therefore assign identical predecessor classes below any such label. Thus  $C$  is initial in both, and agreement follows by testing a pair below its larger label. Every common labelled initial segment satisfies the displayed conditions. If  $C = X$ , the two relations agree everywhere. Otherwise their well-order property supplies least labels outside  $C$ . Their predecessor classes are exactly  $C$ . If those labels were equal, that label would satisfy (S18.4), a contradiction.  $\square$

**Theorem 51.16** (Elementary full lexicographic order). *For distinct  $R, S$ , declare  $R <_{\text{lex}} S$  if  $a < b$  in the numerical order, with  $a, b$  as in Lemma 51.15. This is a strict linear order on the available well-orders of  $X$ . It is elementary in the two class parameters. It requires neither a system of abstract class ordinals nor a principle comparing arbitrary class order types.*

*Proof.* Trichotomy and asymmetry are immediate. For transitivity, compare the common prefixes for  $R, S$  and for  $S, T$ . They are initial segments of the same order  $S$ , hence nested. If the first prefix ends earlier,  $S$  and  $T$  still agree at its next label, so the comparison of  $R, T$  is the comparison of  $R, S$ . The opposite strict containment gives the comparison of  $S, T$ . If the prefixes agree, the three next labels are numerically ordered and transitivity follows in  $X$ .

For explicit elementary definability, use the formula defining  $C$ , assert that the predecessors of  $a$  under  $R$  and of  $b$  under  $S$  are exactly the labels satisfying that formula, and assert  $a < b$ . No existential quantification over an additional class is needed.  $\square$

The theorem extends the usual first-ordinal-difference rule. In the case of distinct set-like orders,  $C$  is a set and has an ordinal length. In the full case, it may already have type  $\text{Ord}$ ,  $\text{Ord} \cdot 2$ , or a more complicated type. The comparison still exists because the two orders use the same labels. Abstractly isomorphic but differently labelled prefixes are not declared equal.

### 51.9.3 Residual cylinders and finite adjacency

Fix a labelled well-order  $Q$  of  $C \subsetneq X$ . Its cylinder is the family of all global orders beginning with  $Q$ . Put  $Y = X \setminus C$ . Restriction to  $Y$  and concatenation with  $Q$  are inverse, order-preserving operations. The cylinder is convex: any order that diverges before finishing  $Q$  lies on the same side of every extension of  $Q$ .

This gives the following useful size-sensitive reading of a cylinder. If  $|Y| = n < \omega$ , its tails form the  $n!$  permutations of  $Y$ . If  $Y$  is an infinite set of size  $\lambda$ , its tails form  $\mathcal{W}(Y)$ , of cardinality  $2^\lambda$  and ordinal spectrum  $\beta < \lambda^+$ . If  $Y$  is proper, its tails form a predicate on class relations. Under GBC this last family contains a uniformly presented copy of every class linear order. Indeed, characteristic functions of initial segments embed any class linear order into binary  $\text{Ord}$  words; independent pair swaps in a fixed enumeration of  $Y$  then embed those words into set-like well-orders of  $Y$ .

Even when  $Y$  is a set, the corresponding full orders of  $X$  are class relations. The statement is a set-parameterized isomorphism with their tails, not the assertion that those class relations themselves form an ordinary set.

**Theorem 51.17** (Adjacency is finite residual adjacency). *Let  $R < S$ , with common prefix  $C$ , next labels  $a < b$ , and residual carrier  $Y = X \setminus C$ . Then  $R, S$  are adjacent if and only if  $Y$  is finite and their residual permutations are consecutive.*

*Proof.* If  $R, S$  are adjacent, no remaining numerical label lies strictly between  $a, b$ , or it could be put next to produce an intermediate order. The tail of  $R$  after  $a$  must be lexicographically greatest: otherwise a greater replacement remains below  $S$ . A greatest well-order tail must list its labels in decreasing numerical order, since any numerical ascent can be transposed to increase the code.

Dually, the tail of  $S$  after  $b$  must be numerically increasing. On  $Y \setminus \{a, b\}$ , numerical order and its reverse would therefore both be well-orders. Such a carrier is finite: otherwise successively taking the least remaining element produces an increasing  $\omega$  sequence with no greatest member, contradicting reverse well-ordering. Conversely, convexity of the cylinder reduces a finite residual carrier exactly to finite permutation adjacency.  $\square$

For example, choose  $a < b$  in  $\mathbf{No}$  and give  $\mathbf{No} \setminus \{a, b\}$  a set-like order  $Q$ . The two orders  $Q + (a, b)$  and  $Q + (b, a)$  are adjacent and have type  $\text{Ord} + 2$ . Neither is set-like. The set-like global order has no adjacent pairs, because a set prefix leaves an entire proper class of unused numerical separators. It is consequently not dense in the full global order: intervals inside a six-point terminal permutation fiber contain only non-set-like orders.

## 52 The canonical block decomposition (source 15; routes of sources 16 and 18)

*Note 52.1* ([merge]; one theorem, three proofs). Three batch-81 sources decompose an arbitrary class well-order at once by the same relation:  $x \sim y$  exactly when the closed interval between  $x$  and  $y$  is a set. Each proves that  $\sim$  is an elementary convex equivalence, that every block is set-like of type  $\text{Ord}$  or a set ordinal, that at most one block is a set and it is final, and that the whole order is canonically the lexicographic sum of  $\text{Ord}$  over the class of proper-block representatives, followed by the optional final set block; each realizes every nonempty class well-order as a block-index order in GBC. The statements are source 15's [theorems 52.3](#) and [52.5](#) and [corollary 52.4](#), source 16's [theorems 52.6](#) and [52.8](#) with (S16.11), and source 18's [lemma 52.10](#), [theorem 52.11](#) with (S18.3), and [theorem 52.14](#). Source 15 is printed first because it also writes out the coordinate map  $x \mapsto (\pi_W(x), r_W(x))$  and the realization of every block profile; the other two follow as routes, whole, because each adds statements of its own: source 16 the largest set final segment ([corollary 52.7](#)) and the uniform family of residual tails; source 18 the functoriality of the decomposition ([proposition 52.12](#)), the cofinality of  $R$  read off its blocks ([corollary 52.13](#)), uniform removal of the first  $\alpha$  blocks by one closed definition, and a class well-order isomorphic to its own block quotient ([proposition 52.15](#)). The first block is source 11's canonical initial part ([theorem 15.1](#)), as all three say. The sources do not cite one another (source 18 was written before sources 15 and 16 arrived), and no source has priority. All three state that the decomposition is elementary in GB, without global choice or ETR, and that GBC is used only to transport an abstract order to  $\mathbf{No}$ . The block decomposition answers the block-index clause of [research question 113.3](#) ([section 60](#)).

### 52.1 Source 15: canonical condensation into proper-class blocks

The preceding extraction of the initial set-like part can be extended to *all* blocks at once. This resolves an ambiguity in the question of how much recursion is required: constructing the canonical first-level decomposition is elementary; enumerating its blocks by a prescribed index order, or iterating the decomposition on an arbitrary input, is a different request.

Interval condensation is a standard construction in order theory [34]. Here the size ideal consists of sets, not of countable subsets. Thus the construction belongs to class theory and depends on which collections are sets in the underlying model. Its comparison with familiar countable-interval condensation is structural, not an identification of the two notions.

Work first in GB, with no choice assumption, and let  $(X, W)$  be a class well-order. We use the

formulation that every nonempty available subclass of  $X$  has a least element. Put

$$[x, y]_W = \{z \in X : x \leq_W z \leq_W y\} \quad (x \leq_W y).$$

**Definition 52.2** (Condensation by set intervals). For  $x, y \in X$ , write  $x \sim_W y$  when the closed interval between them is a set. Let

$$B_W = \{b \in X : \text{there is no } aWb \text{ with } a \sim_W b\}.$$

The *condensation* of  $W$  is the induced order on  $B_W$ .

This definition is elementary. For example, “ $[x, y]_W$  is a set” can be written

$$\exists u \forall z (z \in u \longleftrightarrow (z \in X \wedge x \leq_W z \wedge z \leq_W y)),$$

where  $u, z$  are set variables and  $X, W$  are class parameters. Neither the equivalence classes nor a collection of those classes is being used as an element of another class. Their least representatives are sets and form the legitimate class  $B_W$ .

**Theorem 52.3** (Elementary canonical block decomposition). *In GB, the following hold.*

1. *The relation  $\sim_W$  is a convex equivalence relation. Every equivalence class has a least element, and the class function  $\pi_W : X \rightarrow B_W$  sending an element to that least representative is elementary and unique.*
2. *The order  $(B_W, W)$  is a class well-order. Each fiber  $C_b = \pi_W^{-1}(b)$  is set-like in its induced order. It therefore has the order type of a nonzero set ordinal if it is a set, and has order type  $\text{Ord}$  if it is a proper class.*
3. *Every nonfinal fiber is a proper class. Consequently at most one fiber is a set, and such a fiber must be final.*
4. *There is a uniform class order isomorphism*

$$x \longmapsto (\pi_W(x), r_W(x)), \quad r_W(x) = \text{otp}([ \pi_W(x), x ]_W),$$

*onto a lexicographically ordered subclass of  $B_W \times \text{Ord}$ . Every nonfinal vertical section is all of  $\text{Ord}$ ; a final section is either all of  $\text{Ord}$  or a nonzero set ordinal.*

*No elementary-transfinite-recursion principle is required.*

*Proof.* Reflexivity and symmetry are immediate. In a linear order the interval between  $x$  and  $z$  is contained in the union of the intervals between  $x, y$  and between  $y, z$ . A subclass of a set is a set by Separation with class parameters; hence  $x \sim_W y$  and  $y \sim_W z$  imply  $x \sim_W z$ . If  $x \leq_W z \leq_W y$  and  $x \sim_W y$ , the intervals from  $x$  to  $z$  and from  $z$  to  $y$  are subsets of  $[x, y]_W$ , proving convexity.

For any  $x$ , its equivalence class is nonempty and elementary in the parameters, so it has a  $W$ -least element  $b$ . Such  $b$  belongs to  $B_W$ , and conversely every member of  $B_W$  is the least member of its equivalence class. The graph of  $\pi_W$  is therefore given by one elementary formula. Every nonempty available subclass of  $B_W$  is also a subclass of  $X$ , and its  $W$ -least member belongs to it. This proves the quotient’s well-order property without any theorem comparing abstract class well-orders.

Fix  $b \in B_W$  and  $x \in C_b$ . The predecessors of  $x$  in  $C_b$  are exactly  $[b, x)_W$ , a set. Thus  $C_b$  is set-like. Its set-sized predecessor ranks form an initial subclass of  $\text{Ord}$ . If this initial subclass were a set ordinal while  $C_b$  were proper, the inverse rank map and class Replacement would make  $C_b$  a set.

Therefore the rank range is all of Ord precisely in the proper-class case. In the set case it is the ordinary ordinal order type of  $C_b$ .

Suppose now that  $C_b$  is a set and is not final. Let  $d$  be the least point after this fiber. More explicitly, choose the least member of the nonempty class

$$\{z \in X : bWz \text{ and } z \not\prec_W b\}.$$

Convexity and minimality give  $[b, d)_W = C_b$ . Hence  $[b, d]_W = C_b \cup \{d\}$  is a set, contradicting  $d \not\prec_W b$ . This proves the final-fiber assertion.

For each  $x$ , the set well-order  $[\pi_W(x), x)_W$  has a unique ordinal order type. Its order-isomorphism witnesses are sets, so  $r_W$  is defined by elementary comprehension. Elements in different fibers are compared by their representatives; elements in one fiber are compared by their ranks. The displayed map is therefore a class order isomorphism. Its image is defined directly as the class of pairs that occur, so no symbol denoting a “class ordinal” has to be treated as a set-valued section length.  $\square$

The first fiber is exactly the familiar initial part consisting of elements with set-sized predecessor classes. If  $X$  is proper, the following equivalence is particularly useful:

$$W \text{ is set-like} \iff |B_W| = 1.$$

This is an invariant of the individual class well-order. It does not claim that set-likeness is definable in the *bare lexicographic order of all labeled well-orders*; that reconstruction question remains separate.

**Corollary 52.4** (Allowed block profiles). *Every proper-class well-order is canonically a sum of Ord-blocks indexed by a class well-order, with the sole possible exception of a final block of nonzero set-ordinal type. The index order need not be set-like, or even have type Ord.*

The word “canonically” refers to the least-representative quotient and the rank map above. It does not assert that arbitrary class index orders have canonical set codes or admit an ordinal classification inside GB.

**Theorem 52.5** (Every class well-order occurs as a block index). *Assume GBC. Let  $J$  be any nonempty class well-order, with a set or proper-class carrier.*

1. *There is a class well-order of **No** whose canonical condensation is order-isomorphic to  $J$  and whose every block has type Ord.*
2. *For every nonzero set ordinal  $\alpha$ , there is one whose block index is  $J + 1$ , whose blocks indexed by  $J$  have type Ord, and whose final block has type  $\alpha$ .*

*More generally these realize every profile allowed by Theorem 52.3, subject only to the whole carrier being a proper class.*

*Proof.* Order  $J \times \text{Ord}$  lexicographically, comparing the  $J$  coordinate first. This is a class well-order: a nonempty subclass has a least first coordinate and then a least ordinal coordinate. It is proper because  $J$  is nonempty. The interval between two points of the same row is a set. Between points of different rows lies a final segment of the earlier Ord-row, which is proper. Consequently the rows are exactly the equivalence classes, with representatives  $(j, 0)$ .

Global Choice supplies a class bijection between this proper carrier and **No**. Transfer the relation along it. A class bijection takes sets to sets by class Replacement, and the same is true of its inverse; it therefore preserves the set/proper-class distinction used in the condensation definition. This proves the first assertion.

For the second, append the set ordinal  $\alpha$  to  $J \times_{\text{lex}} \text{Ord}$ . This final tail is one new equivalence class. It does not merge with any preceding row because an interval crossing into it contains a proper final segment of an Ord-row. Transfer again to **No**.

For a desired profile with final set block, remove the final index from its proposed index order and apply the second construction. The remaining order must be nonempty: otherwise the whole carrier would be a set. Profiles with no set block use the first construction.  $\square$

For instance, the formal class-order expression  $\text{Ord} \cdot (\text{Ord} + 1)$  has an  $\text{Ord} + 1$  block index. Its final block occurs after a proper class of complete Ord-blocks. No procedure that lists only set-ordinally many initial blocks reaches it. Here the product denotes the explicitly described ordered sum; it is not an ordinal object larger than every ordinal.

## 52.2 Source 16: simultaneous canonical decomposition into ordinal-class blocks

The earlier report extracts the first set-like part of a class well-order and asks how to organize the successive residual parts. A direct interval definition answers this question without carrying out a class-valued recursion. In this section GB suffices; assume that the given relation already is a class well-order in the sense of [Section 51.2](#).

For  $x, y \in X$ , let  $[x, y]_R$  mean the closed interval between them, regardless of which comes first. Put

$$x \sim_R y \iff [x, y]_R \text{ is a set.} \quad (\text{S16.10})$$

Formally the right side is  $\exists s \forall z (z \in s \leftrightarrow z \in [x, y]_R)$ , with  $s$  a set variable.

**Theorem 52.6** (Canonical block decomposition). *The relation  $\sim_R$  is a convex equivalence relation. Every block has a least member and is set-like in its inherited order. Each block is therefore either a set well-order of ordinal type or a proper class well-order of type Ord. There is at most one set block, and it is terminal.*

Let  $J_R$  be the class of least representatives of the proper blocks, ordered by  $R$ , and let  $\alpha_R$  be the ordinal type of the terminal set block, or zero when it is absent. There is a canonical class order isomorphism

$$(X, R) \cong \left( \sum_{j \in (J_R, R)} \text{Ord} \right) + \alpha_R. \quad (\text{S16.11})$$

All the data and the isomorphism are definable by elementary comprehension. The sum is the ordinary class  $J_R \times \text{Ord}$  ordered lexicographically, not a class whose members are classes.

*Proof.* The interval between  $x$  and  $z$  is contained in the union of the intervals between  $x, y$  and between  $y, z$ . Finite union and separation therefore prove transitivity; the other equivalence properties and convexity follow immediately.

Each block is an available nonempty subclass and has an  $R$ -least point  $m(x)$ . The formula saying that  $j \sim_R x$  and no  $R$ -earlier point is equivalent to  $x$  defines  $m$  elementarily. Thus representatives form a subclass of  $X$ , avoiding a quotient carrier made of proper classes. If  $j = m(x)$ , the predecessors of  $x$  within its block are exactly the set  $[j, x)_R$ . Define

$$\rho_R(x) = \text{otp}([j, x)_R, R).$$

This uses only a set well-order and its unique ordinal type. The range of  $\rho_R$  on the block is an initial subclass of Ord. If that range were a set, Class Replacement applied to its inverse would make the block a set. Hence a proper block has rank range all of Ord; a set block has an ordinal rank range.

Suppose a set block  $B$  were not terminal. Let  $c$  be the least point strictly above all of  $B$ . There is nothing between  $B$  and  $c$ . For  $b \in B$ , the interval  $[b, c]_R$  is contained in  $B \cup \{c\}$ , a set. This contradicts maximality of the equivalence block. Thus a set block is terminal, and there is at most one.

On proper blocks,  $x \mapsto (m(x), \rho_R(x))$  is the desired isomorphism; on the optional final block use its ordinal rank. All assertions defining these graphs quantify over sets with  $R$  as a fixed class parameter, so elementary comprehension suffices.  $\square$

### 52.2.1 Every residual tail is now available uniformly

For  $j \in J_R$  put

$$T_j = \{x : j \leq_R x\}, \quad B_j = \{x : m(x) = j\}.$$

The family of tails is one class relation of pairs  $(j, x)$ . Within  $T_j$ , a point  $x$  has a set of predecessors exactly when  $[j, x)_R$  is a set, equivalently when  $x \in B_j$ . Hence  $B_j$  is precisely the canonical initial set-like part of  $T_j$ . The tail  $T_j$  is what remains after all earlier blocks have been deleted. This supplies the whole successive residual family even when  $J_R$  is non-set-like.

**Corollary 52.7** (Largest set final segment). *The class*

$$A_R = \{x \in X : \{y : x \leq_R y\} \text{ is a set}\}$$

*is always a set. It is the largest set-sized final segment of  $R$ , and is exactly its optional terminal block.*

*Proof.* If  $A_R$  is nonempty, let  $a$  be its least point. Every later point has a tail contained in the set tail above  $a$ , so  $A_R$  is precisely that tail, a set. Every set final segment is contained in  $A_R$  by definition. Conversely, a block containing a point of  $A_R$  is the union of a set of block predecessors and a subset of its set tail, and so is a set block. [Theorem 52.6](#) identifies it.  $\square$

Deleting  $A_R$  leaves a labelled prefix consisting of all the proper blocks and having no nonempty set-sized final segment. If that prefix is fixed, its completions form a convex copy of  $\mathcal{W}(A_R)$ . Appending any well-order on  $A_R$  leaves it the largest set final segment, since a tail meeting an earlier Ord block would already be proper. This refines the earlier first-block decomposition: after every proper block is removed, the residual carrier is always a set.

**Theorem 52.8** (All block-index orders occur). *Every nonempty class well-order  $J$ , whether its carrier is a set or a proper class, occurs as the index of the proper blocks of a class well-order. An arbitrary set ordinal can be prescribed as its final block. In GBC the resulting order can be carried by surreal labels.*

*Proof.* Order  $J \times \text{Ord}$  with the  $J$  coordinate primary. A nonempty subclass has a least occupied  $J$  coordinate and then a least ordinal in that section, so this is a class well-order. Intervals inside one section are sets; an interval crossing two sections contains a proper tail of Ord. Its blocks are exactly the sections. Appending a set ordinal gives the stipulated final block. The product is proper, and global choice supplies a class bijection of its carrier with **No**, along which the relation can be transported.  $\square$

If  $J_R$  is a set of type  $\gamma$ , formula (S16.11) means  $\text{Ord} \cdot \gamma + \alpha_R$ . If  $J_R$  is proper and set-like, it means  $\text{Ord} \cdot \text{Ord} + \alpha_R$ . The example  $\text{Ord} \cdot (\text{Ord} + 1) + \alpha$  has block index  $\text{Ord} + 1$ : an Ord-indexed list of its initial blocks would miss its last full block, whereas (S16.10) finds it directly.

### 52.2.2 What this does and does not require from ETR

The construction resolves successive residual extraction for one original order. Repeatedly condensing the *quotient order itself* is another operation. If  $C_R(D)$  denotes the least representatives of set-interval blocks in the induced order on  $D \subseteq X$ , a tower such as

$$D_0 = X, \quad D_{\beta+1} = C_R(D_\beta), \quad D_\lambda = \bigcap_{\beta < \lambda} D_\beta$$

is an elementary class-valued recursion. Each specified finite iteration is elementary; appropriate ETR supplies a uniform transfinite tower. No necessity or exact reversal is established here. Also, since the block-index order can be an arbitrary class well-order, [Theorem 52.6](#) does not solve abstract class well-order comparability or give a universal class ordinal.

### 52.3 Source 18: a simultaneous decomposition into ordinal-class blocks

The repository asks how much class recursion is needed to iterate the extraction of the initial set-like part of a class well-order. A direct definition organizes all of these blocks simultaneously. It avoids a recursion whose successive states are proper classes.

Work in GB and let  $R$  be a class well-order on a proper class  $X$ . Here “class well-order” means that every nonempty available subclass has an  $R$ -least element. For  $x \leq_R y$ , write

$$[x, y]_R = \{z \in X : x \leq_R z \leq_R y\}.$$

The assertion that this interval is a set is the elementary formula

$$\exists a \forall z [z \in a \longleftrightarrow (z \in X \wedge x \leq_R z \leq_R y)].$$

In particular, no quantification over candidate classes is needed.

**Definition 52.9** (Set-interval equivalence). Put  $x \sim_R y$  when the closed  $R$ -interval with endpoints  $x, y$  is a set. Let  $m_R(x)$  be the  $R$ -least element of the equivalence class of  $x$ . A block is represented by this least label, never by placing a proper class inside another class.

**Lemma 52.10** (Block structure). *The relation  $\sim_R$  is an elementary, convex equivalence relation. Every one of its blocks is set-like in its induced order. Every nonfinal block is a proper class. Consequently there is at most one set-sized block, and if present it is final.*

*Proof.* Reflexivity and symmetry are immediate. For transitivity, the interval between two of three points is contained in the union of the intervals from those points to the third; separation and the union of two sets give the result. Convexity follows by taking subsets of an interval.

Fix a block  $C$ . Its least element  $b$  exists by the assumed class well-ordering. If  $x \in C$ , its predecessors within  $C$  form the set  $[b, x]_R \setminus \{x\}$ . Thus the block is set-like. Suppose now that  $C$  is a set and is not final. There is a least point  $d$  after all of  $C$ . Convexity and this minimality imply  $[b, d]_R = C \cup \{d\}$ . This is a set, so  $d \sim_R b$ , contradicting  $d \notin C$ . The final assertion follows because two distinct final blocks are impossible.  $\square$

Let  $B_R$  be the class of least labels of the proper-class blocks, ordered by  $R$ . If there is a final set block, let  $\theta_R$  be its ordinal order type; otherwise put  $\theta_R = 0$ . Since  $X$  is proper,  $B_R$  is nonempty. It may be a set or a proper class.

**Theorem 52.11** (Canonical division by the ordinal class). *In GB, every class well-order  $R$  on a proper class has a canonical class isomorphism*

$$(X, R) \cong (B_R \times \text{Ord})_{\text{lex}} + \theta_R,$$

where the product compares the  $B_R$  coordinate first. All proper blocks have type  $\text{Ord}$ . The block map, the block index order, and the isomorphism are elementary and uniform in  $R$ . No global choice or elementary transfinite recursion principle is used.

*Proof.* A proper, set-like class well-order has type  $\text{Ord}$ : assign to each point the ordinal type of its set of predecessors. The ranks form an initial subclass of the ordinals; if that subclass were a set, the inverse rank map and class replacement would make the domain a set. Hence the rank range is all of  $\text{Ord}$ .

Apply this observation to each proper block. More explicitly, define

$$\rho_R(x) = \text{otp}(\{z : m_R(x) \leq_R z <_R x\}, R).$$

The displayed predecessor interval is a set. Its restricted relation and its unique ordinal order type are sets as well. Thus the graph of  $\rho_R$  is elementary with class parameter  $R$ , and  $(m_R(x), \rho_R(x))$  gives the desired coordinate in a proper block. The same rank map identifies a final set block with  $\theta_R$ . Convexity of the blocks proves order preservation and exhaustiveness.

The class  $B_R$  consists of actual elements of  $X$ , characterized by an elementary formula. Class well-foundedness restricts to it. None of the construction forms a collection having the blocks themselves as elements.  $\square$

**Proposition 52.12** (Uniqueness and functoriality). *A class order isomorphism preserves set-interval equivalence, induces an isomorphism of the proper-block index orders, and preserves the final ordinal  $\theta_R$ . Hence the pair  $(B_R, \theta_R)$  is unique up to class order isomorphism of its first coordinate. The construction works simultaneously for any uniformly coded set- or class-indexed family of input relations.*

*Proof.* A class isomorphism and its inverse send sets to sets by class replacement. They therefore preserve whether an interval is a set, and send block minima to block minima. Ordinal order types of set tails are unique. Conversely an isomorphism of block indices and equality of the final ordinals combine, using the displayed coordinates, to produce an isomorphism of the original orders. Uniformity follows by inserting the family index into the same elementary formulas.  $\square$

The first proper block is exactly the repository's canonical initial set-like part  $I_R$ . Thus the theorem is a simultaneous form of the successive residual decomposition. It does not prove comparability of arbitrary abstract class well-orders: the remaining index order  $B_R$  can be as complicated as any class well-order.

**Corollary 52.13** (Set-sized cofinality from the blocks). *If  $\theta_R > 0$ , the least size of a set cofinal in  $R$  is  $\text{cf}(\theta_R)$ . If  $\theta_R = 0$  and  $B_R$  has a greatest element, no set is cofinal in  $R$ . If  $\theta_R = 0$  and  $B_R$  has no greatest element,  $R$  has a set cofinal subset exactly when  $B_R$  does, and the least sizes agree.*

*Proof.* A nonempty final set tail determines cofinality. A final proper block has type  $\text{Ord}$ , so every set of points in that block is bounded, while earlier blocks cannot help with cofinality. In the remaining case, projecting a set cofinal subset to block minima gives a set cofinal in  $B_R$ . Conversely a set cofinal in  $B_R$  provides a cofinal set of least block labels in  $R$ : because  $B_R$  has no maximum, a cofinal family includes a block strictly beyond the block of any prescribed point. Class replacement preserves the relevant size inequalities.  $\square$

In a full containing-universe interpretation based on an inaccessible  $\kappa$ , the theorem agrees with ordinary ordinal division. The internal ordinal class is externally  $\kappa$ . An internal class interval is an internal set exactly when its external order type is less than  $\kappa$ : regularity bounds the ranks of fewer than  $\kappa$  labels, and internal sets have size less than  $\kappa$ . Thus a well-order of external ordinal type  $\gamma$ , with  $|\gamma| = \kappa$ , decomposes as

$$\gamma = \kappa \cdot \beta + \rho, \quad \rho < \kappa.$$

The elementary internal argument does not require the existence of such a containing universe.

**Theorem 52.14** (Exact spectrum of block index orders). *In GBC, every nonempty class well-order  $\Gamma$  on a class of set labels occurs as  $B_R$ , up to isomorphism, for a class well-order  $R$  of No. Any prescribed set ordinal can simultaneously be realized as the final remainder  $\theta_R$ .*

*Proof.* Form  $(\Gamma \times \text{Ord})_{\text{lex}} + \theta$ . It is a class well-order: a nonempty subclass either meets the product, in which case choose its least first coordinate and then its least ordinal coordinate, or lies in the final ordinal. Within one product fiber, closed intervals are sets. Between distinct fibers, an interval contains a proper final part of an Ord fiber and is proper. The proper blocks are exactly the fibers, and the final  $\theta$ , when nonzero, is one set block. Global choice supplies a class bijection from this proper carrier to No; transport the order.  $\square$

### 52.3.1 Uniform removal through ordinary ordinal stages

The direct decomposition also answers a narrower recursion question. Let  $K_R$  be the initial set-like part of  $B_R$  (all of  $B_R$  if it is a set), and let  $r_R(b)$  be the ordinal type of the predecessors of  $b$  in  $B_R$ , for  $b \in K_R$ . For every set ordinal  $\alpha$ , put

$$U_\alpha = \{x \in X : m_R(x) \in K_R \wedge r_R(m_R(x)) < \alpha\}.$$

The family  $(U_\alpha)_{\alpha \in \text{Ord}}$  is one elementary class relation. Its complement carries the residual order after removal of the first  $\alpha$  proper blocks. At a successor stage, if a proper residual carrier remains, its initial Ord block is removed; at a limit stage the removed domain is the union of the earlier removed domains. If  $B_R$  is a set, removal stops after its ordinal type, leaving  $\theta_R$ .

Thus even this uniform ordinal-indexed instance of apparently class-valued recursion is already available in GB through a closed definition. This is a statement about this particular operation, not a claim that arbitrary class-valued recursions are provable in GB.

### 52.3.2 A class well-order isomorphic to its own block quotient

Let  $\mathcal{P}$  consist of all functions  $f : \omega \rightarrow \text{Ord}$  with finite support. For distinct  $f, g$ , put

$$f \triangleleft g \iff f(n) < g(n), \quad n = \max\{i : f(i) \neq g(i)\}.$$

**Proposition 52.15** (Self-similar block quotient). *The order  $(\mathcal{P}, \triangleleft)$  is a class well-order. Its set-interval blocks consist precisely of functions that agree at every coordinate  $i \geq 1$ . Every block has type Ord, and its block index order is isomorphic to  $(\mathcal{P}, \triangleleft)$  itself. In GBC the example can be transported to a class well-order of No.*

*Proof.* For a nonempty class of functions, the zero function is least if present. Otherwise choose its least possible largest nonzero support index  $d$ . Among functions with that index, minimize the coefficient at  $d$ , then at  $d - 1$ , and so on through 0. A nonempty class of ordinals has a least element,

and there are finitely many steps. The result is least among functions of degree  $d$ , and every larger degree is greater. This proves class well-foundedness.

If  $f, g$  agree above coordinate 0, every function between them has that same tail, and its zeroth coordinate lies in the set ordinal interval between  $f(0)$  and  $g(0)$ . Their interval is a set. If their tails differ and  $f \triangleleft g$ , keep the tail of  $f$  fixed and let the zeroth coefficient run through all ordinals greater than  $f(0)$ . The resulting proper class lies strictly between  $f$  and  $g$ . This proves the description of blocks.

The least label in a block has zeroth coefficient 0. Deleting that coordinate identifies the class of block minima, with its inherited order, with all of  $\mathcal{P}$ . Varying the zeroth coefficient identifies each block with Ord. Finally apply global choice to transfer the proper carrier to No.  $\square$

This example is a rigorous class analogue of the finite-polynomial presentation informally denoted by  $\text{Ord}^\omega$ . The notation is not needed in the construction. It shows that passage to the block quotient need not reduce the order to a simpler isomorphism type. It does not assert nontermination of every possible limit-stage condensation convention; a limit operation must be defined separately.

### 52.3.3 What remains open after the direct decomposition

The repository's question about uniformly organizing successive initial Ord blocks has an elementary answer above, including an exact unrestricted spectrum of block index orders. A distinct question remains: what is the strength of uniformly iterating the *quotient operation itself* through arbitrary class well-orders, with an explicitly specified limit convention? General ETR is a sufficient framework for suitable elementary class recursions, but the present arguments establish neither its necessity for this specific operation nor the strength of alternative limit conventions. The self-similar example rules out a proof based merely on a claimed strict decrease of quotient isomorphism types.

## 53 Condensation histories and the strength of iterated condensation (source 15; sources 16 and 18)

[merge] Source 15's Section 6 constructs, for every class well-order  $J$ , a class well-order whose iterated condensation runs through exactly  $J$  proper stages before reaching a singleton, by one elementary formula. Sources 16 and 18 discuss the same recursion question in the last subsections of their block sections (printed in [section 52](#)); the three discussions agree: finitely many condensations, fixed externally, are elementary; a uniform transfinite tower of condensations is a class-valued recursion for which a suitable ETR suffices; no source claims that ETR is necessary.

### 53.1 Source 15: explicit condensation histories of arbitrary class length

The block theorem admits an additional extension. Every class well-order can be realized as the order of the nontrivial stages of an explicit condensation history. The construction has a direct elementary formula and therefore does not require a general recursion axiom, even when some stages have proper-class many predecessors.

**Definition 53.1** (Finite ordinal polynomials over a class order). For a nonempty class well-order  $(J, <_J)$ , let  $P(J)$  consist of the *set codes* for finite partial functions

$$f : J \rightarrow \text{Ord} \setminus \{0\}.$$

Values off the finite domain are interpreted as zero. The empty function is denoted 0. For distinct  $f, g$ , let  $j$  be the greatest member of their finite disagreement set and put

$$f <_{P(J)} g \iff f(j) < g(j).$$

For completeness, put  $P(\emptyset) = \{0\}$ . These are finite set codes, not proper-class functions used as elements of a class. The greatest disagreement exists because its domain is finite; there is no last-coordinate assumption on  $J$  itself.

**Lemma 53.2** (The polynomial order is a class well-order). *In GBC,  $P(J)$  is a proper class well-order.*

*Proof.* The order laws reduce to ordinary finite lexicographic comparison on the union of the finitely many supports of the polynomials under comparison. If  $j_0$  is the least point of  $J$ , varying the positive ordinal coefficient at  $j_0$  shows that  $P(J)$  is proper.

We first rule out a descending  $\omega$ -sequence  $(f_n)$ . Its union of supports is a set  $A \subseteq J$ ; the restriction of  $<_J$  to  $A$  is a set well-order. Let  $r : A \rightarrow \eta$  be its ordinal rank map. Choose an additively indecomposable ordinal  $\Lambda$  strictly above every coefficient of every  $f_n$ , for example a sufficiently large power of  $\omega$ . For each  $f_n$ , form the ordinary ordinal

$$v(f_n) = \sum_{j \in \text{supp}(f_n)}^{\text{decreasing } <_J} \Lambda^{r(j)} \cdot f_n(j).$$

This is a finite sum. If two polynomials first differ from the top at  $j$ , all their lower terms are less than  $\Lambda^{r(j)}$ . Indeed, each lower exponent is  $\sigma < r(j)$ , each coefficient is less than  $\Lambda$ , and  $\Lambda^\sigma c < \Lambda^{\sigma+1} \leq \Lambda^{r(j)}$ ; finite sums remain below the latter additive principal ordinal. When  $r(j) = 0$  there are no lower terms. Thus the different coefficients at  $j$  decide the ordinal comparison, and  $v$  preserves it strictly. The sequence  $(v(f_n))$  would be descending in Ord, a contradiction.

For completeness, Global Choice converts a nonempty class with no least member into a descending  $\omega$ -sequence. Given  $f$  in such a class, consider the nonempty class of its smaller members. Its members of least set-theoretic rank form a nonempty set. Apply the fixed global choice function to that set to choose the next member. This is a class function, and ordinary set-valued recursion through  $\omega$  constructs the descending sequence. Hence every nonempty available subclass of  $P(J)$  has a least member.  $\square$

**Lemma 53.3** (One condensation removes the least exponent). *Let  $j_0 = \min J$ . In  $P(J)$ , two polynomials lie in the same set-interval block exactly when they agree at every  $j >_J j_0$ . The least representative of that block has coefficient zero at  $j_0$ . Consequently the canonical condensation is the evident copy of  $P(J \setminus \{j_0\})$ .*

*Proof.* If the polynomials agree above  $j_0$ , every polynomial between them has those same upper coefficients. Its coefficient at  $j_0$  lies in a bounded ordinal interval, so the closed interval is a set.

Conversely let  $f < g$  disagree at a coordinate above  $j_0$ . Keep all coefficients of  $f$  above  $j_0$  fixed and replace its coefficient at  $j_0$  by  $f(j_0) + \beta + 1$ , for  $\beta \in \text{Ord}$ . The resulting polynomials lie strictly above  $f$  and strictly below  $g$ : the greatest disagreement with  $g$  is unchanged. They form a proper class, so  $[f, g]$  is not a set. Finally zero is the least ordinal coefficient, which identifies the least block representative.  $\square$

**Theorem 53.4** (Every class well-order is an explicit condensation length). *In GBC, for every nonempty class well-order  $J$  there is a class well-order of **No** with an elementary, uniformly coded condensation history indexed by  $J + 1$ , such that every stage indexed by  $J$  is proper and the appended final stage is a singleton.*

*Proof.* It suffices to use  $P(J)$  and transfer the result to **No** by a class bijection. For  $j \in J$  define the retained representatives

$$H_j = \{f \in P(J) : \text{supp}(f) \subseteq J_{\geq j}\}, \quad H_* = \{0\},$$

where  $*$  is one new final index. Code the indices with disjoint tags if necessary. The class of pairs  $(j, f)$  satisfying this condition is defined by an elementary formula, including when  $J_{< j}$  is proper.

At the least index,  $H_j = P(J)$ . If  $k$  is the immediate successor of  $j$ , [Lemma 53.3](#) applied to the tail  $J_{\geq j}$  shows that the condensation of the induced order on  $H_j$  is exactly  $H_k$ . If  $j$  is last, that same argument gives  $H_*$ .

At a nonzero limit index  $j$ , a polynomial belongs to every  $H_k$  for  $k <_J j$  if and only if none of its support lies below  $j$ . For if  $t <_J j$  lies in the support, choose  $k$  with  $t <_J k <_J j$ ; then the polynomial is absent from  $H_k$ . Thus

$$H_j = \bigcap_{k <_J j} H_k.$$

This intersection is legitimate elementary notation: membership is the set-quantifier statement  $\forall k (k <_J j \Rightarrow (k, f) \in H)$ . If  $J$  has no greatest element, the same argument shows that the intersection over all  $j \in J$  is  $\{0\} = H_*$ .

For every  $j \in J$ , arbitrary ordinal coefficients supported at  $j$  belong to  $H_j$ , so  $H_j$  is proper. If  $j <_J k$ , the polynomial with coefficient one at  $j$  belongs to  $H_j \setminus H_k$ . The history is therefore strictly decreasing at distinct indices and first becomes a singleton at its appended final stage. All formulas, including the full class of stages, have been supplied explicitly. No invocation of elementary transfinite recursion has occurred.  $\square$

Examples include finite histories, a history of length  $\omega$ , one of length  $\text{Ord}$ , and one of length  $\text{Ord} + \text{Ord}$ . These refer to the order of the nontrivial stages, rather than to additional set ordinals. In particular there is no universal set-ordinal bound on the depth of the proper-class block hierarchy.

*Remark 53.5* (A proper quotient can have the same abstract order type). For  $J = \omega$ , deleting the least exponent leaves a tail isomorphic to  $\omega$ . Hence  $P(\omega)$  is order-isomorphic to its own canonical condensation, even though the retained representatives form a proper subclass. The explicit history nevertheless reaches the singleton at stage  $\omega$ . Likewise every set-ordinal tail of  $\text{Ord}$  is isomorphic to  $\text{Ord}$ , while the history for  $P(\text{Ord})$  becomes a singleton only at its appended class-limit stage. Consequently one cannot prove termination by asserting that each condensation strictly decreases the abstract order type.

### 53.1.1 Exactly what this says about recursion strength

For an arbitrary input  $W$ , every *externally fixed finite* number of successive condensations can be constructed in GB by composing elementary definitions. This finite theorem scheme should not silently be replaced by the assertion that one class uniformly codes all finite iterations. The standard principle  $\text{ETR}_\omega$  is a sufficient hypothesis for that uniform history; its final intersection can then be formed by elementary comprehension. Similarly, an appropriate elementary-recursion principle is a sufficient hypothesis for an arbitrary prescribed class-length history on a general input.

No lower bound or equivalence with  $\text{ETR}_\omega$  is claimed for this particular condensation operator. Proving that such a history exists for every  $W$  in GB, or calibrating its additional strength, remains a sharper reverse-mathematical question. The explicit polynomial histories show why a general warning about class-valued recursion must not be converted into an assertion that every individual long construction needs ETR. Here one elementary formula already defines every stage, even along arbitrary given class well-orders.

### 53.1.2 A full-universe consistency check

Suppose an ambient universe contains a strongly inaccessible cardinal  $\kappa$ , and use the full two-sorted model  $(V_\kappa, \mathcal{P}(V_\kappa))$ . For a subclass of  $V_\kappa$ , being an internal set is equivalent to having ambient cardinality less than  $\kappa$ . One direction uses the strong-limit property; the other uses regularity to bound the ranks of fewer than  $\kappa$  many elements. Thus the preceding condensation becomes condensation by intervals of cardinality less than  $\kappa$ .

If the ambient ordinal type of an internal class well-order is  $\theta$ , write its ordinary left ordinal division by  $\kappa$  as

$$\theta = \kappa \cdot \gamma + \delta, \quad \delta < \kappa.$$

Its canonical blocks are the successive  $\kappa$ -segments, followed by one  $\delta$ -segment if  $\delta > 0$ . The quotient has type  $\gamma$  if  $\delta = 0$  and  $\gamma + 1$  otherwise. This is exactly the canonical block theorem as seen from the containing universe. An internal Ord-block is an ambient  $\kappa$ -block, rather than an ambient proper class.

This check also identifies the essential relativity: changing which collections count as sets changes the condensation ideal. The construction is intrinsic to  $(X, W)$  together with the chosen set/class boundary; it is not absolute between arbitrary universes.

*Note 53.6* ([merge]; the self-similar example of sources 15 and 18). Source 15's [remark 53.5](#) and source 18's [proposition 52.15](#) describe the same class well-order: source 15's  $P(\omega)$ , the finite partial functions  $\omega \rightarrow \text{Ord} \setminus \{0\}$  compared at the greatest coordinate of disagreement, is source 18's  $(\mathcal{P}, \triangleleft)$ , the finite-support functions  $\omega \rightarrow \text{Ord}$  compared at the largest coordinate of disagreement. Both show that it is isomorphic to its own block quotient, so that one condensation step need not lower the isomorphism type; source 18 proves it in full, source 15 deduces it from [lemma 53.3](#). Their full-universe checks agree as well: source 15's subsection above, source 18's remark after [corollary 52.13](#), and source 18's [section 57.5](#) all identify the internal block decomposition in  $(V_\kappa, \mathcal{P}(V_\kappa))$ ,  $\kappa$  inaccessible, with left ordinal division by  $\kappa$ .

## 54 Finite components and trace fibres (source 17; sources 18 and 14)

*Note 54.1* ([merge]; what is repeated and what is new). Source 17's [theorem 54.2](#) is source 11's [theorem 16.2](#) and source 12's [theorem 16.6](#), which it calls a “source result”. Its [theorem 54.4](#) identifies the maximal finite-adjacency components of the unrestricted order: they are the  $n!$  permutations of the maximal finite final segment. Finite permutation blocks after a common prefix are already source 12's [corollary 16.7](#) and, for set alphabets, source 08's [note 6.26](#); new in [theorem 54.4](#) are the maximality of these blocks on the class carrier, the uniqueness of the factorization  $R = P + \tau$ , and the density of the quotient. Source 18 proves the same component theorem independently ([lemmas 58.1](#) and [58.2](#) and [proposition 58.3](#), printed with its countable models in [section 58](#)), and adds that every factorial block size occurs densely ([lemma 58.5](#)).

Source 14's Section 10, printed second, recalls the direct comparison and the canonical initial branch ([lemma 54.5](#); source 11's [theorem 15.1](#), source 13's [proposition 51.8](#), source 15's [proposition 51.10](#)) and proves that the trace of an unrestricted order on the core is the cut of its initial branch ([theorem 54.6](#)). Its [example 54.7](#) (singleton fibres need not be set-like;  $m!$  elements over  $m$  omitted labels) is source 11's [remark 15.4](#) and [proposition 15.3](#), which source 14 does not cite, and its [corollary 54.8](#) is the statement about raw orders printed in Part VIII by sources 13, 15, 16, 17 and 18 ([note 46.5](#)). New in source 14's section is the exact description of the trace fibres over the core as the convex families  $F + Q$ .

### 54.1 Source 17: unrestricted orders and their finite condensation

The restriction to set-like orders is not cosmetic. After a class prefix has exhausted almost every label, the residual alphabet can be finite, and numerical density of **No** is no help. We recall the source's exact adjacency theorem and then identify the maximal components generated by adjacency.

**Theorem 54.2** (Adjacency after a common prefix; source result). *Let  $R <_{\text{lex}} S$  be well-orders of the same labelled class  $X$ , and let  $C$  be their largest common labelled prefix. Write  $a < b$  for the next labels and  $Y = X \setminus C$ . The orders are adjacent if and only if  $Y$  is finite and their permutations of  $Y$  after  $C$  are consecutive in the finite lexicographic order.*

*Proof.* A remaining label strictly between  $a$  and  $b$  would start an intermediate order, followed by a restriction of one given well-order. Also, the tail of  $R$  after  $a$  must be a lexicographically greatest well-order of its remaining labels; otherwise replacing that tail gives an intermediate order. Such a greatest order exists exactly when the native decreasing order is itself a well-order: any pair listed in native increasing order can be transposed to make the enumeration larger. Dually, the  $S$ -tail after  $b$  must be the native increasing order.

Thus  $Y \setminus \{a, b\}$  is well-ordered both in native increasing and native decreasing order. It is finite. Indeed, otherwise successively choosing increasing elements by their well-order creates a strictly increasing  $\omega$ -sequence, a set with no greatest element, contradicting reverse well-ordering. Hence  $Y$  is finite, and no intermediate residual permutation exists precisely when the two permutations are consecutive. The converse follows directly from convexity of the common-prefix cylinder. These are the source's arguments (theorems 16.2 and 16.6).  $\square$

**Definition 54.3** (Finite-adjacency components). Two orders are in the same component when a finite chain of adjacent pairs connects them. This is a uniform relation on the well-order predicates, or an ordinary equivalence relation in an explicitly larger set-universe interpretation. We do not form a same-level class of proper-class equivalence classes.

**Theorem 54.4** (Exact maximal finite components). *Every well-order  $R$  of the whole surreal carrier has a unique factorization*

$$R = P + \tau,$$

*where  $\tau$  is a finite final segment of length  $n$ , and  $P$  has no greatest element. The integer  $n$  may be zero. The finite-adjacency component of  $R$  consists exactly of all  $n!$  permutations of these same  $n$  final labels following the fixed prefix  $P$ .*

*After identifying each such component, the resulting higher-order linear comparison is dense and has no endpoints. A nonsingleton component intrinsically determines its terminal length  $n \geq 2$  from its size  $n!$ . Singleton components do not distinguish terminal lengths 0 and 1.*

*Proof.* Repeatedly delete the greatest point for as long as one exists. This process must stop after finitely many deletions: otherwise set-valued recursion on  $\omega$  produces a strictly descending  $\omega$ -sequence in  $R$ , contradicting the well-order property. The remaining prefix is still a proper class, since only finitely many labels were removed, and has no greatest element. This establishes existence and uniqueness of the maximal finite final segment.

All its  $n!$  permutations form a finite convex block, by common-prefix convexity. Consecutive members are adjacent by Theorem 54.2, so they are in one component. Suppose an order in this block has an adjacent neighbor. Their common prefix is cofinite. It must contain all of  $P$ : if it stopped strictly inside  $P$ , its nonempty residual final part of  $P$  would be finite and would have a greatest element, making  $P$  have a greatest element. That is impossible. Thus an adjacent neighbor

can change only the finite final labels and remains in the displayed block. No adjacency chain leaves it.

All components are finite and consequently have first and last elements. If two distinct components were adjacent in the quotient, the last member of the earlier one and first member of the later one would be adjacent in the original order, joining the components. Hence the quotient is dense. The original comparison has no endpoints: replace its first label by any smaller or larger label, then append the restriction of its well-order to the remaining labels. Since each component is finite, the quotient has no endpoints either. Strict increase of  $n!$  for  $n \geq 2$  proves the intrinsic size assertion.  $\square$

This is a description of the *maximal adjacency components*, not just of some finite cylinders. It does not identify the quotient with  $\mathfrak{W}_{\text{sl}}$  or with **No**. The many non-set-like convex fibres from [Proposition 46.27](#) can retain substantial structure after all finite components have been collapsed.

## 54.2 Source 14: unrestricted class well-orders and the trace quotient

The enumeration picture only covers *set-like* well-orders of the whole surreal class. For arbitrary class well-orders, some elements may have proper-class predecessor collections, so an ordinal-valued position need not exist for every label. We first recall how to compare such orders without inventing those positions.

### 54.2.1 Elementary comparison of labelled relations

Let  $R, S$  be strict class well-orders on the same labelled carrier **No**. For a label  $x$ , write  $\text{Pred}_R(x) = \{y : yRx\}$ . Define  $C$  by

$$x \in C \iff \text{Pred}_R(x) = \text{Pred}_S(x) \text{ and } R \upharpoonright \text{Pred}_R(x) = S \upharpoonright \text{Pred}_S(x).$$

Restrictions in this formula concern binary relations on the indicated predecessor classes. Equality expands into quantifiers over set labels; no class variable is bound. It follows directly that  $C$  is initial in both orders and their restrictions to  $C$  agree. If they differ,  $C$  is proper. Let  $a$  be the  $R$ -least label outside  $C$  and  $c$  the  $S$ -least such label. Their existence uses that the relations are class well-orders. They are distinct: if they coincided, that label too would have identical predecessors and identical predecessor relations, and would belong to  $C$ . Set

$$R <_{\text{lex}} S \iff a < c \text{ in numerical surreal order.}$$

This is the direct comparison developed in the predecessor ([theorems 14.2, 15.1 and 16.2](#); Sections 14–16 at the pin). For completeness, its transitivity has a particularly small proof. If  $R <_{\text{lex}} S <_{\text{lex}} T$ , the common prefixes for  $(R, S)$  and  $(S, T)$  are initial segments of the same well-order  $S$ , hence nested. If one is shorter, its first discrepancy already compares  $R$  with  $T$  in the asserted direction; the third order still follows  $S$  there. If the two prefixes agree, the three next labels satisfy  $a < b < c$  in numerical order. This gives  $R <_{\text{lex}} T$ . Totality and asymmetry follow from the distinct next labels. When both orders are set-like, this definition agrees with enumeration comparison.

There is no step comparing two abstract class order types by a newly constructed class isomorphism. The labels allow comparison by literal agreement of predecessors. That is the reason no appeal to ETR is needed here.

### 54.2.2 The canonical initial branch

**Lemma 54.5** (Initial set-like branch). *Every  $R \in \mathfrak{M}_{\text{all}}$  has a canonical injective class function  $J_R : \text{Ord} \rightarrow \mathbf{No}$  whose range is an initial segment of  $R$ . It is characterized by*

$$J_R(\alpha) = x \iff \text{Pred}_R(x) \text{ is a set and } \text{otp}(\text{Pred}_R(x), R) = \alpha.$$

*Its range is exactly the labels with set-sized predecessor collections. The relation  $R$  is set-like if and only if  $J_R$  is exhaustive.*

*Proof.* For each set ordinal  $\alpha$ , recursively take the least unused label for  $\alpha + 1$  stages. At every intermediate stage the used labels are a set, whereas the carrier is proper, so the remaining class is nonempty and has an  $R$ -least element. Its predecessor set is precisely the labels already chosen. These set-length recursions are unique and compatible. Their elementary characterization in the display gives a class function on  $\text{Ord}$ . Conversely any label with set predecessors occurs at the order type of that predecessor set. Initiality and the remaining assertions follow immediately.  $\square$

For  $F \in \mathfrak{J}$ , put  $X_F = \mathbf{No} \setminus \text{ran } F$ . Concatenate the order given by  $F$  with any class well-order  $Q$  of  $X_F$ , writing  $F + Q$  for the resulting labelled relation. Such a  $Q$  exists, for example by restricting the baseline well-order to  $X_F$ . The concatenation is a class well-order: a nonempty subclass meeting the first block has a least ordinal position there, and otherwise has a least element in the second block. Its initial branch is exactly  $F$ , because every label in the second block has the proper class  $\text{ran } F$  among its predecessors. Thus every injective branch, exhaustive or not, arises as  $J_R$ .

### 54.2.3 What the skeleton can and cannot distinguish

Define the trace of an unrestricted relation on the core by

$$\text{Tr}_b(R) = \{\sigma \in \mathcal{P}_s(b) : E_\sigma <_{\text{lex}} R\},$$

where a core enumeration is identified with its induced set-like well-order relation.

**Theorem 54.6** (Trace fibers and their exact loss of information). *For every unrestricted labelled class well-order  $R$ ,*

$$\text{Tr}_b(R) = D_{J_R}.$$

*Consequently*

$$\text{Tr}_b(R) = \text{Tr}_b(S) \iff J_R = J_S.$$

*For a fixed  $F \in \mathfrak{J}$ , its trace fiber is the convex family*

$$\{F + Q : Q \text{ is a class well-order of } X_F\}.$$

*The quotient by equality of core traces is therefore identified, in the virtual sense, with the lexicographic order  $\mathfrak{J}$ . Its image in the normalized cuts is exactly the branch alternative of [Theorem 43.3](#), not the entire cut collection.*

*Proof.* If  $E_\sigma$  differs from  $J_R$  at  $\alpha$ , the labelled orders agree before that ordinal and their next labels are  $E_\sigma(\alpha)$  and  $J_R(\alpha)$ . Both comparisons therefore have the same sign. If they agree everywhere,  $J_R = E_\sigma$  is exhaustive, so  $R$  is exactly that set-like order and neither strict comparison holds. This proves the trace formula.

If two initial branches differ, [Lemma 41.5](#) gives a core code between them, which belongs to the larger trace but not the smaller one. Thus trace equality forces branch equality. The concatenation

description above proves the asserted fiber and its surjectivity over all  $F$ . Distinct branches are compared at a set coordinate before either tail, so every fiber is convex and the order of fibers agrees with the lexicographic order of  $\mathfrak{J}$ . Finally the trichotomy separates branch traces from cylinder and numerical edges.  $\square$

**Example 54.7** (Singleton fibers need not be set-like). If  $X_F$  is empty, the fiber is the singleton exhaustive order  $F$ . If  $X_F = \{x\}$ , it is again a singleton, but its order is the non-set-like concatenation of an Ord-long initial block with the last label  $x$ . Its trace is not realized by any exhaustive enumeration. Thus “singleton trace fiber” is not a criterion for being set-like. For finite  $|X_F| = m$ , the fiber has exactly  $m!$  elements, ordered as the finite permutations of that residual alphabet. Larger residual alphabets retain their full well-ordering problem inside the fiber.

This gives a useful diagram of interpretations:

$$\mathfrak{W}_{\text{sl}} \subsetneq \mathfrak{J} \longrightarrow \{\text{normalized core cuts}\}, \quad \mathfrak{W}_{\text{all}} \twoheadrightarrow \mathfrak{J},$$

where the first arrow into cuts is injective and the last map has the fibers just described. The braces and arrows here abbreviate virtual relations on classes. They do not form a same-sort diagram of class objects in GBC.

The quotient is not the usual finite condensation of a linear order. It can collapse an infinite, even higher-order, family of tails sharing a proper-class initial branch. Conversely finite adjacent blocks elsewhere in the full order are governed by the finite residual-alphabet analysis of the predecessor. Equality of traces is precisely the observational equivalence given by *all set-supported test enumerations*.

**Corollary 54.8** (Raw orders do not fill every core boundary). *A cylinder-edge or numerical-gap cut of  $\mathcal{P}_s(b)$  is not the trace of any unrestricted class well-order of the full surreal carrier. Allowing non-set-like tails adds realizations of omitted-range branch cuts, but cannot supply all missing core cuts.*

The distinction is sharper than saying that the set-like order is incomplete. Some missing boundaries correspond to an honest Ord-long initial branch with unvisited labels and are supplied by an unrestricted tail. Other boundaries stop at a set stage and are not supplied by any such tail.

## 55 Asymmetric products and the role of semantics (source 13)

### 55.1 Absorbing a class-sized left factor

An isomorphism involving  $\mathfrak{W}_{\text{sl}}$  is understood first as a pair of inverse uniform transformations of class parameters. For example, a map on  $\mathbf{No} \times \mathfrak{W}_{\text{sl}}$  takes a set label and a class enumeration and returns a class enumeration by a fixed definition. It is not asserted to be an ordinary class of pairs whose entries include arbitrary classes.

**Theorem 55.1** (Left-factor absorption). *In GBC there are uniform inverse order isomorphisms*

$$\mathfrak{W}_{\text{sl}} \cong \mathbf{No} \times_{\text{lex}} \mathfrak{W}_{\text{sl}}.$$

*Consequently, for every ordinary class linear order  $K$ , there is a uniform embedding*

$$K \times_{\text{lex}} \mathfrak{W}_{\text{sl}} \hookrightarrow \mathfrak{W}_{\text{sl}}.$$

*Proof.* Use the uniform complement isomorphisms of [Lemma 42.2](#). Given  $(x, E)$ , define  $\Phi(x, E)$  by

$$\Phi(x, E)(0) = x, \quad \Phi(x, E)(1 + \alpha) = h_{\{x\}}(E(\alpha)) \quad (\alpha \in \text{Ord}).$$

The map  $\alpha \mapsto 1 + \alpha$  is the increasing parametrization of the ordinal tail after its first point. The displayed function is a bijection, since its tail covers exactly  $\mathbf{No} \setminus \{x\}$ .

Recover  $x$  as the first value and apply  $h_{\{x\}}^{-1}$  to the tail to obtain the inverse. Different first labels are compared immediately; with the same first label, the increasing complement isomorphism preserves the first tail disagreement. Thus  $\Phi$  is an order isomorphism. Embed  $K$  into  $\mathbf{No}$  by [Lemma 42.2](#) and compose with  $\Phi$ .  $\square$

This includes every ordinary class-indexed lexicographic sum of copies of  $\mathfrak{W}_{\text{sl}}$ , including index orders such as  $\text{Ord}$ ,  $\text{Ord}^*$  and  $\text{Ord} + \text{Ord}$ . It does *not* include the full  $\mathfrak{W}_{\text{sl}}$  as the index order: its members are classes, not set codes.

## 55.2 A dense-core obstruction to splitting every point

**Lemma 55.2** (Split-order density bound). *Let  $M$  be a dense set-sized linear order and let  $D \subseteq M$  be order-dense. If  $K \times_{\text{lex}} 2$  embeds into  $M$ , then  $|K| \leq |D|$  in ZFC.*

*Proof.* For each  $k$ , the images of  $(k, 0)$  and  $(k, 1)$  enclose a nonempty open interval of  $M$ . The intervals for different  $k$  are disjoint. Choose a point of  $D$  in each, using the least one in a fixed well-order of  $D$ . This injects  $K$  into  $D$ .  $\square$

The source pairs may be adjacent; that does not invalidate the argument. An order embedding need not preserve adjacency, and the target's density puts a point between their images. The proof is an interval counting argument rather than a count of all points in the target.

**Theorem 55.3** (No full split in an inaccessible universe). *Work in ambient ZFC and let  $\kappa$  be strongly inaccessible. Interpret internal sets as  $V_\kappa$  and classes as all ambient subsets of  $V_\kappa$ . For the resulting global enumeration order,*

$$\mathfrak{W}_{\text{sl}} \times_{\text{lex}} 2 \not\hookrightarrow \mathfrak{W}_{\text{sl}}.$$

*In particular,  $\mathfrak{W}_{\text{sl}}^2 \not\hookrightarrow \mathfrak{W}_{\text{sl}}$  and  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} \mathbf{No}^{V_\kappa} \not\hookrightarrow \mathfrak{W}_{\text{sl}}$ , although  $\mathbf{No}^{V_\kappa} \times_{\text{lex}} \mathfrak{W}_{\text{sl}} \cong \mathfrak{W}_{\text{sl}}$ .*

*Proof.* Externally, the internal surreal carrier is  $X = \mathbf{No}_{<\kappa}$  of cardinality  $\kappa$ , and the available set-like global enumerations are exactly all bijections  $\kappa \rightarrow X$ . Every restriction to an internal set has ranks bounded below  $\kappa$  by regularity, so these functions are legitimate full-model classes. The cardinality of this order is  $2^\kappa$ : permutations give the upper bound, and independent pair reversals the lower bound.

The core  $D$  of internal set-support codes has ambient cardinality  $\kappa$ . For the upper bound, all its codes belong to  $V_\kappa$ , whose ambient cardinality is  $\kappa$ ; transpositions give the lower bound. The internal interpolation theorem makes  $D$  order-dense in the external enumeration order. This order is dense. Applying [Lemma 55.2](#) would force  $2^\kappa \leq \kappa$ , contrary to Cantor's theorem.

Choose two distinct points in the second factor of either proposed larger product. This gives a suborder isomorphic to  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} 2$ , so both nonembeddings follow. The reverse-order placement of  $\mathbf{No}^{V_\kappa}$  is covered by [Theorem 55.1](#).  $\square$

The earlier report uses the same dense-core mechanism to rule out an embedding of all raw well-orders into the set-like fragment ([theorem 20.1](#)). The new point is that merely splitting *each existing set-like point into two* already creates the obstruction. It is unnecessary to introduce

the entire raw well-order domain. [merge] That proof already uses only the adjacent raw pairs  $F + (a, b) < F + (b, a)$ , with  $F$  ranging over the bijections of  $\kappa$  onto  $X \setminus \{a, b\}$ ; these pairs form a copy of  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} 2$  (the set-like orders of  $X \setminus \{a, b\}$  form a copy of  $\mathfrak{W}_{\text{sl}}$ ). So the proof of [theorem 20.1](#) already establishes [theorem 55.3](#); source 13's theorem isolates that conclusion and states it for  $\mathfrak{W}_{\text{sl}}$  itself, and its “new point” is a new statement, not a new mechanism.

### 55.3 The uniform Kelley–Morse version

**Theorem 55.4** (No definable uniform split embedding). *For each fixed formula, with fixed set and class parameters, that defines a total transformation from  $\mathfrak{W}_{\text{sl}} \times 2$  to  $\mathfrak{W}_{\text{sl}}$ , the theory  $\text{KM} + \text{GC}$  proves that the transformation is not an order embedding. The transformation may be specified relationally by a unique output class for each input. This is a schema about formulas, not quantification over arbitrary third-sort functions.*

*Proof.* Suppose a formula defines an embedding  $\Psi$ . For every  $E \in \mathfrak{W}_{\text{sl}}$ , choose the globally least code  $q_E \in \mathcal{P}_s(b)$  satisfying

$$\Psi(E, 0) < E_{q_E} < \Psi(E, 1).$$

The interval is nonempty and meets the core. The definition of its eligible code class can use the formula for  $\Psi$  and its output classes;  $\text{KM}$  permits the necessary comprehension. For distinct  $E, F$ , the image intervals are disjoint. Hence

$$q_E = q_F \implies E = F.$$

Now form the ordinary class evaluator

$$T(q, \alpha, x) \iff \exists \text{ class } E [E \in \mathfrak{W}_{\text{sl}} \wedge q = q_E \wedge E(\alpha) = x].$$

This is the decisive impredicative comprehension step. Each nonempty row is the graph of a unique enumeration, and every enumeration occurs in some row. It contradicts [Theorem 42.7](#).  $\square$

The same conclusion applies to uniform embeddings of  $\mathfrak{W}_{\text{sl}}^2$  or  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} \mathbf{No}$  into  $\mathfrak{W}_{\text{sl}}$ , by restricting the second coordinate to two fixed choices. The argument adapts the prior report's impredicative inverse-evaluator proof for raw orders ([theorem 20.2](#)). Elementary  $\text{GB}$  comprehension alone does not justify the displayed existential class quantifier in  $T$ , and no claim to that effect is made. [merge] Applied to the same pairs  $F + (a, b) < F + (b, a)$ , the proof of [theorem 20.2](#) is the proof of [theorem 55.4](#).

### 55.4 Externally countable models reverse the conclusion

**Proposition 55.5** (External countable collapse of the order). *Let  $(M, \mathcal{C})$  be an externally countable model of  $\text{GBC}$ . The external order of its available global enumerations is isomorphic to  $(\mathbb{Q}, <)$ . Consequently, with arbitrary external maps,*

$$\mathfrak{W}_{\text{sl}}^2 \cong \mathfrak{W}_{\text{sl}}, \quad \mathfrak{W}_{\text{sl}} \times_{\text{lex}} 2 \hookrightarrow \mathfrak{W}_{\text{sl}}.$$

*Proof.* The collection of available class objects is externally countable. The internal theorems asserting density and absence of endpoints provide actual witnesses among those objects, so its induced external order is a countable dense linear order without endpoints. The classical back-and-forth for such orders identifies it with  $\mathbb{Q}$ . The lexicographic square of a countable dense order without endpoints is again countable, dense, and without endpoints. The two-point split is a countable linear order, which embeds into  $\mathbb{Q}$  by the elementary countable embedding construction.  $\square$

Even if the model also satisfies  $\text{KM} + \text{GC}$ , such an external embedding need not be represented by an internally uniform definition. Likewise, an external countable cofinal sequence need not be an internal set-coded sequence. This explains exactly why the proposition and [Theorem 55.4](#) do not conflict.

The question “does the global order contain its lexicographic square?” therefore has no unqualified model-independent answer until the meaning of the collection and of an allowed map has been fixed.

*Note 55.6* ([merge]; credits, and source 08’s question on products). [Theorem 55.1](#) is proved with the uniform complement isomorphisms  $h_S$  of [lemma 42.2](#) (source 11’s [proposition 5.13](#), source 09’s [theorem 5.17](#)). Its map  $\Phi(x, \cdot)$  is the isomorphism of  $\mathfrak{W}_{\text{sl}}$  onto the first-label cylinder  $C_{(x)}$  constructed in [proposition 19.25](#) and [note 19.26](#), which source 13 does not cite; the absorption theorem assembles these cylinder isomorphisms over all first labels  $x$ . As the merge notes inside the section say, the proofs of [theorems 55.3](#) and [55.4](#) are the proofs of source 11’s [theorems 20.1](#) and [20.2](#) applied to the pairs they already use, and [proposition 55.5](#) is the observation source 11 makes after [theorem 20.2](#) (“for an externally countable model these collections can both be countable”) turned into an isomorphism with  $\mathbb{Q}$ ; source 18’s [theorem 58.6](#) reproves its second clause and classifies the full order ([section 58](#)). Together they answer source 08’s question 7 on full virtual lexicographic products ([section 60](#)); the index of [section 113](#) had it open on 2 October 2026, although the negative half already followed from source 11’s proofs. Source 13’s critical scope conditions apply: the product nonembedding is not claimed as a theorem of bare GBC about a third sort of maps (its status file, item 3).

## 56 Coding, diagonalization, and a sharper comprehension bound (source 16; source 14)

### 56.1 Binary class words and representable suborders

Let  $\mathbb{B}_{\text{Ord}}$  denote binary class functions on  $\text{Ord}$ , with first-disagreement comparison. In the sense of uniform transformations,

$$\mathfrak{W}_{\text{sl}} \simeq_e \mathfrak{J} \simeq_e \mathbb{B}_{\text{Ord}}. \quad (\text{S16.15})$$

For one direction, partition the baseline values into ordinal-indexed pairs and list each pair increasingly or decreasingly according to the input bit. Here the coordinate pairs are  $\{2 \cdot \xi, 2 \cdot \xi + 1\}$ , with ordinal multiplication. This embeds all binary classes into exhaustive enumerations. For the other, globally enumerate the set codes of  $\mathcal{P}_{\text{bd}}(b)$  as  $(q_\xi)_{\xi \in \text{Ord}}$  and send  $F \in \mathfrak{J}$  to

$$D_F = \{\xi : E_{q_\xi} < F\}.$$

If  $F < G$ , density gives a core point strictly between them. Thus  $D_F \subsetneq D_G$ , whose characteristic words have the same first difference direction. Inclusion  $\mathfrak{W}_{\text{sl}} \subseteq \mathfrak{J}$  finishes [\(S16.15\)](#). This extends the earlier report’s coding argument to the injective comparison as well.

Equipmorphism is not isomorphism. Binary class words have least and greatest words and adjacent pairs, while  $\mathfrak{W}_{\text{sl}}$  and  $\mathfrak{J}$  are dense and have no endpoints. Likewise, any one injectively and uniformly indexed class family in  $\mathfrak{W}_{\text{sl}}$  is an ordinary class linear order on its indices, and hence embeds into **No** in GBC. This does not supply an embedding of the entire virtual collection of global enumerations into **No**. There is no exhaustive uniform family at the same level.

**Theorem 56.1** (No exhaustive uniform class of set codes). *In GBC, no class of set indices with one uniform evaluation relation contains every class well-order of **No** among its rows. In fact a set-like well-order is missing from every such family.*

*Proof.* Use global choice to reindex the rows by Ord, repeating a default row if the original family was a nonempty set. For each ordinal  $\xi$ , sort the two labels  $b(2 \cdot \xi), b(2 \cdot \xi + 1)$  as  $a_\xi < c_\xi$ . Define a new enumeration by keeping the pair blocks in ordinal order. Within pair  $\xi$ , place  $c_\xi$  before  $a_\xi$  if  $(a_\xi, c_\xi)$  belongs to relation row  $\xi$ , and otherwise place  $a_\xi$  before  $c_\xi$ . This local rule is elementary even for empty or malformed rows. The new enumeration is exhaustive and set-like; it differs from every well-order row  $\xi$  on that pair. The empty-family case is immediate.  $\square$

Formula strings do not evade this theorem. Each fixed formula defines its own class when comprehension applies, but uniformly evaluating all formulas over the entire universe would require a suitable truth predicate. Neither a metatheoretic list of formulas nor a proper class of their finite syntactic codes supplies such an evaluator.

## 56.2 A sufficient bound below full Kelley–Morse

The prior report proves in KM plus global choice that no fixed definable total transformation from  $\mathfrak{W}_{\text{all}}$  to  $\mathfrak{W}_{\text{sl}}$  is an order embedding, allowing arbitrary formulas defining the transformation. For elementary formulas the following sharper sufficient bound holds.

**Theorem 56.2** (Elementary transformations and  $\Sigma_1^1$  comprehension). *Work in  $\text{GBC} + \Sigma_1^1\text{-CA}$ . Let  $\vartheta(R, E)$  be a fixed formula with only set quantifiers, with fixed set and class parameters allowed. Suppose it specifies a unique class output  $E \in \mathfrak{W}_{\text{sl}}$  for every  $R \in \mathfrak{W}_{\text{all}}$ . The specified transformation is not an order embedding.*

*Proof.* Assume an embedding is specified. Fix numerical labels  $a < c$ . For each class bijection  $F : \text{Ord} \rightarrow \mathbf{No} \setminus \{a, c\}$  form

$$R_F = F + (a, c), \quad S_F = F + (c, a).$$

These are adjacent raw orders, and different  $F$  give disjoint, ordered pairs. Their alleged images  $E_0 < E_1$  have a bounded-support code between them. Let  $q_F$  be the least such code in a fixed global well-order of  $\mathcal{P}_{\text{bd}}(b)$ . The image intervals are disjoint, so  $q_F = q_G$  implies  $F = G$ .

The required inverse-evaluation predicate has precisely the form

$$\begin{aligned} \text{Eval}(q, \xi, x) \iff \exists F \exists E_0 \exists E_1 [ & \text{Bij}(F) \wedge \vartheta(R_F, E_0) \wedge \vartheta(S_F, E_1) \\ & \wedge \text{LeastBetween}(q, E_0, E_1) \wedge F(\xi) = x ]. \end{aligned} \quad (\text{S16.16})$$

The three displayed existential variables range over classes; the matrix has only set quantifiers. The constructed raw orders can be substituted directly into the elementary formula  $\vartheta$ , and “least code between” quantifies only over set codes. Thus  $\Sigma_1^1$  class comprehension forms this evaluator.

Its rows are empty or unique bijection graphs, and every such  $F$  occurs as a row. Compose each nonempty row with a fixed bijection  $\mathbf{No} \setminus \{a, c\} \rightarrow \mathbf{No}$ , and fill empty rows with a default. This is an exhaustive uniformly class-indexed family of global enumerations. Replace each bijection row by its induced well-order relation, an elementary conversion, and apply [Theorem 56.1](#) to obtain the contradiction.  $\square$

This proves a sufficient comprehension bound, not a reversal. It does not show that  $\Sigma_1^1$  comprehension is necessary, nor that the same proof works for arbitrary  $\vartheta$  with unrestricted class quantifier alternations. The syntax of the claimed transformation is part of the theorem. The distinction between elementary and impredicative class definitions is consistent with the known hierarchy around ETR and KM [\[27, 22, 24\]](#).

### 56.3 Source 14: binary class words and global permutations

A characteristic function  $d : \text{Ord} \rightarrow \{0, 1\}$  can be turned into a global enumeration by pair orientations. Partition the ordinals into pairs  $2 \cdot \alpha, 2 \cdot \alpha + 1$ ; ordinal multiplication has 2 on the left. Sort the corresponding baseline labels as  $u_\alpha < v_\alpha$ . Put the pair in order  $(u_\alpha, v_\alpha)$  when  $d(\alpha) = 0$  and  $(v_\alpha, u_\alpha)$  when  $d(\alpha) = 1$ . Every baseline label is used exactly once. The first differing bit produces the first differing pair in the correct lexical direction.

Conversely, enumerate the core codes by a fixed class bijection  $\text{Ord} \rightarrow \mathcal{P}_s(b)$ . The characteristic function of  $D_E$  in this schedule is an order embedding of  $\mathfrak{W}_{\text{sl}}$  into binary class words: if  $E < F$ , then  $D_E \subsetneq D_F$  by core density, and the first changed bit is 0 versus 1. Thus the known equimorphism

$$\mathfrak{W}_{\text{sl}} \simeq_e (\{0, 1\}^{\text{Ord}}, <_{\text{lex}})$$

is entirely uniform. It is not an isomorphism. The binary class-word order has endpoints and adjacent pairs of the form  $p \frown (0) \frown (1, 1, \dots)$  and  $p \frown (1) \frown (0, 0, \dots)$ ;  $\mathfrak{W}_{\text{sl}}$  is dense without endpoints. These are class-word constructions, not sets of every binary class.

**Theorem 56.3** (No exhaustive uniform class of codes, inherited). *There is no uniformly Ord-indexed family containing every member of  $\mathfrak{W}_{\text{sl}}$ . More generally no ordinary class of set codes, with one uniform evaluation relation, exhausts all global enumerations.*

*Proof.* Suppose  $(E_\alpha)_{\alpha \in \text{Ord}}$  were such a family. In the pair at  $2 \cdot \alpha, 2 \cdot \alpha + 1$ , choose the orientation whose first entry differs from  $E_\alpha(2 \cdot \alpha)$ . At least one of the two orientations works, since the pair labels are distinct. The resulting class function is a bijection, as it only reorders disjoint baseline pairs, and it differs from every row  $E_\alpha$  at the designated coordinate. This is an elementary diagonal construction.

An ordinary proper class of set codes admits a set-like global enumeration in GBC; a set of codes can be padded to an Ord-indexed family. Either kind of exhaustive uniform evaluation would therefore contradict the first assertion. This is the predecessor's diagonal obstruction in an explicit pair form.  $\square$

A skeleton is therefore a dense *test family*, not a list of all objects. The new cut recognition theorem explains what extra information a class cut of that test family can encode; it does not defeat the diagonal theorem by relabelling cuts as sets.

*Note 56.4* ([merge]; repetitions, and the new comprehension bound). The binary-class equimorphism (S16.15) and source 14's display are source 11's [theorem 19.32](#) (with source 08's [note 19.35](#) and source 12's [theorem 19.34](#)); source 16 adds the injective words  $\mathfrak{J}$  between the two ends, by the same core-density argument. The diagonal theorems [theorem 56.1](#), [theorem 56.3](#) and source 15's [theorem 57.4](#) (printed with source 15's foundations in [section 57](#)) are source 11's [theorem 19.37](#) and source 12's [theorem 19.38](#), as are source 13's [theorem 42.7](#), source 17's [theorem 42.16](#) and source 18's [theorem 42.19](#) printed in Part VIII; all credit this report. New is source 16's [theorem 56.2](#): for transformations defined by a formula with only set quantifiers, GBC with  $\Sigma_1^1$  class comprehension suffices to refute an order embedding of  $\mathfrak{W}_{\text{all}}$  into  $\mathfrak{W}_{\text{sl}}$ , where source 11's [theorem 20.2](#) used KM + GC and arbitrary formulas. It is a sufficiency result; source 16 asks for the reversal ([research question 113.63](#)). Its proof uses the adjacent raw pairs only through the disjointness of their image intervals; with the pairs  $(E, 0) < (E, 1)$  of  $\mathfrak{W}_{\text{sl}} \times_{\text{lex}} 2$  in place of  $R_F < S_F$  the same  $\Sigma_1^1$  evaluator can be formed, which bears on source 13's [research question 113.24](#). (This adaptation is an observation of the merge, not a theorem of either source.)

## 57 Larger universes, class realizations and paradox avoidance (sources 16, 14, 13, 15 and 18)

*Note 57.1* ([merge]; Part V counterparts). Five sources discuss the full-class model  $(V_\kappa, \mathcal{P}(V_\kappa))$  at an inaccessible  $\kappa$  and the relativity of class notions. Source 16's [theorem 57.2](#) is source 12's exact external identification [theorem 21.1](#) (both identify  $\mathfrak{W}_{\text{sl}}$  with  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$  and  $\mathfrak{W}_{\text{all}}$  with  $\mathcal{W}(\mathbf{No}_{<\kappa})$ ), and its [theorem 57.3](#) is source 11's [theorem 20.1](#) with one sharpening: already  $\mathcal{W}_{\kappa+2}(X)$  does not embed into  $\mathcal{W}_\kappa(X)$ , although by [theorem 27.2](#) both have density and cellularity  $\kappa$ . Source 18 proves the same nonembedding by counting cellularity, display (S18.5). Source 14's model subsection recalls source 12's and source 09's calculations ([theorems 21.1](#) and [22.1](#)), and source 15's full-universe paragraph repeats the coding-length contrast of [theorem 21.1](#). The rest of these sections are foundational discussions in the manner of Part V ([section 23](#)); they are printed whole, in the order 16, 14, 13, 15, 18, because each states its own list of invalid inferences and its own boundary of comprehension.

### 57.1 Source 16: an explicit larger-universe interpretation

To treat the entire collections as actual sets, choose an ambient ZFC universe and assume that  $\kappa$  is strongly inaccessible. Consider the two-sorted structure

$$\mathcal{M} = (V_\kappa, \mathcal{P}(V_\kappa)).$$

Its sets are the elements of  $V_\kappa$ , and its available classes are *all* external subsets of  $V_\kappa$ . It satisfies KM plus global choice. Inaccessibility controls replacement: the image of an internal set under any available class function has size less than  $\kappa$  and bounded rank. Full class comprehension is immediate from the external power set. Such full models are a standard way to make the next logical level explicit [28].

**Theorem 57.2** (Exact external identification). *In this full model the internal surreal class is externally  $X = \mathbf{No}_{<\kappa}$ , of cardinality  $\kappa$ . Internally set-like well-orders are exactly the externally well-ordered relations of type  $\kappa$  on  $X$ . All internal class well-orders correspond exactly to the full external set  $\mathcal{W}(X)$ . Thus the two comparisons become*

$$\mathfrak{W}_{\text{sl}}^{\mathcal{M}} = \mathcal{W}_\kappa(X), \quad \mathfrak{W}_{\text{all}}^{\mathcal{M}} = \mathcal{W}(X). \quad (\text{S16.17})$$

*Proof.* All sign sequences of length below  $\kappa$  belong to  $V_\kappa$ , and these are exactly the internal sign sequences. Strong inaccessibility gives  $|X| = 2^{<\kappa} = \kappa$ . Every external binary relation on  $X$  is an available internal class. Well-foundedness agrees in this full interpretation; in particular any external descending  $\omega$ -sequence has bounded rank below  $\kappa$  and is an internal set witnessing failure.

A subset of  $X$  is an internal set exactly when it has external size less than  $\kappa$ . One direction follows from the strong-limit property of  $V_\kappa$ ; the other follows from regularity bounding the ranks of fewer than  $\kappa$  elements. Consequently an external well-order of cardinality  $\kappa$  is internally set-like exactly when all its proper initial segments have cardinality less than  $\kappa$ , which is exactly external order type  $\kappa$ . All other external well-orders are still admitted classes, yielding the unrestricted identification.  $\square$

**Theorem 57.3** (Strict embedding separation in the full model). *In the preceding external interpretation,*

$$\mathfrak{W}_{\text{sl}}^{\mathcal{M}} \hookrightarrow \mathfrak{W}_{\text{all}}^{\mathcal{M}}, \quad \mathfrak{W}_{\text{all}}^{\mathcal{M}} \not\hookrightarrow \mathfrak{W}_{\text{sl}}^{\mathcal{M}}.$$

*Indeed even  $\mathcal{W}_{\kappa+2}(X)$  does not embed into  $\mathcal{W}_\kappa(X)$ , although both have density and cellularity  $\kappa$ .*

*Proof.* Inclusion gives the forward embedding. The target  $\mathcal{W}_\kappa(X)$  is dense and has a dense subset of size  $\kappa$ . For fixed  $a < c$  there are  $2^\kappa$  prefixes  $F : \kappa \rightarrow X \setminus \{a, c\}$ . Their two completions  $F + (a, c) < F + (c, a)$  are disjoint adjacent pairs in  $\mathcal{W}_{\kappa+2}(X)$ . An order embedding into the dense target would turn these pairs into  $2^\kappa$  disjoint nonempty open intervals. Each interval must meet the  $\kappa$ -sized dense subset, contradicting Cantor's theorem.  $\square$

This rederives the earlier report's full-model nonembedding, while identifying why equal cardinality, ordinal spectra, density, and cellularity can still fail to imply equimorphism. The adjacent pairs provide an additional obstruction when the target is dense.

### 57.1.1 Henkin models and internal well-foundedness

For a general model  $(M, \mathcal{C})$ , one has only the admitted classes  $\mathcal{C} \subseteq \mathcal{P}(M)$ , not automatically every external subset. External families of these classes need not be coded by any one internal family relation. If the model is externally countable, both virtual collections can be externally countable, and the external dense set-like order can admit an external copy of the raw order. Such an embedding need not be internally definable or uniformly represented, and so does not contradict [Theorem 56.2](#) or the internal diagonal theorem.

There is also a precise correction to a common ambiguity. Over GBC, for a fixed class relation, well-foundedness on nonempty sets, well-foundedness on all available nonempty subclasses, and absence of a set-coded descending  $\omega$ -sequence are equivalent. Therefore two class expansions with the same sets agree about internal well-foundedness of any relation they share. Expanding the class collection can add relations; it does not change that property of a shared relation. Nevertheless, even a transitive class model can contain a relation it regards as well-founded that is externally ill-founded; one must distinguish a general model from a  $\beta$ -model [27, §3].

The full inaccessible model removes this ambiguity by its explicit fullness and rank closure. A singular birthday cutoff is a legitimate set alphabet for [Note 32.1](#); it is not an automatic replacement for  $V_\kappa$  in this model-theoretic construction.

## 57.2 Source 14: universe-relative models and paradox avoidance

### 57.2.1 A full-class model with externally set-sized objects

For a concrete interpretation, assume in an external set universe a strongly inaccessible cardinal  $\Omega$  and consider

$$(V_\Omega, \mathcal{P}(V_\Omega)).$$

Internally the ordinal and surreal collections are proper classes; externally they are the sets  $\Omega$  and  $X = \mathbf{No}_{<\Omega}$ . Strong inaccessibility gives  $|X| = \Omega$ . A baseline is externally a bijection  $b : \Omega \rightarrow X$ . The core consists of permutations with support of size  $< \Omega$ , equivalently bounded support in  $\Omega$ , and has external cardinality  $\Omega$ . The external global-enumeration order is

$$\text{Bij}(\Omega, X), \quad |\text{Bij}(\Omega, X)| = 2^\Omega.$$

These are the predecessor's full-model calculations ([theorems 20.1](#), [21.1](#) and [22.1](#); the universe-model sections at the pin). The lower bound for the second cardinality is pair orientation; the upper bound counts graphs. For the core, each bounded stage has fewer than  $\Omega$  permutations by the strong-limit property, while first-entry transpositions supply  $\Omega$  distinct codes.

Internally “every set cut” means externally cuts with fewer than  $\Omega$  parameters. Thus the core and  $X$  are externally  $\Omega$ -sized  $\eta_\Omega$ -orders. The full enumeration order has strictly more points while

the core remains dense in it. This is an ordinary set-theoretic example of a dense order and a larger order of its selected cuts; no paradox occurs.

The new trichotomy becomes an external classification of cuts using prefixes of length  $< \Omega$ . A branch extending through all internal ordinals has external length  $\Omega$ . It is not an internally set prefix to which one may apply a small-cut theorem. The coverage condition is precisely surjectivity onto  $X$ .

All external well-orders on  $X$  also allow order types  $\alpha$  with  $\Omega < \alpha < \Omega^+$ . They correspond to internal non-set-like orders, not to additional bijections  $\Omega \rightarrow X$ . Consequently “increase the universe so everything is a set” does not license replacing one interpretation by another without recording the allowed ordinal lengths.

### 57.2.2 ZFC schemes, GBC, KM, and higher sorts

In ordinary ZFC, sign sequences and their set-sized fragments can be handled directly; global statements can be treated as schemes for specified definable class parameters. A definable baseline must be supplied where needed. Formula codes alone do not solve the uniformity problem: evaluating every possible class definition in the whole universe requires truth resources not furnished by a list of formulas.

In two-sorted GBC, the class parameters and set-coded skeleton are literal objects of their respective sorts. The classification theorem has the form “for every class cut  $D$ , one of the stated alternatives holds.” It is not a third-sort object containing all those cuts. Stronger comprehension in KM does not change the rule that proper classes cannot be members of ordinary classes. A literal collection of class orders or cuts requires a specified additional sort or an external universe. Relative consistency assumptions for any such enlargement must be stated separately.

In a universe-polymorphic type theory, one can form a type of relations on a fixed small carrier. A larger-universe type can hold all such relations without identifying it with the original carrier. Lifting a carrier changes its ambient type level, not its mathematical elements; constructing surreals with larger allowed ordinal birthdays adds new elements. These are different operations. A proof assistant should not hide the distinction under coercions or ambiguous names.

### 57.2.3 Which assertions depend on the class realization?

Changing the available classes while retaining the same sets leaves each existing support code and each existing prefix unchanged. It can add new global enumerations, binary class words, and cut classes. [Theorem 48.1](#) is a more precise invariant than merely saying that first disagreements are unchanged: it prohibits a new enumeration from realizing an *old* cut. At the same time the external cardinality and order type of the entire admitted enumeration collection can change. The results are compatible, because a new point brings a new trace parameter.

For unrestricted orders, having an initial branch reconstructible from an old trace does not similarly force an arbitrary new *tail* to be old. The trace deliberately forgets that tail. This illustrates why one must not generalize the absoluteness theorem from set-like realizations to uniqueness of raw realizations.

### 57.2.4 A short paradox audit

There is no set ordinal containing all ordinals, no surreal whose sign sequence has domain Ord, and no application here of the surreal cut constructor to arbitrary proper-class option sets. All recursive histories used for the main constructions at a set stage are sets. Class predicates such as “is a global enumeration” are never turned into same-sort membership objects. Equal abstract class

types are not silently represented by a canonical set ordinal. The baseline choice is explicit. Finally, class-model absoluteness is proved from formulas with the stated old parameters, not assumed for all higher-order properties. These restrictions are what allow the positive theorems, rather than obstacles to developing the subject.

### 57.3 Source 13: foundational interpretations without paradoxes

#### 57.3.1 Ordinary set theory: the cutoff-first route

For any set ordinal  $\theta$ , the sign sequences of birthday below  $\theta$  form a set. Relations on this set form another set, and the subset satisfying well-order axioms is available by separation. All fixed-carrier order theory therefore lives in ordinary ZFC; no inaccessible cardinal or extra class sort is needed.

When a proof uses a family of all birthday cutoffs, the family is a class description rather than a set containing the entire surreal line. A compatible directed system requires explicitly commuting transition maps. Merely proving existence of an embedding at each cutoff does not make the union of independently chosen maps a function.

For set-length words, a word is itself a set of ordered pairs. The class of all such words is a legitimate class of sets. It is not the same logical object as the totality of class-length words.

#### 57.3.2 Two-sorted class theory: quantify, do not collect

In GB or GBC, class variables can stand for relations on **No**. One may assert

$$\forall R \forall S [\text{ClassWO}(R) \wedge \text{ClassWO}(S) \implies R = S \vee R <_{\text{lex}} S \vee S <_{\text{lex}} R].$$

There is no need to form an object whose members are  $R$  and  $S$ . The fraktur notations  $\mathfrak{W}_{\text{sl}}, \mathfrak{J}, \mathfrak{W}_{\text{all}}$  used here abbreviate precisely such restricted class quantification.

A family indexed by an ordinary class  $K$  of sets is supplied by one class relation  $T(k, \alpha, x)$ . First-disagreement comparison of two rows is elementary in  $T$ . If repeated rows occur, a fixed set-like global well-order selects the least set code in each equal-row class; row equality itself quantifies only over set coordinates and values. The distinct-row representatives then form an ordinary class linear order, which embeds into **No**.

This explains how every uniformly class-coded portion of  $\mathfrak{W}_{\text{sl}}$  can embed into **No** while an exhaustive uniform code family is impossible. The local statement is about a particular class evaluator. It does not quantify a class of all evaluators or identify all class functions with their set codes.

#### 57.3.3 The exact comprehension boundary of the new proofs

The crossing predicate

$$\text{Cross}(L, p) \iff (\exists d \in \mathcal{P}_s(b)_p \ d \in L) \wedge (\exists d \in \mathcal{P}_s(b)_p \ d \notin L)$$

quantifies over set codes. “For every ordinal length a crossing prefix exists” is therefore elementary with  $L$  as a class parameter. The uniqueness lemma makes  $F(\alpha) = p_{\alpha+1}(\alpha)$  an elementary class definition. This is the reason cut reconstruction does not need ETR or impredicative comprehension.

The uniform complement isomorphisms, support completions, and active prefixes similarly use set histories. In contrast, the inverse evaluator in [Theorem 55.4](#) asks whether *some class enumeration* produced a specified code. That is a genuine existential class quantifier in a class comprehension formula. The proof uses KM at exactly this point.

General elementary transfinite recursion allows class-valued stages along a class well-order. It is distinct from the set-valued recursion used above. Its relevance to abstract class-well-order comparison is discussed in [27]; none of our direct labeled comparison arguments relies on the stronger comparison theorem.

#### 57.3.4 Kelley–Morse does not turn classes into members

KM permits class quantifiers in comprehension formulas, but its classes still have sets as members. Thus even KM does not justify an ordinary power class whose elements are all class well-orders of **No**. A third sort, a containing universe, or a fixed syntactic schema is necessary for arbitrary maps, topologies, or families whose elements are such classes.

Hyperclass forcing is an example of work that explicitly addresses this higher level, with additional model and coding hypotheses [28]. Its existence as a theory should not be read as permission to suppress the level distinction in an argument stated only over GB or KM.

#### 57.3.5 Full universes versus selected class realizations

The full interpretation  $(V_\kappa, \mathcal{P}(V_\kappa))$  at a strongly inaccessible  $\kappa$  is a convenient sufficient model for our external cardinal arguments. The available internal surreals are externally the set **No** $_{<\kappa}$ , and internal set-like enumerations have external length  $\kappa$ . A raw well-order may have any external ordinal type of cardinality  $\kappa$ ; types beyond  $\kappa$  create proper-class predecessor segments internally.

For a nonfull model  $(M, \mathcal{C})$ , only classes in  $\mathcal{C}$  are available. Changing  $\mathcal{C}$  can change the available branches, global enumerations, cuts, and external maps without changing the underlying set universe. The cut theorem remains an internal statement about the cuts actually present. If an outer class realization adds a normalized cut satisfying the crossing criterion, its unique branch becomes available there by elementary comprehension from that cut. Thus missing classes, not merely missing set elements, are part of the geometry.

Internal well-foundedness must also be kept separate from external well-foundedness. Over the relevant global-choice class theories, class well-foundedness can be tested by the absence of a set-coded descending  $\omega$ -sequence; an external descending sequence need not be so coded in the model [27, Section 3]. This is why an arbitrary internally well-ordered class is not automatically a well-order in a surrounding metatheory. Our full inaccessible model avoids that particular ambiguity, while Proposition 55.5 deliberately studies an external order of available objects.

[merge] Source 13’s subsection “Relation-bit lexicography is a different order” comes here in its text; it is printed in section 38.

#### 57.3.6 A concise list of invalid inferences

The most tempting false steps are logically different. A proper-class ordinal word is not a surreal; a predicate on surreals is not necessarily a small set; a set of individual class witnesses is not automatically a uniform family; a class well-order need not be set-like; an order embedding need not preserve suprema, cuts, or adjacency; and equal cardinality, equimorphism, and isomorphism are three distinct claims. Finally, the isomorphism type of an external available-object order need not describe the internally definable transformations on that order. Each of the main theorems above uses at least one of these distinctions essentially.

### 57.4 Source 15: formalization without paradoxes

#### 57.4.1 Four sound frameworks and their different meanings

| Framework                               | What it directly represents                                                                        | Important boundary                                                            |
|-----------------------------------------|----------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------|
| ZFC, fixed sets                         | Relations on a set $X$ , all ordinal enumeration types, binary cubes, birthday cutoffs             | No set of all surreals; a definable-class claim is a scheme or a formula.     |
| Two-sorted GB/GBC                       | Individual class orders, uniform families, elementary raw comparison and set-interval condensation | Classes contain sets, not other proper classes.                               |
| KM and recursion extensions             | Stronger class comprehension; appropriate class-valued recursions                                  | Stronger comprehension does not add a third sort automatically.               |
| Containing universe or stratified types | A lower universe's classes become higher-universe objects                                          | Size and well-foundedness are relative; lifting does not identify all levels. |

### 57.4.2 Why Burali–Forti and unrestricted cuts do not arise

In the sign presentation, each birthday is a set ordinal, while birthdays are unbounded in the class of ordinals. The order type of an arbitrary class well-order is not asserted to be a set ordinal. An expression such as  $\text{Ord} + \text{Ord}$  abbreviates a relation on a class of tagged sets. A collection of all these relations is treated either by class-variable predicates or in a genuinely larger universe.

Likewise, the cut principle permits sets  $L < R$ . Substituting all of **No** on the left and the empty class on the right would demand a surreal greater than every surreal and is outside that principle. The represented cut theorem explicitly admits unfilled class cuts, so it does not smuggle in such an unrestricted principle.

**Theorem 57.4** (No exhaustive uniform class of set codes). *In GBC no class of set codes with one uniform decoder can list every class well-order of **No**. An omitted order can always be chosen set-like.*

*Proof.* Reindex any proposed family by  $\text{Ord}$ , repeating a default row if the indexing class is a set. Let its rows be  $R_\alpha$ . Partition a baseline enumeration of **No** into consecutive two-label blocks, using positions  $2 \cdot \alpha, 2 \cdot \alpha + 1$ . In block  $\alpha$ , place its two labels in the order opposite to their relative order in  $R_\alpha$ . Listing these blocks constructs a class bijection  $\text{Ord} \rightarrow \text{No}$ , and its well-order differs from each row on that row's designated pair. Its definition uses only the one family relation and the baseline as class parameters.  $\square$

This is the prior report's diagonal obstruction, restated to locate the size boundary (theorems 19.37 and 19.38; Theorems 19.37–19.38 at the pin). An ordinary class of codes may be dense and realize every set cut without listing every global enumeration. Formula strings do not evade the theorem: a uniform semantic evaluation of all formulas of the universe would require an appropriate truth predicate. Individual formulas, an external collection of definable classes of a model, and an internal universal evaluator are different resources.

### 57.4.3 Exactly where recursion principles enter

In GBC, for a class strict linear order, the following internal conditions are equivalent: every nonempty subclass has a least element; every nonempty set subset has a least element; and there is no descending  $\omega$ -sequence in the model. If a subclass has no least element, choose below each of its

members a witness of least possible set rank, then use global choice within that rank. Ordinary recursion with this class parameter constructs a descending  $\omega$ -sequence, whose range is a set by class replacement. The other implications are the usual set well-foundedness arguments. This explains the role of choice in the equivalence; the article's primary definition remains the subclass minimum condition [27, Section 2].

Set-valued recursion along Ord can be assembled from its unique set initial solutions using elementary comprehension. This covers the ordinary surreal forth construction and prefix completions. The raw comparison formula, simultaneous canonical block quotient, and persistent-cut reconstruction do not even need a class-valued recursive construction.

A general recursion whose stage value is itself a proper class is a stronger request. The principle ETR supplies elementary transfinite recursion along class well-orders. It suffices for comparison of arbitrary abstract class well-orders by initial-segment isomorphisms [27, Theorem 6]. That is a different problem from comparing identical labelled prefixes. The cited work poses converse-strength questions; we do not turn those questions into a claimed independence theorem or assert that their historical open status is settled as of the date of this article. For general class recursion and truth-predicate strength see [22, 35].

For condensation, a fixed finite number of iterations is available by substituting elementary formulas. A uniform history on every arbitrary input is a separate statement; ETR of the appropriate length is sufficient, but this article proves no necessity. In the polynomial examples the entire history already has an elementary formula, including at stages with proper-class many predecessors. A warning about general recursion must not be used to reject an explicitly defined construction.

#### 57.4.4 Full-universe and Henkin interpretations

Let a containing universe have an inaccessible  $\kappa$ , and consider  $(V_\kappa, \mathcal{P}(V_\kappa))$ . Internally, the surreals are  $\mathbf{No}_{<\kappa}$  and the ordinals are the ambient  $\kappa$ . Every external subclass of the set universe is available as a class. Internal class well-foundedness therefore agrees with external well-foundedness for these relations.

The internal set-like enumeration space becomes the ambient  $\mathcal{W}_\kappa(\mathbf{No}_{<\kappa})$ , while the full raw space becomes all ambient well-orders of the carrier. Both have cardinality  $2^\kappa$ , and both embed exactly the ordinals below  $\kappa^+$ , but their finer structure differs. The set-like space is equimorphic with  $\mathbb{B}_\kappa$ ; the unrestricted one has unbounded binary coding lengths below  $\kappa^+$  and cannot embed into that one cube. This is a genuine nonembedding theorem in a specified external model, not a same-level cardinality argument about a class of classes (theorems 20.1, 21.1 and 22.1; Sections 20–22 at the pin).

For a general two-sorted model  $(M, \mathcal{C})$ , only the classes in  $\mathcal{C}$  may occur as relations or witnesses. A relation can be internally well-founded while an external descending sequence is absent from  $\mathcal{C}$ . A countable model may have externally countably many classes without possessing an internal exhaustive decoder. Adding classes can add new global enumerations and can destroy the internal well-foundedness of an old relation by adding a descending witness. The elementary first-disagreement formula on previously available valid orders remains the same, but the ambient totality and existence assertions may change.

### 57.5 Source 18: containing universes, class realizations, and paradox avoidance

The mathematical distinctions above are also distinctions between formal objects. A type, a set, a definable class, an available class in a two-sorted model, and a collection of available classes

have different membership and quantifier rules. A rigorous development should choose one of the following settings for each theorem.

### 57.5.1 Ordinary ZFC and bounded birthday stages

All results about  $\mathcal{W}_\alpha(\mathbf{No}_{<\kappa})$  are ordinary set theorems. There is no need for class theory, an inaccessible cardinal, or a global well-order to construct these spaces. Choice well-orders the set alphabet, and all enumerations and cuts live in ordinary power sets. In particular, the exact gap spectrum does not rest on the existence of an external model or on an unformalized “class ordinal.”

One may also work in ZFC with definable classes as metanotation. A particular formula defines a particular global relation, but one must not silently quantify in the object theory over all formulas and their semantic truth sets. A uniform truth predicate for the whole set universe is unavailable. A scheme covering each fixed defining formula is different from a single theorem about all available classes.

### 57.5.2 GBC and named class parameters

GBC is a natural setting for supplied global orders, uniform families, the elementary common-prefix comparison, the block decomposition, and the represented-cut criterion. These constructions use actual set labels to represent their quotients or prefixes. A block minimum is a set; the proper block it represents is not an element.

The status of a well-order is relative to the class realization. In a model  $\mathcal{M} = (M, \mathcal{X})$ , “every nonempty subclass” means every appropriate member of  $\mathcal{X}$ . An external descending sequence might not be represented in  $M$  or  $\mathcal{X}$ . Consequently external countability or external ill-foundedness cannot simply be substituted for internal set size or internal well-foundedness. The factorial-shuffle theorem carefully uses external countability and, for its finite blocks,  $\omega$ -standardness; it does not assume that all internal well-orders are externally well-founded.

### 57.5.3 A full-class model at an inaccessible cardinal

For a concrete comparison with the external countable setting, let  $\lambda$  be strongly inaccessible in an ambient ZFC universe and consider the full class model

$$(V_\lambda, \mathcal{P}(V_\lambda)).$$

Its internal surreal carrier is the ambient set of sign sequences of length below  $\lambda$ , of ambient cardinality  $\lambda$ . Every ambient subset of the carrier is available as a class. Class well-foundedness therefore means actual external well-foundedness. An internal predecessor class is a set precisely when its ambient cardinality is below  $\lambda$ : regularity bounds the ranks of a small set of elements of  $V_\lambda$ , and inaccessibility gives the converse cardinal bound.

It follows that, from the ambient viewpoint,

$$\mathfrak{W}_{\text{sl}} = \mathcal{W}_\lambda(\mathbf{No}_{<\lambda}), \quad \mathfrak{W}_{\text{all}} = \mathcal{W}(\mathbf{No}_{<\lambda}).$$

The former has cellularity  $\lambda$ , since  $\lambda^{<\lambda} = \lambda$ . The latter has cellularity  $2^\lambda$ : fix a residual set of three labels and vary the  $\lambda$ -long prefix on its complement. Each of  $2^\lambda$  disjoint cylinders contains a nonempty open interval. Hence

$$\mathfrak{W}_{\text{all}} \not\rightarrow \mathfrak{W}_{\text{sl}} \quad \text{in this full-class interpretation.} \tag{S18.5}$$

An order embedding would send the endpoints and an interior point of each such interval to  $2^\lambda$  disjoint nonempty intervals in the target, contradicting its cellularity.

There is no conflict with the external countable-model embedding in the preceding section. The two class realizations have different external sizes and admit different external families. There is also no conflict with surreal universality:  $\mathfrak{W}_{\text{all}}$  is an external set of size  $2^\lambda$ , not an internal class of set labels to which the internal universality theorem applies.

The canonical block theorem supplies a further consistency check. An ambient order of the carrier has ordinal type  $\gamma$  with  $|\gamma| = \lambda$ . Its division

$$\gamma = \lambda \cdot \beta + \rho, \quad \rho < \lambda,$$

is exactly the external interpretation of the internal decomposition into Ord blocks and a final set tail. Thus the class theorem recovers ordinary ordinal division in this model without treating Ord as an internal set.

#### 57.5.4 KM, stronger recursions, and genuine higher sorts

KM permits impredicative class comprehension. It remains a two-sorted theory: classes are not members of classes. To make the whole domain of global well-orders an object one needs, for example, an explicitly specified higher sort, an external containing universe, or a carefully defined unrolling. These are substantive changes of framework, not notation that erases the diagonal in [Theorem 42.19](#).

The use of ETR should be equally explicit. General class-valued recursions, including iterated truth constructions, exceed GBC [24]. ETR is a sufficient framework for suitable abstract class well-order comparisons and recursive quotient constructions [35]. In contrast, three procedures in this article have elementary closed definitions or set-valued histories: comparison of shared labels, simultaneous set-interval decomposition, and reconstruction of a branch from unique set prefixes. None requires ETR. We do not infer an exact reverse-mathematical equivalence for an unspecified iteration of the quotient operator.

#### 57.5.5 A concise list of invalid identifications

The following substitutions would change a theorem's meaning or invalidate its proof.

1. Replacing Ord by a set ordinal while still claiming to enumerate all surreals of the same universe.
2. Treating all class relations as members of a class merely because each individual relation is available.
3. Replacing an arbitrary class well-order by an Ord enumeration; this discards its later proper blocks and set tail.
4. Replacing a proper-class cut by a set cut when applying surreal interpolation.
5. Using cardinal multiplication where the proof concerns ordinal lexicographic coding length.
6. Assuming that an order embedding preserves suprema or density in the ambient order.
7. Treating a set-indexed uniform family of classes as an ordinary set of class objects.
8. Extending numerical lexicography to isomorphism classes after discarding the labels on which it depends.

These are mathematical type distinctions, not additional consistency axioms imposed on the bounded results.

*Note 57.5* ([merge]; internal well-foundedness under class extensions). The last paragraph of source 15’s subsection on full-universe and Henkin interpretations (in [section 57.4](#)) says that adding classes “can destroy the internal well-foundedness of an old relation by adding a descending witness”. For class realizations that are models of GBC with the same sets this is not so, and source 16’s subsection on Henkin models proves the opposite: over GBC a class relation is well-founded on all admitted subclasses exactly when no set-coded descending  $\omega$ -sequence exists (source 15 proves the same equivalence in its subsection “Exactly where recursion principles enter”), and a descending  $\omega$ -sequence admitted by a larger realization is a set of the common set part, by class Replacement, so it was already present. Hence two GBC realizations with the same sets agree on the internal well-foundedness of every relation they share. Source 15’s sentence can hold only for a larger class collection in which that equivalence fails, for example one that is not a model of global choice; as a statement about GBC realizations it is withdrawn here. The same correction was made to source 08’s foundations after the Hilbert’s-tenth review of batch 80 ([section 5.6](#) and the note before it). Source 15’s [research question 113.56](#) asks which statements “require well-foundedness preservation”; by the argument above, none does among GBC realizations with the same sets.

## 58 An exact external classification in countable models (source 18)

The distinction between an internal class and an external collection of classes leads to a surprisingly uniform external order type. The statement below concerns the raw labelled comparison of all admitted class well-orders, including those that are not set-like. It does not concern their abstract order types. It strengthens the observation that an external countable collection of admitted orders can embed into the external rational line.

For a linear order  $L$ , write  $x \sim_{\text{fin}} y$  when the closed interval between  $x$  and  $y$  is finite. These equivalence classes are the *finite-condensation blocks*. For a nonempty countable collection  $\mathcal{A}$  of linear order types, its *shuffle*  $\sigma(\mathcal{A})$  is obtained by densely colouring  $\mathbb{Q}$  with one colour for each member of  $\mathcal{A}$ , then replacing a point by the order type of its colour. A colour-preserving back-and-forth proves that the resulting order type is independent of the chosen dense colouring. These are standard order-theoretic constructions; see, for example, Dimitrov–Harizanov–Morozov–Shafer–Soskova–Vatev, *On cohesive powers of linear orders*, Definitions 3.3 and 6.2, [36]. The identification with the well-order space below is derived here.

### 58.1 Terminal tails and finite-condensation blocks

The next arguments can first be carried out internally in GBC. Let  $X$  be an infinite linearly ordered class, and consider the predicate of all class well-orders of  $X$ , with the raw labelled lexicographic comparison. It is enough that the required well-orders and constructions exist; for  $X = \mathbf{No}$ , global choice supplies them.

**Lemma 58.1** (The maximal finite terminal tail). *Every class well-order  $R$  on an infinite carrier has a unique finite terminal segment  $T_R$  such that  $R$  restricted to  $X \setminus T_R$  has no greatest element. Write  $n(R) = |T_R|$ . Every finite terminal segment of  $R$  is contained in  $T_R$ .*

*Proof.* If  $R$  has no greatest element, take  $T_R = \emptyset$ . Otherwise start at the greatest element and repeatedly take its immediate predecessor, for as long as one exists. If this process did not terminate at a finite stage, ordinary set-valued recursion with parameter  $R$  would produce a descending  $\omega$ -sequence. Class Replacement makes its range a set, contradicting well-foundedness. At termination

the selected finite chain is terminal and the remaining prefix has no greatest element. Any finite terminal segment is obtained by finitely many of the same uniquely determined predecessor steps, proving maximality and uniqueness.  $\square$

**Lemma 58.2** (Adjacency forces a finite residual carrier). *Suppose  $R < S$  are adjacent in the lexicographic order of all class well-orders of  $X$ . Let  $C$  be their common labelled prefix, and let  $a = \min_R(X \setminus C) < \min_S(X \setminus C) = b$  in the ambient label order. Then  $Y = X \setminus C$  is finite.*

*Proof.* Keep the prefix  $C$ , then the next label  $a$ , fixed. The  $R$ -tail must be the greatest available well-order in that prefix cylinder: any greater tail gives an order strictly between  $R$  and  $S$ . At each subsequent position, therefore, its label must be the greatest remaining label. Otherwise choose a larger remaining label and well-order the remaining carrier to obtain a greater tail. Consequently the reverse ambient label order on  $Y \setminus \{a\}$  is a class well-order.

The symmetric argument, fixing  $C$  then  $b$ , shows that the ambient label order on  $Y \setminus \{b\}$  is a class well-order. On  $Z = Y \setminus \{a, b\}$ , both an order and its reverse are therefore well-orders. This forces  $Z$  to be finite. Indeed, if  $Z$  were infinite, repeatedly choosing the least unused point in one of those well-orders would produce an ascending  $\omega$ -sequence in that order, hence a descending  $\omega$ -sequence in the other. Thus  $Y$  is finite.  $\square$

**Proposition 58.3** (Factorial blocks). *The finite-condensation block containing  $R$  consists exactly of the orders obtained by keeping  $R$  fixed on  $X \setminus T_R$  and permuting the  $n(R)$  labels in  $T_R$ . It is a finite chain of size  $n(R)!$ .*

*Proof.* The common-prefix cylinder with residual carrier  $T_R$  is convex and contains exactly its  $n(R)!$  permutations. In lexicographic order they form a finite chain, so they lie in one finite-condensation block.

Conversely, any adjacent order  $S$  has a finite residual carrier at the first disagreement, by the preceding lemma. That residual is a finite terminal segment in  $R$ , hence lies in  $T_R$ . Thus an adjacent step cannot leave the displayed permutation cylinder. A finite interval is a finite chain of adjacent steps; no member outside this cylinder can be at finite distance from  $R$ . This proves the assertion.  $\square$

The cases  $n = 0$  and  $n = 1$  both give a singleton block. The maximal finite-tail length distinguishes these as labelled well-orders, but their block sizes do not distinguish them in the pure linear order.

## 58.2 Every factorial block size occurs densely

**Lemma 58.4** (An interval across different blocks contains an infinite residual cylinder). *If  $R < S$  belong to different finite-condensation blocks, there is a labelled prefix cylinder lying entirely inside  $(R, S)$  whose residual carrier is infinite. The prefix may be a proper class.*

*Proof.* Let  $C$  be the common prefix,  $Y = X \setminus C$ , and let  $a < b$  be the first unequal labels. The class  $Y$  is infinite, since a finite residual would put the two orders in one finite permutation cylinder.

Consider the following two possible changes. In  $R$ , at a position  $x \in Y \setminus \{a\}$  outside  $T_R$ , keep the whole earlier prefix and replace  $x$  by a larger unused label. In  $S$ , at a position  $x \in Y \setminus \{b\}$  outside  $T_S$ , keep the whole earlier prefix and replace  $x$  by a smaller unused label. A change of the first kind gives a prefix cylinder above  $R$  and below  $S$ , because the earlier first label  $a$  remains fixed; a change of the second kind gives the same conclusion with the first label  $b$  fixed. The unused

carrier before such a change is infinite, since the changed position lies outside the maximal finite terminal tail. Removing one label leaves the new cylinder with infinite residual carrier.

At least one such change must be possible. Otherwise let

$$Z = Y \setminus (\{a, b\} \cup T_R \cup T_S).$$

This class is infinite. In  $R$ , every  $x \in Z$  must be numerically greater than each of its  $R$ -successors in  $Z$ , since any larger unused successor would permit the first change. Thus  $R \restriction Z$  is the reverse ambient label order. In  $S$ , every  $x \in Z$  must be numerically smaller than each of its  $S$ -successors in  $Z$ , since a smaller one would permit the second change. Thus  $S \restriction Z$  is the ambient order. Both restrictions are class well-orders, contradicting the infinitude of  $Z$  as in the preceding proof. The orders in this cylinder also lie in blocks different from both endpoint blocks. For an upward change, its first disagreement with  $R$  occurs while the residual is infinite, and its first disagreement with  $S$  occurs at the original infinite residual  $Y$ ; the downward case is symmetric.  $\square$

**Lemma 58.5** (Prescribing the finite tail). *For every  $n \in \omega$ , every interval joining different finite-condensation blocks contains an order  $W$  with  $n(W) = n$ .*

*Proof.* Take the cylinder from Lemma 58.4, with prefix  $P$  and infinite residual carrier  $Y$ . Choose  $n$  distinct labels  $F \subseteq Y$ . Well-order  $Y \setminus F$  without a greatest element: if it is a set, use its infinite initial cardinal as order type; if it is a proper class, use a set-like well-order of type Ord. Both are available in GBC. Append these labels after  $P$ , and then append the  $n$  labels of  $F$  in any order. The resulting well-order belongs to the cylinder, and its maximal finite terminal tail is exactly  $F$ .  $\square$

These arguments are parameterwise constructions of individual classes. They do not assert that the collection of all orders, or its quotient, is an internal class whose elements are classes.

### 58.3 The external classification

Let  $\mathcal{M} = (M, \mathcal{K})$  be an externally countable two-sorted model of GBC. Write  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}}$  and  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  for the external sets of its admitted set-like and arbitrary class well-orders of its internal surreal carrier. Comparisons are those computed in  $\mathcal{M}$ .

**Theorem 58.6** (Countable-model factorial-shuffle theorem). *If  $\mathcal{M}$  is  $\omega$ -standard, then, externally,*

$$\mathfrak{W}_{\text{all}}^{\mathcal{M}} \cong \sigma(\{1, 2, 6, 24, 120, \dots\}) = \sigma(\{n! : n \in \omega\}).$$

*Its finite-condensation quotient is a copy of  $\mathbb{Q}$ , and each factorial block size occurs densely in that quotient. In particular, the pure external order type is independent of the particular countable  $\omega$ -standard model and its admitted collection of classes.*

*For every externally countable model of GBC, even without  $\omega$ -standardness,*

$$\mathfrak{W}_{\text{sl}}^{\mathcal{M}} \cong \mathbb{Q}.$$

*Proof.* Internal linearity gives an actual external linear order on each admitted collection. The collections are countable because the entire class sort is externally countable. Internal nonemptiness and variation of the first surreal label make them infinite and give no endpoints.

In an  $\omega$ -standard model, the number  $n(R)$  of Lemma 58.1 is a standard natural number. Its  $n(R)!$ -element permutation cylinder is therefore genuinely externally finite. Proposition 58.3 identifies all external finite-condensation blocks. Its converse is also external: an external finite interval is a

standard finite chain of adjacent steps, and adjacency has its literal external meaning because the class sort ranges over precisely the admitted orders.

The quotient is countable, has no endpoints, and is dense by [Lemma 58.5](#). The same lemma makes every block-size colour dense. The countable colour-preserving back-and-forth identifies it with the densely coloured rational order used in the definition of the shuffle. Each finite block is a rigid chain, so this quotient isomorphism lifts uniquely within each block to the claimed order isomorphism.

For the set-like orders, their internal lexicographic order is dense: at the first unequal ordinal position, the common prefix is a set; choose an unused surreal strictly between the next two labels and complete the prefix to a global enumeration. The surreal cut-filling property permits avoidance of the set of used labels. There are no endpoints by varying the first label. Thus its external order is a countable dense linear order without endpoints, hence isomorphic to  $\mathbb{Q}$ . This part does not use  $\omega$ -standardness.  $\square$

*Remark 58.7* (An explicit computable presentation). For  $q \in \mathbb{Q}$ , let  $d(q) > 0$  be its denominator in lowest terms, and set  $c(q) = (1 + v_2(d(q)))!$ . Then the lexicographically ordered set

$$\{(q, i) : q \in \mathbb{Q}, 0 \leq i < c(q)\}$$

is an explicit computable copy of the factorial shuffle. For each fixed  $k \geq 0$ , reduced rationals with denominator of 2-adic valuation  $k$  are dense: choose a sufficiently large odd denominator factor and an odd numerator inside the desired interval. Cancelling common odd factors does not change that valuation. This computable presentation does not supply a computable decoder for the model's class relations.

*Remark 58.8* (The hypothesis cannot simply be dropped). If  $\mathcal{M}$  is  $\omega$ -nonstandard, choose a nonstandard  $N \in \omega^{\mathcal{M}}$  and append an internally  $N$ -element tail to a global well-order without a last element. The corresponding internal  $N!$ -element permutation cylinder is externally an infinite discrete interval with endpoints. Starting at its first element and taking the immediate successor any standard finite number of times produces infinitely many points in one external finite-condensation block. Consequently the external blocks need not be finite, and the displayed factorial-shuffle classification fails. The proof requires standardness of  $\omega$ , not external well-foundedness of every admitted class relation; no  $\beta$ -model assumption is needed.

**Corollary 58.9** (External embeddings and intrinsic automorphism orbits). *In an externally countable  $\omega$ -standard model, the unrestricted order is not externally isomorphic to its set-like suborder: it has adjacent pairs. Nevertheless it externally embeds into that suborder, since every countable linear order embeds into  $\mathbb{Q}$ .*

*The automorphism group of the unrestricted external order is the automorphism group of the rational quotient coloured by factorial block size. Its point orbits are indexed by a factorial block size and a position within that block.*

*Proof.* Only the automorphism assertion needs comment. Finite-distance blocks and their sizes are preserved by every order automorphism. Every colour-preserving quotient automorphism lifts uniquely because finite chains are rigid. Conversely, the colour-preserving back-and-forth is transitive on the quotient points of each fixed colour. Hence two points lie in the same orbit exactly when their block sizes and within-block positions agree.  $\square$

**Corollary 58.10** (Set-likeness is not definable from the external order). *In the countable  $\omega$ -standard setting, the distinguished subset  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}}$  is not first-order definable, even with a finite tuple of parameters, in the pure linear order  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$ .*

*Proof.* Set-like orders have no last element and hence lie in singleton blocks. Orders of type  $\text{Ord} + 1$  also lie in singleton blocks, since their maximal finite terminal tail has size one, but they are not set-like. The preceding automorphism description can exchange any two singleton-block points.

To allow finitely many parameters, take a surreal label smaller than the first labels of all the parameter orders. There are both a set-like order and an order of type  $\text{Ord} + 1$  starting with that label. They lie below all the parameters and occupy singleton blocks. A colour-preserving quotient back-and-forth sends one to the other while fixing each parameter block, and its lift fixes the parameter points. No formula with those parameters can distinguish the two points.  $\square$

The natural inclusion of  $\mathfrak{W}_{\text{sl}}^{\mathcal{M}}$  in  $\mathfrak{W}_{\text{all}}^{\mathcal{M}}$  is not dense. For example, fix a proper class prefix of type  $\text{Ord}$  leaving three labels, and vary the final three labels. The resulting six-point cylinder has a nonempty open interval containing no set-like order. More substantially, leaving an infinite set of labels gives whole intervals between different finite-condensation blocks that contain no set-like order. Thus the pure order classification does not classify the expanded pair  $(\mathfrak{W}_{\text{all}}^{\mathcal{M}}, \mathfrak{W}_{\text{sl}}^{\mathcal{M}})$ , or the external evaluation relation connecting these orders to their surreal labels. Those richer structures remain appropriate further research targets.

*Note 58.11* ([merge]; relation to sources 13 and 17 and to Part V). The second clause of [theorem 58.6](#) ( $\mathfrak{W}_{\text{sl}} \cong \mathbb{Q}$  externally in every externally countable model) is source 13’s [proposition 55.5](#), with the same proof; source 11 already observed, after [theorem 20.2](#), that in such a model the external set-like order can admit an external copy of the unrestricted order, which source 18’s [corollary 58.9](#) makes precise. [Lemmas 58.1](#) and [58.2](#) and [proposition 58.3](#) are a second proof of source 17’s [theorem 54.4](#). New in this section are the factorial-shuffle classification of the full order in countable  $\omega$ -standard models, its computable presentation, the failure without  $\omega$ -standardness, the description of the automorphism orbits, and the non-definability of set-likeness in the pure order ([corollary 58.10](#)).

## 59 Formalization plans of sources 13–18

*Note 59.1* ([merge]; status of the six plans). None of sources 13–18 ships Lean code, and no statement of theirs is formalized ([section 1.5](#)). Their plans are printed whole, in source order. Every existing declaration they cite exists at the current revision, including `SignSequence`, `SignSequence.lt_iff`, `birthdays_bounded`, `small_bounded`, `not_small`, `ordinalOrderEmbedding`, `small_cut_fillers`, `exists_cut_separator_of_birthday_lt`, `cut`, `cut_realizes`, `birthday_cut_le_iSup`, `exists_separator_of_small_sets`, `existsUnique_simplest_separator`, `SmallCutData`, `noUnrestrictedCuts`, and, cited by source 18, `le_iff_options_lt` and `lt_iff_exists_option` in `SignSequenceComparison.lean`. The modules they propose do not exist: source 14’s nine (`LabelledCommonPrefix ... ClassRealizations`), source 17’s eight files under `WellOrders/`, `ClassOrders/` and `Surreal/`, and source 16’s `WellOrderOn X`; sources 13, 15 and 18 describe layers without file names. Source 14’s remark that the existence half must be imported separately is already carried out in the tree (the merge note inside its plan).

### 59.1 Source 13: a formalization plan tied to the inspected Lean code

#### 59.1.1 What already exists at the pinned snapshot

The inspected source `Surreal/Foundations/SignSequence.lean` defines [7]:

```
structure SignSequence : Type (u + 1) where
  birthday : Ordinal.{u}
  signAt : Ordinal.{u} -> SignType
```

```
signAt_ne_zero_iff :
  forall i, signAt i != 0 <-> i < birthday
```

This display is an ASCII schematic rendering of the actual declaration, not a new compiled Lean file. The source uses Lean’s native logical notation. Its numerical linear order is lifted from the lexicographic order of zero-extended sign functions.

| Inspected declaration                            | Role in this development                                                                                           |
|--------------------------------------------------|--------------------------------------------------------------------------------------------------------------------|
| <code>SignSequence.lt_iff</code>                 | First-disagreement characterization of numerical comparison.                                                       |
| <code>ordinalOrderEmbedding</code>               | The all-plus embedding of the ordinal carrier into the sign carrier.                                               |
| <code>birthdays_bounded</code>                   | A strict birthday bound for a family with an explicit lower-universe smallness instance.                           |
| <code>not_small</code>                           | The whole sign carrier is not small in the universe indexing its birthdays.                                        |
| <code>small_bounded</code>                       | Each fixed birthday-bounded fragment is small relative to that lower universe.                                     |
| <code>exists_cut_separator_of_birthday_lt</code> | A separator of exactly a prescribed birthday above all option birthdays; the fresh separator lemma’s direct input. |
| <code>small_cut_fillers</code>                   | The constructed carrier realizes every small strict cut.                                                           |

The last two are in `SignSequenceCut.lean` [8]. They are not merely postulated field axioms: the inspected source constructs them from fixed-length Boolean lexicographic words. We inspected the files, not a fresh build of the project. No theorem in this manuscript is thereby automatically a kernel-checked theorem.

### 59.1.2 Relative smallness must stay visible

`SignSequence.{u}` and `Ordinal.{u}` both live in `Type (u + 1)`, while bounded sign sequences and initial segments are small relative to `u`. A `Set SignSequence` is merely a predicate on the larger carrier. It need not be an admissible small family of options. The formal counterpart of “set cut” therefore requires an index type with `Small.{u}`, not just the word `Set` in a declaration.

The same applies to supports and prefix lengths. A support that is a predicate on a larger type is not automatically a small support. A code should carry a small graph or an explicit smallness proof. Otherwise the completion bound, the dense-core distinction, and the diagonal interpretation can silently change meaning.

A universe-relative approach may take a baseline equivalence

$$b : \text{Ordinal}.\{u\} \simeq \text{SignSequence}.\{u\}$$

as an explicit parameter. Its existence is not inferred merely because the types occupy the same universe. A formal project must either construct the required equivalence, with the intended small-initial- segment properties, or retain it as a stated assumption.

### 59.1.3 Suggested modules and their proof obligations

The following names are proposals, not claims about existing files.

**Exhaustive orders and finite predicates.** A first module should define exhaustive ordinal enumerations on a small carrier, prove prefix-freeness, and compare the relation-based and enumeration-based first-disagreement definitions. These proofs do not require surreal arithmetic or class theory. The finite checker included here provides examples, not a substitute for this module.

**Prefix codes and completion.** Represent a moved-point graph canonically and prove evaluation injective on codes. Prove the complement-cardinality extension lemma before using any prefix-completion operation. Formulate cylinders by restriction equality and prove convexity and same-level disjointness.

**Small-family interpolation.** Use an explicit small index type for the two families. Establish a bound on cross first-disagreement coordinates, then implement the active-row invariant with a set-sized history. The stopping lemma, not a generic unbounded recursion tactic, is the critical finite-length formal obligation at this stage.

**Cut traces and failure.** Define crossing by two existential code witnesses. Same-level uniqueness and restriction coherence are purely order-theoretic. Under all-level existence, reconstruct the value at  $\alpha$  from the unique prefix of length  $\alpha + 1$ . Prove trace equality with the no-greatest-lower normalization stated explicitly. For first failure, split successor from limit ordinals and prove the boundary formula rather than assuming that crossing commutes with limit intersection.

**Products and recoding.** First formalize [Lemma 55.2](#) for ordinary set types and an order-dense subset. It has no class-theoretic ambiguity and should be a small, reusable result. The uniform complement-map interface then supports prefix insertion and finite-block automorphisms. The KM inverse evaluator belongs in a model or syntax layer, not in an unqualified theorem about arbitrary Lean functions on a larger type.

**Central words.** Represent termination by an option type or by a reserved symbol with an explicit proof that it is not a letter. For injective words, retain injectivity as an invariant when selecting the shared next letter. The explicit sign-block embedding can be formalized independently of the class back-and-forth isomorphism.

#### 59.1.4 Three complementary formalization routes

The *cutoff-first route* proves the fixed-set and density-bound lemmas inside ordinary types. It requires the least foundational infrastructure and makes cardinal hypotheses explicit.

The *universe-relative route* abstracts a large ordered carrier with a lower-universe small-cut operation, a set-like enumeration, and support codes. It can certify the local combinatorics and many of the new constructions relative to those interfaces. It should not be described as a proof of every GBC or KM metatheorem merely because it uses two universes.

The *deep model route* formalizes a two-sorted class theory or a specified model  $(M, \mathcal{C})$ . This is the route for the exact comprehension schema, the external countable contrast, and the full-model interpretation. Taking all predicates on an arbitrary carrier as “classes” does not by itself establish the intended replacement or universe axioms; the model assumptions must be proved or supplied.

### 59.1.5 Verification boundary

A completed formalization should pin both the repository revision and its dependency revisions, compile the new modules, and audit theorem axioms and unfinished proofs. None of those actions is claimed here. The deliverable is a proof manuscript, a reproducible LaTeX build, and finite consistency checks. Existing Lean inputs are identified by actual declarations and source hashes in the audit appendix, so that a future formalization has concrete starting points.

## 59.2 Source 14: a realistic formalization plan

The new proofs admit a modular formalization in which most of the work is ordinary order theory. A full class-theoretic metamodel should not be the first dependency. The finite checks shipped with this article are useful regression tests, but do not discharge any infinite or class-level theorem.

### 59.2.1 A generic set-level kernel

Start with a type  $X$  carrying a linear order and a chosen ordinal or well-ordered index type. An exhaustive presentation is a bijection from that index type to  $X$ . For arbitrary well-order types on one fixed carrier, relations are often easier than a dependent sum over every ordinal: a relation together with linearity and well-foundedness proofs is already a set-sized object at the carrier's type level.

Prove the labelled common-prefix comparison before importing surreal arithmetic. Its main obligations are initiality, agreement of the restricted relations, existence and inequality of the two next labels, and transitivity via nested initial segments. For fixed-domain words, prove the equivalent least-disagreement formulation. Finite relation matrices and permutation words give independently checkable examples.

A second module handles partial-injection extension. Its specification must retain *agreement on a prescribed prefix* and the *support cardinality bound*; bare existence of an extension is not enough for the compression theorem. The finite case and the infinite buffer case should be separate lemmas, since equality of infinite cardinalities of domain and range alone does not imply equality of their complement cardinalities.

### 59.2.2 An abstract saturated alphabet interface

The core theory needs an ordered alphabet with set-cut filling and fresh separators, a global baseline in the class version, and set-prefix completion. Numerical surreal field operations are not required. A bounded preliminary development may use a regular-cardinal saturated set order and prefix lengths below that cardinal, with all relevant smallness hypotheses explicit. It proves the crossing-chain and bounded versions of the trichotomy without formalizing surreal addition.

For actual sign sequences, the pinned repository already supplies simplicity lemmas. The inspected declaration `existsUnique_simplest_separator` requires a proof that a separator exists. The appropriate architecture imports an independent small-cut existence theorem and then applies this uniqueness result; it does not erase the hypothesis to manufacture saturation. [merge] The pinned tree already has this architecture: `small_cut_fillers` in `SignSequenceCut.lean` proves that small cuts have fillers, and `cut` in `SignSequenceCutOperation.lean` is defined from `existsUnique_simplest_separator` applied to it (section 1.5; the same remark in source 14's audit section, section 40).

### 59.2.3 Proposed modules and theorem dependencies

| Proposed module      | Principal obligations                                                                          |
|----------------------|------------------------------------------------------------------------------------------------|
| LabelledCommonPrefix | Initiality, next labels, lexical linearity; comparison with ordinal enumerations.              |
| SupportExtension     | Finite extension; infinite buffer; preservation of fixed positions; cardinal bounds.           |
| CoreCylinders        | Canonical support codes, prefix completion, convex cylinders, ordered children.                |
| CrossingPrefixes     | Elementary crossing predicate; chain and uniqueness by length; union graph.                    |
| CutTrichotomy        | Unbounded branch; bounded limit edge; terminal numerical gap; uniqueness.                      |
| ExhaustiveTrace      | Coherence and coverage; graph reconstruction; trace injectivity.                               |
| SupportSaturation    | Support compression; union bound at cf $\kappa$ ; sharp forced-prefix configuration.           |
| RawTraceFibers       | Canonical set-like initial branch; tail concatenation; equality and convexity of trace fibers. |
| ClassRealizations    | Same-set structures and elementary absoluteness with old parameters.                           |

These are proposed modules, not files claimed to exist or compile. A dependency path is

completion  $\longrightarrow$  cylinders  $\longrightarrow$  crossing chain  $\longrightarrow$  trichotomy  $\longrightarrow$  recognition.

Support compression can instead import the predecessor's verified-in-writing core interpolation theorem while that path is being formalized. The character theorem and support threshold then provide two largely independent audits of the prefix machinery.

### 59.2.4 Class-level interfaces and avoiding a hidden third sort

A formal metatheory of GBC can express cuts and enumerations as class variables and use elementary comprehension explicitly. An alternative is to formalize the external inaccessible model, where all relevant collections are sets in a larger type universe. These routes have different assumptions and should not be conflated.

The central reconstruction specification can be written schematically as

```

Crosses(D, p) :=
  exists a b, InCylinder(a,p) and InCylinder(b,p)
    and D(a) and not D(b)

RecoveredGraph(D, alpha, x) :=
  exists p, Crosses(D,p) and alpha in domain(p) and p(alpha)=x

Coherent(D) := forall alpha, exists p,
  domain(p)=alpha and Crosses(D,p)

Covers(D) := forall x, exists p, Crosses(D,p) and x in range(p)

```

This is logical pseudocode, not Lean syntax and not compiled code. Its purpose is to display the quantifiers:  $a, b, p, \alpha, x$  are set objects. No line chooses a class as an element of a class family. The proof of functionality precedes any use of the recovered graph as a function, and the coverage theorem is a separate proof of surjectivity.

### 59.2.5 What must be checked before a kernel-verification claim

A completed formalization must pin its Lean and Mathlib revisions, compile all files, expose any axioms beyond the chosen foundations, and connect the generic ordered alphabet to the actual surreal carrier. It must also verify that internal ordinals, universe lifts, and prefix domains match the statements. None of those steps has been completed for the new theorems in this package; the package contains conventional written proofs and executable finite diagnostics only.

## 59.3 Source 15: a concrete Lean architecture

The inspected ProveIt declaration is

$$\text{SignSequence.}\{u\} : \text{Type } (u+1).$$

Its birthday belongs to  $\text{Ordinal.}\{u\}$ . The file provides `ordinalOrderEmbedding`, `birthdays_bounded`, `small_bounded`, `not_small`, and a well-founded simplicity relation, among other declarations [7]. The essential statement is relative smallness: the entire sign carrier is not  $u$ -small, even though it is a legitimate type one universe higher. The official Lean universe rules support this distinction [29]. This article has inspected those declarations but has not rebuilt the repository or certified any new theorem in Lean.

A practical development should use the following dependencies.

1. **Generic set layer.** Define exhaustive ordinal enumerations of an arbitrary linearly ordered carrier; prove prefix-freeness, first-difference comparison, pair orientation, and the successor-cardinal obstruction. Surreal arithmetic is unnecessary.
2. **Bounded surreal layer.** Reuse sign order and birthdays. Formalize the 00/11 code with terminal 01, ordinal concatenation, the max-coordinate scheduler, and the three coding-length cases. Track ordinal products explicitly instead of replacing them by cardinalities.
3. **Relative-smallness layer.** For a relation on a higher-universe carrier, express the assertion that an interval or predecessor type is  $u$ -small. Implement the least-representative condensation and its rank map. This models the chosen set/class boundary without a type of all types.
4. **Prefix and cut layer.** Define one uniform evaluation relation on small support codes. State crossing using quantification over small prefixes and codes, and reconstruct a persistent branch. Quantify over the cut as a parameter at the permitted universe level.
5. **Model layer.** To claim a theorem about GB, GBC, or KM itself, formalize a model or an axiomatic interface for that theory. Universe polymorphism alone is not a proof that a chosen type-theoretic encoding satisfies precisely those set-theoretic axioms.

Each layer should record its universe parameters, smallness assumptions, choice use, and available recursion principle. A relation on the entire higher-universe sign type with ordinary Lean well-foundedness may encode external well-foundedness stronger than a Henkin model's internal class condition. These should be separate definitions, linked only by proved translation theorems.

## 59.4 Source 16: a concrete formalization plan tied to ProveIt

### 59.4.1 Inspected primitives and actual status

The following declarations were inspected at the pinned repository revision. They are existing foundations, not formal proofs of the new results of this article. The earlier well-order report explicitly states that no theorem with its `swo:` labels has a Lean mapping.

| Existing file                                               | Relevant declarations or interface                                                                                                             | Reuse here                                                                                         |
|-------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------|
| <code>SignSequence.lean</code>                              | <code>SignSequence</code> , <code>birthday</code> ,<br><code>birthdays_bounded</code> , <code>small_bounded</code> ,<br><code>not_small</code> | Carrier, numerical order,<br>bounded birthday stages,<br>and properness relative to a<br>universe. |
| <code>SignSequenceCut.lean</code>                           | <code>small_cut_fillers</code> , <code>exists_cut_sep</code><br><code>arator_of_birthday_lt</code>                                             | Small-cut realization and<br>prescribed upper birthday<br>control.                                 |
| <code>SignSequenceCutOperati</code><br><code>on.lean</code> | <code>cut</code> , <code>cut_realizes</code> ,<br><code>birthday_cut_le_iSup</code> ,<br><code>exists_separator_of_small_sets</code>           | Canonical separators with<br>explicit smallness<br>assumptions.                                    |
| <code>SignSequenceSimplicity</code><br><code>.lean</code>   | <code>existsUnique_simplest_separator</code><br>and minimum-birthday results                                                                   | Deterministic choices and<br>control of sign-prefix cuts.                                          |
| <code>SizeObstructions.lean</code>                          | <code>SmallCutData</code> , <code>noUnrestrictedCuts</code>                                                                                    | Keep small inputs distinct<br>from an unrestricted<br>self-cut.                                    |

All paths in the table lie below `Algebra/SurrealNumbers/Surreal/Foundations/`; the pinned sources are recorded in the bibliography [7, 8, 9, 31]. No Lean build was performed for this article, and no proposed module name below should be read as an existing theorem declaration.

### 59.4.2 Two formalization routes

The most economical first route is ordinary type-theoretic order theory. Use a bounded birthday carrier known to be small, transport it with `Shrink` if convenient, and prove the set-alphabet theorems. Store the numerical label order separately from the well-order being encoded. A proposed `WellOrderOn X` can store the binary relation, strict linearity, and `WellFounded` evidence; an enumeration stores an ordinal domain with a bijection to  $X$ . Prove the relation/enumeration correspondence, prefix-incomparability, and first-disagreement comparison before taking any quotient. Quotienting first by abstract isomorphism would destroy the required labels.

The second route explicitly formalizes a model of class theory. Introduce separate carriers of set and admitted-class codes, membership, formula semantics, and internally admitted family relations. State elementary comprehension, replacement, and any GC or ETR assumptions at that level. This route is appropriate for exact axiom-strength claims and Henkin models. It is heavier than proving the bounded combinatorial theorems, but it prevents an accidental use of all ambient predicates as internal classes.

### 59.4.3 Universe levels and logical levels are different

ProveIt's actual carrier is

$$\text{SignSequence.}\{u\} : \text{Type } (u + 1), \quad \text{birthday} : \text{Ordinal.}\{u\}.$$

Its small-cut interfaces explicitly require `Small.{u}` for the index families. A bounded birthday subtype is small at that level, while the full sign carrier is not.

One must not say that every power set automatically forces the next syntactic Lean universe. If  $S : \text{Type } (u + 1)$ , then both `Set S` and `S → Prop` also inhabit `Type (u + 1)`. Being well-typed does not make them  $u$ -small, nor does it identify them with the class collection of an internal GBC model. Native quantification over all such predicates is an ambient full-type interpretation. Likewise, native `WellFounded R` asserts ambient well-foundedness, which is not automatically a model's internal assertion [29, 38, 30].

For a direct universe-relative global development, keep a baseline  $b : \text{Ord}^u \simeq \mathbf{No}^u$  as an explicit parameter until its existence is separately established. Encode supported permutations by genuinely small data, and represent families of their evaluated graphs uniformly. This gives meaningful theorems without pretending that every ambient type is an internal set or every function on class predicates is a same-level class function.

#### 59.4.4 Suggested milestones

1. **Finite and set-alphabet layer.** Formalize first disagreement, prefix convexity, pair coding, and the stabilization bound. This isolates the ordinal-spectrum theorem from all surreal-specific facts.
2. **Topological layer.** Formalize the no-cross-fiber-jump lemma, prefix families meeting every open set, and disjoint finite-tail cylinders. Then prove the countable incompleteness construction and the regular-stage gap spectrum.
3. **Small-support layer.** Formalize normalization, completion of a small prefix, and the bounded common-prefix interpolation search. Reuse the existing small-cut separator rather than postulating a new unrestricted cut operation.
4. **Cut recognition.** Define straddling on set codes, prove uniqueness and coherence at each length, and implement the direct formula (S16.14). Only then package the exhaustive branch criterion and first-failure classification.
5. **Class semantics layer.** In an explicit model interface, formalize set-interval equivalence, least representatives, local rank, and the terminal set. These are elementary constructions; a general class-recursion engine is unnecessary for them.
6. **Higher comprehension.** State the inverse evaluator with its exact syntactic complexity before invoking a comprehension axiom. Prove the elementary diagonal theorem independently, and use it as the final contradiction in the nonembedding theorem.

These milestones deliberately separate ordinary mathematics about a large type from metatheorems about a two-sorted model. No new consistency axiom is needed for the bounded results, and the inaccessible model is an optional explicit interpretation rather than a prerequisite for the whole subject.

### 59.5 Source 17: formalization routes and a practical verification plan

#### 59.5.1 Start with the alphabet interface, not surreal arithmetic

The new set-sized results depend on a small interface. A formal development can begin with a linear order  $X$  of infinite cardinality  $\mu$ , with  $\mu$  elements in every nonempty open interval and ray. It should record its ray and point character  $r$  and the gap spectra of deletions of fewer than  $\mu$  elements. Prefix completion, clopen cylinders, divergence bounds, the cut trichotomy, and fusion can then

be proved abstractly. The birthday sign alphabet is one implementation of this interface. This organization prevents arithmetic lemmas about surreal addition or multiplication from obscuring a proof that uses only order and signs.

The exact gap theorem has four independently testable mathematical interfaces: a gap is a two-sided partition without endpoints; a straddling prefix is a set witness; the first stopping stage is a successor, a proper limit, or full length; and each resulting character is computed separately. Separating them makes it difficult to accidentally substitute point character  $q$  for cylinder character  $r$ .

The support theorem is another independent target. Its statement needs only a set partial injection, the necessarily moved domain and range, cardinal addition, and a complement bijection. No surreal construction appears until the final composition with a baseline.

### 59.5.2 Proposed modules and proof obligations

The following names describe a proposed architecture, not files claimed to exist in the repository or in this package.

| Proposed module                                 | Principal obligation                                                                   |
|-------------------------------------------------|----------------------------------------------------------------------------------------|
| <code>WellOrders/CommonPrefix.lean</code>       | Elementary predecessor formula, maximality, first residual labels, transitivity        |
| <code>WellOrders/PartialSupport.lean</code>     | Mandatory support, deficiency balance, exact reserve cardinal and extension            |
| <code>WellOrders/PrefixTopology.lean</code>     | Completion, convex clopen cylinders, point versus cylinder character, base cardinality |
| <code>WellOrders/CutTrichotomy.lean</code>      | Unique straddling path, first failure, limit boundary, nonexhaustive branch            |
| <code>Surreal/CutoffGapSpectrum.lean</code>     | Sign-path classification of alphabet gaps and stability under small deletion           |
| <code>WellOrders/Fusion.lean</code>             | Dense-open refinement with explicit coverage of the alphabet                           |
| <code>ClassOrders/BranchRecognition.lean</code> | A chosen model or size interface; elementary reconstruction from unique set witnesses  |
| <code>ClassOrders/CoreAutomorphisms.lean</code> | Represented-cut preservation, uniqueness of extension, nonextension witness            |

For the topology modules, one should formalize the definition of cellularity as a supremum before claiming an exact cardinal value. A supremum of disjoint-family sizes need not be attained. Likewise the gap spectrum should not include point cuts of character 1, and the recognition module should not quietly switch between open and closed principal lower cuts.

### 59.5.3 Universe-relative type theory

Lean’s universes offer a practical way to keep a fixed smaller universe separate from a larger carrier. A type, a type of relations on it, and a universe of all smaller types must have their levels checked explicitly. Function types do not automatically jump one level merely because they represent a mathematically large collection: their levels are computed from the domain and codomain. Universe polymorphism supplies a family of declarations, not an internal type of all universes; and universe lifting is explicit rather than an automatic cumulative coercion [29].

For this project, choose a lower notion of “small” and an ordinal index which well-orders the intended large carrier with small proper initial segments. State the cut operation only for lower-small families. A back-and-forth argument along an arbitrary choice well-order of the large type is unsafe:

its proper initial segments may be too large for the assumed cut operation. The correct interface is the small-history property used in the proof of [Corollary 42.14](#).

A set-sized cutoff implementation avoids this difficulty entirely. Every object is an ordinary type with explicit cardinal bounds, and a formal proof can be instantiated at many cardinals. A universe-relative version then transports the argument, without equating an ordinal type from one universe with all ordinals from every universe.

#### 59.5.4 A deep model-theoretic alternative

To study exactly which comprehension principles suffice, formalize a specified two-sorted model  $(M, \mathcal{K})$  and its elementary comprehension and replacement axioms. Each theorem about global rows is then a theorem about admissible class relations of that model. This is the most direct route for [Theorem 48.4](#) and for questions comparing GBC, ETR, and KM.

The two routes should not be conflated. A successful theorem about types in a fixed universe does not, without an interpretation theorem, prove a conservativity or axiomatic-strength statement about class theory. Conversely, a GBC proof with explicit class variables is not automatically a compiled theorem about the repository’s current sign-sequence carrier.

#### 59.5.5 Verification boundary

No Lean code accompanies this article and no kernel-verification claim is made. The source’s foundation modules were not rebuilt. A future formalization should pin both the repository and Mathlib revisions, compile the modules, reject unfinished proofs, and audit theorem axiom dependencies. The companion Python checks test only finite mechanisms. They cannot decide the existence of class maps, prove cardinal cofinality formulas, or certify the infinite support obstruction.

### 59.6 Source 18: a concrete formalization plan for ProveIt

#### 59.6.1 What the inspected source actually provides

The source audit used the pinned revision `83befe707f2840c2b53e0606701d8a2b28598e47`. The relevant files are in `Algebra/SurrealNumbers/Surreal/Foundations/`. The following declarations were inspected directly in the source files [\[32\]](#), rather than inferred from a report’s title.

| Source file                              | Useful declarations and their role                                                                                                                                                                                                     |
|------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>SignSequence.lean</code>           | <code>SignSequence : Type (u + 1)</code> , numerical linear order, <code>lt_iff</code> , <code>birthdays_bounded</code> , <code>small_bounded</code> , <code>not_small</code> , prefixes, truncations, and the ordinal order embedding |
| <code>SignSequenceCut.lean</code>        | <code>exists_cut_separator_of_birthday_lt</code> and <code>small_cut_fillers</code> ; the bounded and small-family separator interface                                                                                                 |
| <code>SignSequenceSimplicity.lean</code> | <code>existsUnique_simplest_separator</code> and minimum-birthday uniqueness; deterministic choice of separators where appropriate                                                                                                     |
| <code>SignSequenceComparison.lean</code> | <code>le_iff_options_lt</code> , <code>lt_iff_exists_option</code> , and canonical-cut comparison                                                                                                                                      |

The declaration `SignSequence.{u}` living in `Type (u+1)` is crucial. It contains the surreals with  $u$ -small birthdays; the theorem `not_small` says that this whole type is not itself  $u$ -small. The existence of a Lean type is therefore not the same as being a set at the intended smaller size level. Lean’s universe hierarchy enforces these distinctions [\[29\]](#). A Tarski–Grothendieck implementation

is another well-developed option; Pāk and Kaliszyk’s Mizar formalization illustrates a concrete universe-based route [37].

This article does not assert that the new spectrum, condensation, or shuffle theorems are already formalized in these files. No Lean build or complete imported-axiom audit was performed for this article. Reading a proof file is not equivalent to running its elaborator and kernel in the pinned environment.

### 59.6.2 The first set-level modules

The most reusable initial target is independent of surreal arithmetic. Represent a labelled well-order by a relation on a fixed carrier and its well-order proof, or by a bijection from an ordinal domain. Prove the equivalence of these representations and the absence of proper prefixes for exhaustive enumerations. Keep “increasing by numerical order” as an extra predicate on words, not as part of the definition of a well-order code.

The suggested sequence is:

1. **Ordinal words.** First disagreement, concatenation, prefix cones, alternative terminators, and the finite permutation adjacency criterion.
2. **Set spectra.** Pair coding, eventual coordinate stabilization, and the  $\mu^+$  obstruction. The central induction is on a regular successor cardinal, with the domain and range cardinalities stated separately.
3. **Permutation topology.** Order topology, dense sets, disjoint interval families,  $Q_n(X)$ , and the density/cellularity transition. Include global endpoints in dense-set constructions for arbitrary alphabets.
4. **Surreal cutoff interface.** Large sign cones, preservation of cut characters after deleting fewer than  $\mu$  labels, and  $\text{cf}(2^{<\kappa}) \geq \text{cf } \kappa$ .
5. **Cut classification.** Encode the chain of straddling prefixes and prove its three cases. The multiplicity theorem then uses explicit injections and the cardinalities of the prefix tree and full branch set.

This order gives a checkable sequence of finite dependency boundaries. The proof of the gap spectrum depends only on order, ordinal words, cardinal arithmetic, and the cutoff interface. It does not require surreal addition, multiplication, or real closedness.

### 59.6.3 The class-level modules

There are two sensible implementations.

*Semantic set/class models.* Define a first-order set universe and a collection of admitted class predicates, with the GB axioms made explicit. A class well-order is a relation in that collection with the internal well-order property. Then prove the elementary common-prefix theorem, set-interval decomposition, uniform branch criterion, and factorial-block facts as statements about that model. An external countability hypothesis subsequently gives the shuffle classification. This route preserves the exact meaning of internal set size and available classes.

*Universe-relative carriers.* Fix the smallness level  $u$ , work with a larger carrier type, and formulate set-likeness using  $u$ -small predecessor types. Relations on that carrier live in an appropriate larger universe. This is convenient for a concrete containing-universe development, but theorems must say which subsets are admitted and which smallness level “set” means. Merely forming the type of all relations in the next universe does not identify it with a particular GBC class realization.

In either route, give quotient blocks actual representatives. For set-interval condensation use the least label of a block; for the external finite-condensation quotient use the usual set quotient in the ambient universe. Their types and their purposes differ.

#### 59.6.4 Suggested proof obligations and trust reporting

For a mechanized milestone, require the following explicit outputs: the precise theorem statement with universe levels; a compiling source file against the pinned toolchain; an imported-axiom report; and a short explanation of the semantic correspondence with the article. Finite examples can test a comparator implementation, but they do not verify the  $\mu^+$  argument, Global Choice equivalence, or any claim about proper classes. The current deliverable supplies conventional proofs and source provenance, rather than presenting finite computations as certificates for infinitary assertions.

## 60 What this Part answers

[merge] Dated notes, 3 October 2026, in the form of [section 33](#); where the question index of [section 113](#) (dated 2 October 2026) says otherwise, these notes supersede it.

- (a) *Source 11's research question 113.3 and source 12's research question 113.14, iterated residual decomposition and proper-class blocks*: the block-index clause is **answered**. Every class well-order decomposes at once, elementarily in GB, into proper blocks of type Ord indexed by a class well-order, followed by at most one final set block; every nonempty class well-order occurs as the index, with any final set ordinal ([note 52.1](#)); explicit condensation histories of every class length exist ([theorem 53.4](#)). In particular all the subpredicates  $\text{Ord} \cdot \gamma + \alpha$  of [research question 113.14](#) are nonempty and are recognized by their block profile. Open: the strength needed to iterate the condensation of an arbitrary input uniformly ([research question 113.48](#), [research question 113.64](#), [research question 113.86](#)), and, for [research question 113.14](#), the embedding and nonembedding theorems between those subpredicates and the set-like order, of which only the full-model separation  $\mathcal{W}_{\kappa+2} \not\leftrightarrow \mathcal{W}_{\kappa}$  ([theorem 57.3](#)) is proved.
- (b) *Source 11's research question 113.2, weakest comprehension for the uniform nonembedding*: answered in part. For transformations defined by formulas with only set quantifiers, GBC with  $\Sigma_1^1$  class comprehension suffices ([theorem 56.2](#)); whether it is necessary, and whether GBC alone suffices, is open ([research question 113.63](#)). The question's bounded variant, comparing density and cellularity of all well-orders of  $\mathbf{No}_{<\kappa}$  with the minimal stratum, is answered by [theorem 27.2](#) (Part VI).
- (c) *Source 08's question 7, full virtual lexicographic products* ([section 113.4](#)): **answered** for the interpretations it names. In GBC,  $\mathcal{W}_{\text{sl}} \cong \mathbf{No} \times_{\text{lex}} \mathcal{W}_{\text{sl}}$  and every ordinary class-indexed lexicographic sum of copies of  $\mathcal{W}_{\text{sl}}$  embeds into  $\mathcal{W}_{\text{sl}}$  ([theorem 55.1](#)); in the full inaccessible universe  $\mathcal{W}_{\text{sl}} \times_{\text{lex}} 2 \not\leftrightarrow \mathcal{W}_{\text{sl}}$ , hence  $\mathcal{W}_{\text{sl}} \times_{\text{lex}} \mathcal{W}_{\text{sl}} \not\leftrightarrow \mathcal{W}_{\text{sl}}$  ([theorem 55.3](#)); no fixed definable uniform embedding exists in  $\text{KM} + \text{GC}$  ([theorem 55.4](#)); in externally countable models  $\mathcal{W}_{\text{sl}} \times_{\text{lex}} \mathcal{W}_{\text{sl}} \cong \mathcal{W}_{\text{sl}}$  externally ([proposition 55.5](#)). The negative half already followed from the proofs of [theorems 20.1](#) and [20.2](#) ([note 55.6](#)). A finer absorption spectrum (source 13's [research question 113.25](#)) is open.
- (d) *Source 12's research question 113.17, automorphisms and finite condensation*: answered in part. The maximal finite components of the unrestricted order are the  $n!$  permutations of the maximal finite final segment, and the condensed order is dense without endpoints ([theorem 54.4](#), [proposition 58.3](#)); in every countable  $\omega$ -standard model the full order is externally the factorial

shuffle and its automorphism orbits are known ([theorem 58.6](#), [corollary 58.9](#)). The internal classification of the condensed order (source 17’s [research question 113.77](#)) is open.

- (e) *Source 11’s [research question 113.8](#), source 12’s [research question 113.18](#) and source 08’s question 12, class realizations*: answered further. In addition to [section 50](#) (e): the pure external order of all admitted class well-orders is the same factorial shuffle in every countable  $\omega$ -standard model, so it records nothing about the class realization there, and set-likeness is not definable in it even with parameters ([theorem 58.6](#) and [corollary 58.10](#)); among GBC realizations with the same sets, internal well-foundedness of a shared relation never changes ([note 57.5](#)). The expanded structures with the set-like predicate or the label evaluation are open ([research question 113.88](#)).
- (f) *Source 11’s [research question 113.4](#), recovering prefix structure from the bare order*: a further negative part. Set-likeness is not first-order definable, even with finitely many parameters, from the pure order of all admitted class well-orders of a countable  $\omega$ -standard model ([corollary 58.10](#)); within one class well-order it is recognized by the number of blocks (source 15:  $W$  is set-like exactly when it has one block). With [section 50](#) (c), the question’s negative half is settled; the positive question, which extra predicates suffice, stays open.
- (g) *Comprehension questions* (source 12’s [research question 113.16](#), source 09’s direction 2, source 08’s question 10): bear. The direct comparison, the block decomposition, the represented-cut reconstruction and the uniform removal of blocks all have elementary definitions in GB or GBC (sources 15, 16 and 18); no reversal is proved.
- (h) *Source 11’s [research question 113.10](#), source 09’s direction 9 and source 08’s question 15 (Kanovei–Shelah)*: not affected; sources 14 and 17 restate the size boundary ([section 4](#)).

The questions of sources 13–18 that a sibling source answers are marked in [section 113](#).

[merge] Dated note, 3 October 2026 (batch 83). Items (a), (d), (e) and (f) are answered further by Parts XIII and XIV: over GBC, canonical terminating condensation histories exist exactly when class well-orders are strongly comparable (source 29), the countable class models and the common theory of their external orders are described, and the extra predicates that recognize exhaustive branches are identified ([sections 105 and 112](#); [section 113.25](#) (d), (e), (g), (h)).

## Part X

# Set-sized strata, topology and permutation groups

[merge] (3 October 2026.) The first Part of the batch-83 addition, sources 19–30 (provenance in [section 1.9](#), notation in [section 1.3.2](#)). Part VI ([part VI](#)) determined the density, cellularity, point characters and gap spectra of the set-sized strata and the coding lengths of the types  $\mu \cdot \gamma + n$ ; it left open the topology of these spaces beyond their cardinal invariants, the strata with an infinite remainder below  $\mu$ , and the isomorphism type and homogeneity of the minimal slice ([section 33](#), items (b) and (e)). Nine batch-83 sources continue exactly there. This Part prints what they prove about set-sized enumeration orders as ordered and topological spaces, about the permutation groups acting on them, and about the class analogue of prefix completion:

- thick alphabets, prefix cylinders and the prefix topology, with the sources’ re-proofs of Parts I and VI as notes ([section 62](#));

- residual cylinders, the weight and the point characters of every fixed-length stratum (source 22, [section 63](#));
- the exact binary-cube spectrum of every fixed enumeration type, and its coding sandwich (source 19, with source 30's independent route, [section 64](#));
- three completions of the minimal slice: forward prefix completion (source 24), the closure of the minimal stratum in the full order (source 21) and normal forms for the Dedekind completion (source 19) ([section 65](#));
- a generalized Baire model of the minimal slice at every regular size (source 24, [section 66](#));
- the countable cutoff, printed once from source 24, with the other six proofs and source 21's homogeneity theorem ([section 67](#));
- the countable strata of types  $\omega + n$  (sources 29 and 30, [section 68](#));
- singular cardinalities: continuity of the permutation operations, the exact complete-metrizability classification, non-Borel boundaries and closed universality (sources 24 and 26, [section 69](#));
- maximality, self-normalization and the canonical group envelope of the boundedness-preserving permutation group (source 28, [section 70](#));
- the class analogue: global prefix completion, small-net rigidity and inverse stabilization (source 24, with sources 26 and 28, [section 71](#)).

[Section 72](#) records which questions of this report, of its batch-81 sources and of the batch-83 sources the Part answers.

The bases are chosen by generality and by what each source alone proves, as in Parts VI–VIII: source 24 for the prefix topology and the three completions (every infinite alphabet), source 26 for complete metrizable and Borel complexity (every infinite cardinal), source 28 for the permutation groups (every admissible coordinate ideal), source 19 for the infinite residual tails (the only source that determines the cube spectrum in every case), source 22 for weights and characters, and source 29 for the countable strata (it alone compares the order topology with the coordinate topology at every countable length). Source 26 answers source 24's complete-metrizability question; source 28 read source 24 but not source 26, and its own leading question is the one source 26 answers ([note 70.13](#)). Sources 29 and 30 were written without knowledge of each other and prove the same countable-strata theorems; the countable-cutoff theorem is proved seven times in the batch ([note 67.1](#)). Source 30's residual-code sections reprove source 19's [section 64](#) independently.

*Conventions.* Throughout,  $\kappa$  is an infinite cardinal used as a birthday cutoff,  $\mu = 2^{<\kappa} = |\mathbf{No}_{<\kappa}|$ ,  $r = \text{cf } \kappa$  and  $q = \text{cf } \mu$ , as in [section 1.3.1](#); a general alphabet  $X$  is an infinite linearly ordered set of cardinality  $\mu$ , identified with its initial ordinal when it is used as a domain. The following renamings are made in this Part and listed in the batch-83 notation addendum ([section 1.3.2](#)).

- The minimal slice  $\text{Bij}(\mu, X)$  is  $\mathcal{W}_\mu(X)$ . Sources 24, 26 and 28 write  $\mathcal{P}_\mu(X)$ ; *false reading*: this  $\mathcal{P}$  is neither the core  $\mathcal{P}_{\text{bd}}$ ,  $\mathcal{P}_s$  nor source 11's  $\mathcal{P}_\lambda$ , which was already renamed  $\mathcal{W}_\lambda$  ([section 1.3](#)). Where these sources write  $\mathcal{P}$  for the slice itself it is printed  $P$ , as in Part VI.
- $\mathcal{I}_\mu(X) = \text{Inj}(\mu, X)$ , the injective words of length exactly  $\mu$ , is the length- $\mu$  layer of this report's  $\mathcal{I}(X)$ ;  $\mathcal{I}_{<\mu}(X)$  is the set of injective words of length below  $\mu$  (source 24's  $\mathcal{T}_\mu(X)$ , renamed because  $\mathcal{T} = \mathcal{T}$  is the class of all words). Sources 24, 26, 28 and 21 write  $\mathcal{I}_\mu(X)$ , which agrees.
- Source 26 writes  $\kappa$  for  $|X|$  and  $\theta$  for the birthday cutoff; they are printed  $\mu$  and  $\kappa$ . Its  $\mathcal{B}^+$  and source 28's  $\mathcal{I}_\mu^b$  (the boundedness-preserving injections) are one object, printed  $\mathcal{I}_\mu^b$ .
- Source 28's bounded ideal  $\mathcal{B}_\mu$  is printed  $\mathcal{J}_b$  (its  $\mathcal{B}$  would read as this report's cubes  $\mathbb{B}$ ), and

its one-sided loci  $B_\mu^+$ ,  $B_\mu^-$  are printed  $H_\mu^+$ ,  $H_\mu^-$ , so that  $H_\mu = H_\mu^+ \cap H_\mu^-$ ; its admissible ideals  $\mathcal{J}$  keep their letter (*false reading*:  $\mathcal{J}$  is not  $\mathfrak{J} = \mathfrak{J}$ ). The cofinality cf  $\mu$ , written  $\delta$  by source 28 and  $r$  in one proof of source 24, is printed  $q$ .

- The cores of sources 24, 26 and 28 ( $\mathcal{C}_b$ ) code a set-supported permutation by its restriction to the least ordinal bounding its support; they are printed  $\mathcal{P}_{\text{bd}}(b)$ . Their  $\mathfrak{E}$  is  $\mathfrak{W}_{\text{sl}}$  and source 24's  $\mathfrak{J}$ , source 26's  $\mathfrak{J}$  are  $\mathfrak{J}$ .
- Source 19's  $r_\kappa$  is  $\rho_\kappa$  and its  $D_{\rho,m}$  is  $\mathbb{B}_\rho \times_{\text{lex}} m$ , as for source 15 (section 1.3.1); its residual weights  $r(\lambda)$ ,  $u_\kappa(\lambda)$  and their sums  $R$ ,  $U$  are printed  $\text{wt}(\lambda)$ ,  $\text{wt}_\kappa^+(\lambda)$ ,  $\varrho_{\text{lo}}$ ,  $\varrho_{\text{up}}$ , as source 29's are in Part XI, because  $r = \text{cf } \kappa$  and  $R$  is a raw class order elsewhere. Source 30's weight  $r(\nu)$  is printed  $\text{wt}(\nu)$ .
- In the countable strata (section 68) the countable dense alphabet is  $D$  and  $P_\alpha = \mathcal{W}_\alpha(D)$ ; source 30's  $P_n$  (length  $\omega + n$ ) is printed  $P_{\omega+n}$ , which is source 29's index; source 30's alphabet  $X$ , its set  $D_n$  of nonisolated points and its relation-table space  $\mathcal{T}_n$  are printed  $D$ ,  $S_n$  and  $\text{Tab}_n$ ; source 29's real completion  $C$  is printed  $\hat{I}$ .

Set-sized results are theorems of ZFC; the class-level results of section 71 are stated in GBC as schemes about supplied class parameters. Labels written for the merge in this Part begin `swo:x::`.

*Status.* All nine sources describe themselves as research manuscripts with written proofs that are neither refereed nor machine-checked, and none claims historical priority. Source 24: “an AI-assisted, unrefered proof manuscript . . . not by a new Lean verification or a claim of historical priority. Finite regression checks are included but do not prove the transfinite theorems.” Source 26: “AI-assisted and unrefered . . . no new Lean verification or historical-priority claim is made.” Source 28: “AI-assisted, unrefered mathematical manuscript . . . not by a claim of historical priority or a new Lean kernel verification. Finite regression checks accompany the text but do not prove its infinitary statements.” Sources 19–22, 29 and 30 say the same in their status sections; source 30 calls its proofs “conventional mathematical arguments with independent AI-assisted proof review”. Nothing in this Part is formalized.

## 61 The twelve batch-83 sources: scope and interpretations

[merge] (3 October 2026.) Each of the twelve batch-83 sources (section 1.9) opens with a statement of what it continues and claims, and with a map of what “the lexicographic order of all well-orders of the surreal numbers” can mean. These opening sections are printed here, whole and in source order, one subsection per source section, before the mathematics of Parts X–XIV (the maps of sources 23, 27, 29 and 30 are printed in Part XII, beside the word orders and relation tables they concern), as the batch-80 sources' introductions were (section 4) and the batch-81 sources' maps were (section 34). They keep every scope statement, priority caveat and non-claim of their sources. The sources read this report at three pins (d5bd4a67b: sources 19, 20, 22; 109aaca15: sources 21, 23, 24; 7ff7736ec: sources 25–30), the first two before Parts VI–VIII were written; where a sentence says that this report lacks something it now has, the sentence is kept as pinned provenance and a dated [merge] footnote or remark gives the present state. The maps agree with one another and with the earlier sources; note 61.5 lists what they repeat. Notation follows section 1.3.2; each subsection names the symbols it renames.

### 61.1 Source 19: scope, sources, and the meaning of further study

[merge] Source 19's Sections 1 and 2, printed whole. Its  $X_\kappa$  is printed  $\mathbf{No}_{<\kappa}$ , its  $r_\kappa$  is printed  $\rho_\kappa$  (this report's  $r$  is cf  $\kappa$ , section 1.3.1), and its weighted lower and upper lengths  $R$ ,  $U$  are printed  $\varrho_{\text{lo}}$ ,

$\mathcal{Q}_{\text{up}}$ , since  $R$  names raw class orders here (section 1.3.2).

The repository already establishes a substantial foundation for this problem. Its merged surreal report [39] treats fixed set alphabets, birthday cutoffs, set-length words, set-like global enumerations, and arbitrary class well-orders. Its elementary largest-common-labelled-prefix comparison is particularly useful: it compares raw class relations directly, even when their common prefix is a proper class. It therefore avoids any preliminary assignment of “class ordinals.”

Three same-day continuation manuscripts [44, 43, 46] go further.<sup>1</sup> Among other things, they analyze bounded gap characters, simultaneous decomposition into set-interval blocks, representability of core cuts, fixed types with finite tails, and the external order in countable  $\omega$ -standard models. These are treated as prior work here. In particular, the exact identification of a persistent cut fiber with a residual well-order space is a starting point, not a new claim of this article.

The present continuation asks what those results leave unresolved. The principal advances are a stronger analysis of infinite residual types; completion formulas retaining the residual fibers; extension criteria for automorphisms; the nonstandard countable-model case and a common elementary theory; a full restriction-map theorem; and a normal form for points in the bounded Dedekind completion. The last sections explain how each result can be formalized without identifying objects from different size levels.

Throughout, “new” means developed in this continuation relative to the sources just identified. No claim of historical priority in the literature is made. A proof supplied here is a conventional mathematical proof. Existing Lean lemmas are named only when their source declarations were inspected; no new Lean development is asserted.

### 61.1.1 A precise historical connection

The motivation from Kanovei and Shelah should be stated accurately. Their construction [16, §2]<sup>2</sup> lexicographically orders maps from the continuum cardinal into  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters. The maps need not be injective. It is not, literally, the set of all well-order relations on  $\mathbb{R}$ . The relevant common mechanism is ordinal-indexed first-disagreement comparison of labelled codes. Passing to surreal labels introduces proper-class and representation questions absent from that set-sized index construction.

### 61.1.2 Notation and conventions

For a linear order  $X$  and an ordinal  $\alpha$ ,

$$\mathcal{W}_\alpha(X) = \{f : \alpha \longrightarrow X : f \text{ is bijective}\}, \quad \mathbb{B}_\alpha = (\{0, 1\}^\alpha, <_{\text{lex}}).$$

We write  $L \hookrightarrow M$  for an order embedding and  $L \simeq_e M$  for embeddings in both directions. Equimorphism is weaker than isomorphism. All sums, products, and inequalities between ordinal indices are ordinal operations unless explicitly called cardinal. Thus  $\kappa \cdot \kappa$  and  $\kappa$  have the same infinite cardinality and different ordinal meanings.

For an infinite initial cardinal  $\kappa$ , put

$$\mu = |\mathbf{No}_{<\kappa}| = 2^{<\kappa}, \quad \rho_\kappa = \begin{cases} \kappa \cdot \kappa, & \kappa \text{ singular and strong limit,} \\ \mu, & \text{otherwise.} \end{cases} \quad (\text{S19.1})$$

<sup>1</sup>[merge] These are sources 16, 15 and 18 of this report, printed in Parts VI–IX; source 19 read them as unplaced manuscripts and saw this report at d5bd4a67b, with Parts I–V only.

<sup>2</sup>[merge] Section 2 of the published paper; the index is defined in Section 1, page 2, of the preprint, which the other sources and this report’s bibliography cite.

A strong limit cardinal  $\lambda$  satisfies  $2^\rho < \lambda$  for every cardinal  $\rho < \lambda$ . The exceptional ordinal  $\rho_\kappa$  is the repository's singular birthday transition ([theorem 8.3](#)).

We use **GB** for Gödel–Bernays set theory with ZF in its set sort and no choice assumption built into the notation. We use **GBC** for **GB** with Global Choice. Purely set-sized results are proved in ZFC. Results involving all admitted class relations as an actual domain are stated externally over a specified set-sized two-sorted model. This distinction is repeated wherever it affects a theorem.

### 61.1.3 The main conclusions at a glance

The complete fixed-type cube spectrum is stated in [Theorem 64.11](#). Divide the residual ordinal into finitely many decreasing cardinal layers,

$$\alpha = \mu\gamma + \sum_{i < k} \lambda_i \eta_i + n, \quad \mu > \lambda_0 > \cdots > \lambda_{k-1}, \quad n < \omega.$$

Give a singular strong-limit layer weight  $\lambda_i \cdot \lambda_i$  and every other residual layer weight  $\lambda_i$ , and add those weighted lengths to  $\rho_\kappa \gamma$  to obtain  $\varrho_{\text{lo}}$ . Then

$$\mathbb{B}_\theta \hookrightarrow \mathcal{W}_\alpha(\mathbf{No}_{<\kappa}) \iff \theta \leq \varrho_{\text{lo}} + \lfloor \log_2(n!) \rfloor.$$

When the explicitly computed coding upper bound agrees with  $\varrho_{\text{lo}}$ , the least binary coding length is  $\varrho_{\text{lo}} + \lfloor \log_2(n!) \rfloor$ . This agreement holds for every enumeration type when  $\mu \leq \aleph_\omega$ .

The global reconstruction theorem, [Theorem 98.2](#), works externally over any set-sized **GBC** model. It replaces each cut of the core by the completed interval of its admitted raw-order fiber, or by one point when the fiber is empty. Retaining this decoration is exactly what is needed to decide extension of core automorphisms ([Theorem 98.5](#)). The at-most-two trace ambiguity for general residual alphabets is isolated in [Proposition 99.2](#). [Proposition 99.3](#) characterizes its occurrence by a set deletion exposing numerical initial and final segments of types  $\text{Ord}$  and  $\text{Ord}^*$ .

For externally countable models, [Theorem 109.1](#) gives the two pure order types

$$\sigma(\{1, 2, 6, 24, \dots\}) \quad \text{and} \quad \sigma(\{1, 2, 6, 24, \dots\} \cup \{K\}), \quad K = \omega + \sum_{q \in \mathbb{Q}} \mathbb{Z} + \omega^*.$$

The second occurs in the  $\omega$ -nonstandard case. The two orders are nonisomorphic but satisfy the same first-order sentences; indeed the same complete theory arises from every externally set-sized **GBC** model ([Theorem 109.9](#)).

Two more concrete conclusions are the exact restriction classification ([Theorem 73.1](#)) and the first-cutoff topology ([Theorem 67.13](#)): its permutation order is homeomorphic to Baire space and has real-line completion, while omitting continuum many completion points in every interval.

## 61.2 The interpretations that must be distinguished

The ambiguity has several independent sources. One may fix a set of surreal labels or use the entire proper class; fix an enumeration type or vary it; keep labels or quotient by isomorphism; compare labels in their numerical order or compare relation bits in a background schedule; and regard a collection externally or attempt to represent it internally. There are arbitrarily many artificial encodings, so no finite list can exhaust every possible meaning. The following table covers the natural mathematical interpretations and makes their differences explicit.

| Interpretation                | Objects                                                                         | Comparison and size                                                                         |
|-------------------------------|---------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------|
| Fixed set, fixed type         | Bijections $\alpha \rightarrow X$ , with $X \subset \mathbf{No}$ a set          | First unequal numerical labels; a set                                                       |
| Fixed set, all types          | All well-orders of the same $X$                                                 | Compare their unique ordinal enumerations; a set                                            |
| Variable set support          | Injective ordinal-length surreal words                                          | Must specify proper-prefix rule; a class of sets                                            |
| Induced numerical well-orders | Increasing ordinal-length words, or subsets well-ordered by the numerical order | A special family of labelled words; termination still matters                               |
| Set-like global orders        | Class well-orders of all $\mathbf{No}$ with set predecessors                    | Equivalent in GBC to bijections $\text{Ord} \rightarrow \mathbf{No}$ ; predicate on classes |
| Fixed class index             | Exhaustive enumerations indexed by a specified class well-order $J$             | Comparisons depend on $J$ ; may go beyond $\text{Ord}$                                      |
| All global orders             | Arbitrary class well-orders of the entire carrier                               | Common labelled initial segment; predicate on classes                                       |
| Unlabelled order types        | Well-orders modulo order isomorphism                                            | Set case reduces to ordinals; label lexicography does not descend                           |
| Rank or relation codes        | Inverse rank functions, or characteristic functions of order relations          | A different lexicographic order, dependent on a background coordinate well-order            |

### 61.2.1 The numerical order is not a global well-order

The surreal line is densely ordered and has no endpoints. It contains descending sequences such as  $0, -1, -2, \dots$ . Consequently the phrase “a well-order of the surreal numbers” cannot mean the numerical ordering of the whole class. It means an additional relation imposed on the labels, or a restriction to a numerically well-ordered subclass. Every set ordinal embeds numerically into  $\mathbf{No}$ , but  $\mathbf{No}$  itself is not an ordinal.

For set-supported numerical well-orders, each subset has exactly one increasing enumeration. Allowing different well-orders of the same subset gives many distinct words, one unique ordinal enumeration per relation. A prefix such as  $\langle 2, -1 \rangle$  is a valid injective well-order code and cannot be an increasing numerical code.

For a proper subclass, even numerical well-ordering need not be set-like. For instance,

$$a_\alpha = 1 - \frac{1}{\alpha + 2} \quad (\alpha \in \text{Ord})$$

is a strictly increasing proper-class sequence below 1. Adjoining 1 yields a numerically well-ordered class of type  $\text{Ord} + 1$ ; the new last point has a proper class of predecessors. The arithmetic is ordinary surreal field arithmetic, and  $\alpha$  denotes its ordinal surreal representative.

### 61.2.2 What happens when labels are forgotten

For a set  $X$  of infinite size  $\mu$ , the isomorphism types of well-orders of  $X$  are exactly the ordinals  $\alpha$  with  $\mu \leq \alpha < \mu^+$ . Their natural comparison is the ordinary ordinal order. It has little to do with the lexicographic order of their labelled representatives. Two different permutations of a fixed ordinal type are isomorphic as well-orders while occurring in different positions in the label order. In fact the isomorphism classes need not be convex. On the natural-number labels,

$$R = (0, 1, 2, \dots), \quad S = (1, 2, 3, \dots, 0), \quad T = (2, 0, 1, 3, 4, \dots)$$

satisfy  $R < S < T$  and have types  $\omega, \omega + 1, \omega$ . Thus numerical lexicography does not induce an ordered quotient by unlabelled order type.

For arbitrary class well-orders the situation is more delicate: the existence of an isomorphism or comparison between two abstract class orders is a separate class-theoretic problem. The elementary labelled comparison below never requires that problem to be solved.

### 61.2.3 Termination is part of the definition

When supports vary, one word can properly extend another. The shorter-first convention declares  $p < p \frown q$  for nonempty  $q$ . A centered convention introduces a termination token  $\dagger$  and compares it with the next actual label. With 0 excluded from the alphabet, one can use

$$\mathbf{No}_{<0} < \dagger < \mathbf{No}_{>0}.$$

For increasing words this can reverse the comparison of a word with one of its extensions: appending a negative allowed label places the extension below its prefix, while a positive label places it above.

The previous continuations prove that arbitrary and injective centered set-word orders are isomorphic to **No** in GBC, whereas increasing words have additional limit-prefix obstructions [46] ([merge] printed in Part VII: sections 36.5 and 37). Under shorter-first comparison, arbitrary, injective, and increasing words are mutually isomorphic as ordered prefix trees in GBC. Their order is still not **No**: if  $p$  has nonzero limit length, its proper prefixes have supremum  $p$ . A set of surreals in the full numerical line has no least strict upper bound, by the set-cut property.

Keeping an actual zero and placing a distinct terminator immediately below it creates adjacent increasing words  $p < p \frown \langle 0 \rangle$  when every entry of  $p$  is negative. Identifying a terminator with zero instead identifies distinct words unless a quotient convention is imposed. These are actual mathematical changes, not different notations for one order.

### 61.2.4 Inverse ranks and relation-bit codes

For a set carrier  $X$ , fix a well-order  $j$  as a coordinate schedule. A well-order  $R$  of  $X$  can be encoded by the ordinal rank of each label, and these ranks can be compared in  $j$ -order. This inverse-rank comparison need not agree with the comparison of the forward enumerations. Alternatively, well-order the coordinate set  $X \times X$  and compare the bits  $1_{xRy}$ . The result is again a linear order on codes, but it depends on the chosen pair schedule and on which bit is called smaller. Such encodings remain useful for implementation, provided their order is not silently identified with the numerical label order.

Ordinal-valued inverse ranks extend to set-like global well-orders, but are not available for arbitrary proper-class predecessor segments. Relation-bit coding remains available for supplied raw class orders when a genuine class well-order scans the pair coordinates. The code is then a class of bits. This changes none of the size boundaries: a class code is not an element of the set universe.

## 61.3 Source 20: what this continuation adds

[merge] Source 20's Sections 1 and 2, printed whole. Its bounded-support core  $\mathcal{C}_b$  (normalized permutation codes) is printed  $\mathcal{P}_{\text{bd}}(b)$ , and its  $\mathfrak{W}_{\text{sl}}, \mathfrak{W}_{\text{all}}$  are this report's  $\mathfrak{W}_{\text{sl}}, \mathfrak{W}_{\text{all}}$ .

The ProveIt report [39] already gives an extensive account of the fixed-set spectrum, the role of Global Choice, direct comparison of arbitrary class well-orders, and the bounded-support core. The subsequent continuation [46]<sup>3</sup> adds cardinal invariants and gap spectra, simultaneous decomposition

<sup>3</sup>[merge] Source 18 of this report, printed in Parts VI–IX. Source 20 saw this report at d5bd4a67b, with Parts I–V only, and none of sources 13–17.

into proper-class blocks, a criterion for represented cuts, and a countable  $\omega$ -standard model theorem. Those results are the starting point here. We do not treat their proposed research questions as a certified catalogue of unsolved problems in the published literature.

The main advances concern information that is lost when a rich enumeration structure is replaced by its underlying linear order. They also explain which limiting procedures genuinely recover global objects. The distinction is productive: the same family of bounded spaces supports a directed system recovering a surreal-sized core and a coherent restriction system recovering every admitted class well-order.

| Direction              | Earlier starting point                      | Further result here                                                                             |
|------------------------|---------------------------------------------|-------------------------------------------------------------------------------------------------|
| Birthday compatibility | Arbitrary tail choices need not compose     | Coherent gluing, finite changes, club detection of set-likeness, and compatible tail extensions |
| Core automorphisms     | Set homogeneity; extension problem proposed | Cut-orbit classification and automorphisms that have no global extension                        |
| Size of raw intervals  | Some finite or set residual fibers          | Exact local set/class-codeability dichotomy                                                     |
| Condensation           | One simultaneous block decomposition        | Uniform histories under ETR and a termination bound                                             |
| Countable models       | Factorial shuffle when $\omega$ is standard | Nonstandard shuffle, external finite blocks, elementary equivalence, and decidability           |
| Countable topology     | Density and gap counts                      | Permutation topology, Baire space, and the real-line completion                                 |

The contributions are intentionally stated at their actual foundational level. A theorem about a class of set codes is not automatically a theorem about a collection whose individual members are proper classes. An external classification of a countable model does not create an internal enumeration of its class objects.

## 61.4 The interpretations, separated

### 61.4.1 The choices that determine the question

A complete formulation specifies six things: the carrier, whether its labels are retained, whether its given numerical order must be respected, the allowed enumeration types, the comparison convention, and the universe in which the collection is formed. Varying these choices produces the following natural interpretations. There are infinitely many artificial coding conventions; “all interpretations” here means an account of these mathematically distinct choices, not an enumeration of every possible arbitrary encoding.

| Object                                               | Meaning of one point                                     | Size and comparison                                         |
|------------------------------------------------------|----------------------------------------------------------|-------------------------------------------------------------|
| $\mathcal{W}(X)$ for a set $X \subseteq \mathbf{No}$ | An arbitrary labelled well-order of the same carrier $X$ | A set; compare exhaustive ordinal enumerations              |
| $\mathcal{W}_\alpha(X)$                              | Such an order with specified ordinal type $\alpha$       | A set stratum, nonempty exactly when $ \alpha  =  X $       |
| Injective set words                                  | A well-order of a variable set of surreal labels         | A proper class of sets; a rule for termination is necessary |

| Object                                   | Meaning of one point                                                     | Size and comparison                                                                   |
|------------------------------------------|--------------------------------------------------------------------------|---------------------------------------------------------------------------------------|
| Numerically increasing set words         | A set well-ordered by the numerical surreal order                        | No arbitrary permutation of the chosen subset                                         |
| $\mathfrak{W}_{\text{sl}}(\mathbf{No})$  | A set-like well-order of the whole surreal class                         | A predicate on classes; equivalently a bijection $\text{Ord} \rightarrow \mathbf{No}$ |
| $\mathfrak{W}_{\text{all}}(\mathbf{No})$ | Any class well-order of the whole surreal class                          | A predicate on classes; common prefixes may be proper classes                         |
| Variable class domains                   | A class well-order on an arbitrary subclass of $\mathbf{No}$             | A class-variable predicate; one whole order may be a proper prefix of another         |
| Numerical class well-orders              | A subclass well-ordered by the inherited numerical order                 | Can have proper predecessor classes; not restricted to set-like orders                |
| Isomorphism types                        | Labels are forgotten                                                     | Numerical lexicography does not descend to the quotient                               |
| Relation-table words                     | Membership bits of the order relation, scanned in a fixed order of pairs | A valid different lexicographic comparison                                            |
| Objects of a smaller universe            | All orders available in a specified model or universe                    | Sets externally; the answer depends on the chosen notion of “available”               |

#### 61.4.2 Fixed labels and forgotten labels

For a set  $X$  with its numerical order, a well-order has a unique increasing enumeration relative to that well-order,  $e : \alpha \rightarrow X$ . The word “increasing” here refers to the new well-order, not to the numerical order used to compare the entries of two enumerations. If two exhaustive enumerations of the same  $X$  are distinct, neither is a proper prefix of the other. Thus their first differing entries determine their comparison without a termination rule.

Forgetting the labels changes the problem completely. On  $\{0, 1\}$  the orders enumerated by  $(0, 1)$  and  $(1, 0)$  are isomorphic, yet the first is lexicographically smaller. Consequently lexicography is not invariant under arbitrary relabelling and gives no induced order on well-order isomorphism types. If one instead orders set well-order types by their ordinals, the resulting order is simply the usual ordinal order; that is a different construction.

Nor does “all well-orders” mean that the lexicographic order itself is a well-order. Even on an infinite fixed alphabet it contains descending chains. Numerical negation of every label gives an order reversal between the spaces for  $X$  and  $-X$ ; when  $X = -X$ , this is a self-duality of the enumeration order.

#### 61.4.3 Inherited numerical well-orders

The numerical order of  $\mathbf{No}$  is not well-founded. For example, the negative integers form a descending sequence. Its well-ordered subclasses are therefore a restriction on the domain, not choices of a new order on the entire domain.

They need not be set-like. For each ordinal  $\alpha$ , let  $s_\alpha$  be the surreal whose sign sequence has length  $\alpha + 1$ , begins with a minus sign, and has only plus signs afterward. These labels strictly increase with  $\alpha$  and remain below 0. Their class followed by 0 has numerical order type  $\text{Ord} + 1$ . The

last point has a proper class of predecessors. More generally, under Global Choice the universality of the surreal line realizes every supplied class linear order as a numerical suborder, so inherited numerical class well-orders realize all supplied class well-order types as well. This is an existence statement, not a canonical choice of a representative for every type.

#### 61.4.4 Variable domains and termination

For set words, the usual dictionary convention puts a proper prefix before every proper extension. This convention has an empty least word and permits small cofinal sequences at limit-length words: the proper prefixes of a word of length  $\omega$  increase to that word. Hence this word order is not isomorphic to the set-cut-saturated surreal line.

For a variable-domain order the carrier is part of the object; an empty strict relation alone would not distinguish an empty domain from a one-point domain. The same prefix-first convention works for variable class domains. Use the largest common labelled initial segment. If both remainders are nonempty, compare their least labels numerically; if just one is empty, put the exhausted order first. A proper-class order of type  $\text{Ord}$  can then be a proper prefix of one of type  $\text{Ord} + 1$ . This possibility is absent when both orders exhaust the same carrier. The elementary common-prefix argument below proves transitivity in this variable-domain setting as well, with an exhausted branch treated as a least terminator.

An alternative is to place a terminator at a numerical cut of the digit alphabet. In particular, a terminator between the negative and positive nonzero surreal digits behaves like the undefined sign in a surreal sign sequence. The earlier continuation proves that arbitrary and injective set words with this centered convention are isomorphic to **No** in GBC, while increasing words retain a limit-prefix obstruction [46] ([merge] sections 36.5 and 37). If the digit 0 is also retained immediately above a distinct terminator, the empty suffix and the suffix (0) become adjacent. Endpoint and gap conclusions therefore require the convention to be stated.

Reversing the significance of coordinates introduces another issue. Two infinite words need not have a last differing position, so a proposed “compare the last difference” rule is not a total order without a support restriction. Comparing order types before labels also changes the order: it is a type-priority sum of strata, rather than native enumeration lexicography.

#### 61.4.5 The Kanovei–Shelah connection

Kanovei and Shelah use a definable lexicographic order of maps  $a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters; repetitions are allowed. The entries are compared by their characteristic functions. This is not the collection of all well-orders of the reals, and their construction does not identify it with one of the orders above [16, §1]. The shared idea is to retain many ordered codes instead of selecting one privileged representative. Transferring that idea to class-sized indices requires a separate account of uniformity and support.

### 61.5 Source 21: the problem and the further results

[merge] Source 21’s Sections 1 and 2, printed whole. Its  $\mathcal{T}$  (macro `\Words`), the class of *all* set-length words, is printed  $\mathcal{T}$ ; this report’s  $\mathcal{I}$  is the injective class. Its internal labels `g1:` stay under its own prefix (`swo:fu:g1:`) and are unrelated to source 11’s `swo:g1:`.

The surreal numbers supply an unusually effective testing ground for lexicographic constructions. Their numerical order can interpolate every set-sized strict cut, yet the collection of all surreals is a proper class. Thus a finite or set-sized argument may remain perfectly valid while an apparently harmless change from “each” to “all” crosses a logical size boundary. The order of presentations

introduces a second source of complexity: labels, enumeration lengths, and terminal tails can survive in a lexicographic order even when the presented well-orders are abstractly isomorphic.

The pinned ProveIt treatment [39] is a substantial synthesis of four earlier manuscripts. It proves general set-alphabet spectra, surreal birthday-stage results, word codings, a direct comparison of class well-orders, dense bounded-support cores, and size obstructions. Its open-question list asks about prefix recovery, automorphisms, noncardinal cutoffs, coherent embeddings, and changes of the class realization. The present paper concentrates on these directions.<sup>4</sup> Canonical block decompositions and represented-cut criteria also arose in the preceding research; we include the versions needed for the new arguments rather than treating every restatement as a new result.

The main conclusions are these.

1. **An exact obstruction to extending core automorphisms.** The bare order of a surreal-sized dense core does not distinguish the large cuts arising from exhaustive global enumerations, those arising from nonexhaustive injective branches, and certain cuts arising from no class well-order at all. An automorphism can interchange these kinds. Consequently some core automorphisms admit no extension to an order embedding from the set-like space into the full class-well-order space. Preservation of exhaustive represented cuts is the exact criterion for automorphism extension within the set-like space.
2. **A concrete failure of prefix recovery.** For  $P = \mathcal{W}_\omega(\mathbb{Q})$ , all nonempty open intervals and open rays have order type  $P$ . Every finite increasing partial map extends to an automorphism, but the family of positive-length prefix cylinders is not preserved by all these automorphisms. No such cylinder is definable from the pure order using finitely many parameters.
3. **A precise topology behind the countable example.** The order topology of  $P$  is its topology of finite agreement. It is homeomorphic to  $\omega^\omega$ , but its order is not that of the irrationals. There are continuum many missing cuts even inside each prefix cylinder, caused both by numerical cuts and by failure to enumerate every label.
4. **Fibers and closure for set-sized alphabets.** Every well-order of an infinite  $X$  starts with an injective word of length  $|X|$ . Fixing this word leaves exactly the lexicographic order of all well-orders of the unused labels. Under a natural large-interval hypothesis, the closure of the minimum-length stratum consists of that stratum together with the existing endpoints of these fibers.
5. **Further bounded and model-theoretic information.** We compute basic invariants at noncardinal birthday cutoffs, construct coherent embeddings over bounded chains of equal cardinality, and separate standard finite permutation blocks from the externally infinite blocks hidden in nonstandard models. The abstract countable set-like order is always  $\mathbb{Q}$ , while the distinguished core retains information that this bare order forgets.

The conclusions are deliberately sensitive to interpretation. A dense class isomorphic to **No** does not turn the entire family of class enumerations into an ordinary class. A homeomorphism does not imply an order isomorphism. An internally finite terminal block need not be externally finite. These distinctions are mathematical content, not merely precautions about notation.

<sup>4</sup>[merge] Source 21 read this report at 109aaca15, before Parts VI–VIII were written. Part VIII has since answered the prefix-recovery, automorphism and class-realization questions in part (section 50); noncardinal cutoffs (research question 113.12) and coherent embeddings (research question 113.19) were still open there, and source 21's Sections 5 and 6 answer them in part (section 113.25).

### 61.5.1 The relation to Kanovei–Shelah

The motivating analogy should be stated accurately. In Kanovei–Shelah’s construction [16, §1], the index set is

$$A = \{a : \mathfrak{c} \longrightarrow \mathcal{P}(\mathbb{N}) : \text{ran}(a) \text{ is an ultrafilter on } \mathbb{N}\}.$$

They order these maps by first disagreement, using the characteristic function order on  $\mathcal{P}(\mathbb{N})$ . The maps can repeat values. This is not literally the set of all well-orders of  $\mathbb{R}$ , and their resulting index order is not itself a well-order. What carries over to our problem is the usefulness of a linear order on a sufficiently rich family of presentations. Their definable hyperreal construction is not a theorem identifying any of the surreal spaces studied below.

## 61.6 Interpretations and the logical size boundary

### 61.6.1 Surreals as sign sequences

We use the sign representation

$$\mathbf{No} = \bigcup_{\alpha \in \text{Ord}} \{-, +\}^\alpha.$$

The union is class notation. Each individual sign sequence has a set ordinal as its length, called its birthday  $\text{bd}(x)$ . At the first place where two sequences differ, termination is compared by

$$- < \text{undefined} < +.$$

This is the numerical order of the surreals, not the rule that a shorter word always comes first. The sign construction and its relation to the simplicity tree are classical [55, 12].

For an ordinal  $\theta$  put

$$\mathbf{No}_{<\theta} = \{x : \text{bd}(x) < \theta\}$$

(source 21’s  $X_\theta$ ). This is a set. If  $\kappa$  is an infinite initial ordinal, then  $|\mathbf{No}_{<\kappa}| = 2^{<\kappa}$ , where  $2^{<\kappa} = \sup_{\lambda < \kappa} 2^{|\lambda|}$ . Each set of surreals has bounded birthdays. Conversely, allowing all birthdays produces a proper class, since the all-plus sign sequences already give a copy of  $\text{Ord}$ .

The cut property used in this paper is:

$$A, B \text{ sets, } A < B \implies \exists x \in \mathbf{No} (A < x < B). \quad (\text{S21.1})$$

Empty sides are allowed. This is often called the  $\eta_{\text{Ord}}$  property or the absolute linear continuum property [15]. It does not assert interpolation for arbitrary class-sized sides. For example, there is no surreal greater than every ordinal.

### 61.6.2 The main natural readings

No finite list exhausts every artificial coding convention. The following table covers the natural readings that change the mathematical problem. Independent choices in different rows can also be combined.

| Reading                | Objects being ordered                                             | Size and principal distinction                                                            |
|------------------------|-------------------------------------------------------------------|-------------------------------------------------------------------------------------------|
| Fixed carrier          | All well-order relations on a fixed set $X \subseteq \mathbf{No}$ | A set $\mathcal{W}(X) \subseteq \mathcal{P}(X^2)$ ; labels matter.                        |
| Fixed enumeration type | Bijections $\alpha \rightarrow X$ , where $ \alpha  =  X $        | A stratum $\mathcal{W}_\alpha(X)$ ; different $\alpha$ need not have the same invariants. |

| Reading                         | Objects being ordered                                                                                | Size and principal distinction                                                                                                    |
|---------------------------------|------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------|
| Varying set carrier             | Well-orders of arbitrary set-sized subsets of $\mathbf{No}$                                          | An ordinary class of set-coded objects; equivalent to injective set-length words after choosing a termination rule.               |
| Arbitrary words                 | Functions $\alpha \rightarrow \mathbf{No}$ , possibly with repetitions                               | An ordinary class; repetitions make these words different from well-order presentations of their ranges.                          |
| Numerically increasing subsets  | Sets or classes well-ordered by the inherited numerical $<$                                          | An additional monotonicity restriction; an auxiliary well-order is no longer being chosen.                                        |
| Set-like global well-orders     | Class bijections $\text{Ord} \rightarrow \mathbf{No}$ , or their induced relations                   | Each object is a class. Their totality is a predicate on classes, denoted $\mathfrak{W}_{\text{sl}}(\mathbf{No})$ .               |
| Unrestricted global well-orders | Class well-order relations on all of $\mathbf{No}$ , with possibly proper-class predecessor segments | A predicate on classes, denoted $\mathfrak{W}_{\text{all}}(\mathbf{No})$ ; ordinal enumeration need not exist.                    |
| Relation-table lexicography     | Characteristic functions of well-order relations, read in a separately chosen order of $X^2$         | A different order on the same relations; depends on the coordinate code.                                                          |
| Unlabelled order types          | Isomorphism classes of the preceding well-orders                                                     | Numerical first disagreement does not descend to this quotient. For set well-orders, the usual comparison gives ordinals instead. |
| Universe-relative collection    | All well-orders of the surreals small in a fixed universe                                            | A larger-universe set or type; smallness must remain fixed throughout a theorem.                                                  |

### 61.6.3 Set presentations and termination

For a set  $X$  with a fixed linear order  $<$ , a well-order relation  $R$  on  $X$  has a unique increasing enumeration  $e_R : \alpha_R \rightarrow X$  in the order  $R$ . Here “increasing” refers to  $R$ , not to the numerical order on  $X$ . For two different relations on the same  $X$ , their enumerations cannot be proper extensions of one another: the shorter enumeration would already have used all of  $X$ . Thus they have a first disagreement, and

$$R <_{\text{lex}} S \iff e_R(\delta) < e_S(\delta) \text{ at their first disagreement } \delta.$$

No termination convention is needed in this fixed-carrier situation.

For varying carriers, a word can be a proper prefix of another. Three different choices should be kept separate: shorter-first lexicography, longer-first lexicography, and a termination symbol at a specified cut of the alphabet. Shortlex, which first compares lengths and only then uses lexicography, is another order altogether. The usual surreal sign order uses a termination symbol between  $-$  and  $+$ ; that special three-way convention should not be imported silently into words whose letters are arbitrary surreals. The repository gives explicit prefix-safe embeddings of set-length words into  $\mathbf{No}$  and analyzes the one-sided limit-word cuts [39, Sections 9–11] ([merge] Part II, [part II](#)).

**Example 61.1** (The unlabelled quotient is incompatible with lexicography). Let  $X = \mathbb{Q}$ . Choose minimum-length enumerations beginning with 0 and 2, and an enumeration of type  $\omega + 1$  beginning with 1. In lexicographic order the third lies between the first two. The two outer well-orders are isomorphic, while the middle well-order has a different type. Therefore equality of abstract order

type is not a convex equivalence relation. There is no induced linear order on order types obtained by comparing arbitrary representatives in numerical lexicography.

The inherited numerical order on all of  $\mathbf{No}$  is not a well-order, as the sequence  $0, -1, -2, \dots$  witnesses. Nevertheless, each set ordinal occurs as the type of a numerically increasing subset of  $\mathbf{No}$ , using ordinal surreals. The proper class  $\text{Ord} \subset \mathbf{No}$  is a numerically well-ordered class. These facts concern one inherited order, not the many auxiliary well-orders of the whole numerical line.

Under GBC, every given class well-order has a numerical copy in  $\mathbf{No}$ , by the class-order universality proved below. Such a copy need not be set-like. For example, using surreal field operations,

$$\left\{ -\frac{1}{\alpha + 1} : \alpha \in \text{Ord} \right\} \cup \{0\}$$

has numerical type  $\text{Ord} + 1$ : the negative points increase with  $\alpha$ , and the last point has a proper class of predecessors.

One can also fix a particular class well-order  $J$  and compare class bijections  $J \rightarrow \mathbf{No}$  at the  $J$ -least disagreement. This is a legitimate fixed-domain stratum, for example with  $J = \text{Ord} + 2$ . It does not supply a common ordinal coordinate system for all possible class domains. The labelled-relation comparison in [note 86.10](#) avoids that need.

Relation-table coding is different even on two labels. With  $0 < 1$ , the word  $(0, 1)$  is lexicographically before  $(1, 0)$ . But if the first off-diagonal table coordinate is  $(0, 1)$  and  $0 < 1$  is the bit order, the first relation has bit 1 and the second bit 0, reversing this comparison. At the class level a fixed enumeration of  $\mathbf{No}^2$  similarly makes first-bit comparison legitimate, but it remains an auxiliary-coordinate order. Its binary-class equimorphism result in the repository does not identify it with the labelled-prefix order [[39](#), Section 17] ([[merge](#)] [proposition 17.1](#)).

#### 61.6.4 Sets, classes, and predicates on classes

Our class theory convention is explicit. GB has the usual set and class axioms with elementary class comprehension and class replacement, but no choice principle by definition.  $\text{GBC} = \text{GB} + \text{GC}$ , where global choice includes a set-like global well-order of the set universe. Set-only results are proved in ZFC. The class constructions below use GBC unless a weaker hypothesis is stated.

In these theories classes contain sets, not proper classes. A class relation  $R \subseteq \mathbf{No}^2$  is a legitimate single class. The notation “the class of all such  $R$ ” is not legitimate as an ordinary class. Instead, write a formula  $\text{CWO}(R)$  with a class variable, and write a formula  $\text{Lex}(R, S)$  for comparison. A theorem such as

$$\forall R, S (\text{CWO}(R) \wedge \text{CWO}(S) \longrightarrow \text{exactly one comparison holds})$$

is a second-order theorem. It requires no object having all those classes as elements. We use the symbols  $\mathfrak{W}_{\text{sl}}$  and  $\mathfrak{W}_{\text{all}}$  as readable shorthand for this predicate-level language.

An ordinary class family of global enumerations must have an explicit uniform code, for instance a class  $E \subseteq I \times \text{Ord} \times \mathbf{No}$  whose sections  $E_i$  are enumerations and whose indices  $i$  are sets. Quantifying over such a coded family is different from quantifying over every externally conceivable family of classes. Every interpolation and back-and-forth statement below respects this distinction.

#### 61.6.5 What stronger foundations do and do not provide

KM permits class quantifiers in class comprehension. It still does not make proper classes into elements of an ordinary class. A genuine collection of all classes requires a third sort, a suitable

hyperclass theory, or a larger surrounding set universe. Higher-order comprehension and choice principles then have to be stated for that additional level. Global choice chooses sets from nonempty classes; it is not an unrestricted choice principle for selecting one class from each family of classes. This remains a real distinction even over KM [66].

Likewise, an ordinal-stage construction does not automatically require ETR. If the state at each stage is a set and the previous stages form a set, ordinary set-valued recursion suffices in GBC. In contrast,  $\text{ETR}_{\text{Ord}}$  permits class-valued slices at each ordinal stage and is a substantive strengthening [24]. Our set-sized partial isomorphisms and prefix reconstructions belong to the former situation. We do not assert a uniform isomorphism-comparison theorem for arbitrary unlabelled class well-orders from this observation.

The universe-relative alternative is equally precise. Fix a universe  $\mathcal{U}$  of small sets and form surreals whose birthdays and cut families are  $\mathcal{U}$ -small. The encompassing surreal object belongs to a larger universe. The HoTT construction states this shift explicitly [56, §11.6]. In an inaccessible-universe model,  $V_\Omega$  plays the role of the small universe and its classes can be treated externally as subsets of  $V_\Omega$ . This is a model for a specified interpretation, not a proof that every abstract GBC model has its full external power set as its class part.

## 61.7 Source 22: scope and relation to the earlier work

[merge] Source 22’s Sections 1 and 2, printed whole. Its core  $\mathcal{D}_b$  (support codes) is printed  $\mathcal{P}_s(b)$ , its  $\mathfrak{C}$  is  $\mathfrak{W}_{\text{sl}}$ , and its prefix tree  $\mathcal{T}$  of injective set-length words is printed  $\mathcal{I}$  (here  $\mathcal{T} = \mathcal{T}$  is the class of all words). The maintained ProveIt report [39, 40] already develops fixed set alphabets, birthday fragments, set-length words, global-choice issues, set-like and unrestricted class well-orders, and a set-coded dense core of global enumerations. Its README explicitly distinguishes mathematical manuscripts from formalized declarations. We inspected the revision

d5bd4a67b41b89688a079997574a94bcd855bb83.

The maintained report is a union of four manuscripts, not a sequence of superseding editions. Its current guide describes a 116-page compiled text.<sup>5</sup>

We also consulted two previous continuation manuscripts supplied through the user’s Library: *Lexicographic Well-Orders of the Surreal Numbers, II* [45], and *Lexicographic Orders of Surreal Well-Orderings: Cut reconstruction, asymmetric products, prefix non-rigidity, and size-safe foundations* [41]. Their results are not presented here as new.<sup>6</sup> In particular, the first gives minimal-stratum cut spectra and point characters; both develop labelled cylinder recognition of global branches. They explicitly ask about nonminimal enumeration types, whether unranked cylinders suffice, and how much of a class realization can be reconstructed.

The present work answers substantial versions of those three questions. “Extension” means relative to the inspected manuscripts, not a claim of priority in the literature.

**The principal advances.** The cardinal topological invariants of *all* fixed-length strata are classified, with a sharp transition at two and three extra positions. Local characters are computed for  $\mu + n$  and  $\mu + \omega$ . Prefix heights are recovered from cylinder inclusion rather than supplied as additional data. A labelled trace structure faithfully recovers the available class

<sup>5</sup>[merge] True at the pin d5bd4a67b, which has Parts I–V. The report now merges thirty sources; its README is updated with this addition.

<sup>6</sup>[merge] They are sources 17 and 13 of this report (printed in Parts VI–IX). Source 22’s audit says that they “are not assumed to have been merged into the pinned current repository”; that was true at d5bd4a67b and is no longer so.

predicates over a fixed set universe.

### 61.7.1 What is deliberately not asserted

We do not classify all nonprincipal cuts at every nonminimal length, the full automorphism group of the global enumeration order, or the order type of every unrestricted class-well-order quotient. The reconstruction theorem retains labels and fixed coding parameters; it does not recover a class model from the bare linear order alone. No unrestricted class-cut filling principle is assumed. No existence assertion about all proper-class well-orders is smuggled into an ordinary set or an ordinary class.

### 61.7.2 Reading paths

For the new set-sized mathematics, read [note 62.15](#) and [sections 63.1, 63.2 and 63.4](#). For the global reconstruction results, read [sections 86.3, 87 and 102.1](#). [Sections 61.8, 111.10 and 111.11](#) specify the interpretation and formalization boundaries. Every new result is proved within its stated framework.

## 61.8 The interpretations that must be kept separate

### 61.8.1 A numerical order is not a chosen well-order

The numerical order on **No** is a dense linear order, not a well-order. For example,  $0, -1, -2, \dots$  is descending. A well-order  $R$  of a labelled set  $X \subseteq \mathbf{No}$  is generally unrelated to the numerical order. Its unique exhaustive  $R$ -increasing enumeration

$$e_R : \alpha \longrightarrow X$$

need not be numerically increasing. To compare  $R$  and  $S$  lexicographically, we compare  $e_R$  and  $e_S$  at their first unequal label, using the *numerical* order of those labels.

For a fixed carrier  $X$ , distinct exhaustive enumerations cannot be proper prefixes of one another: a proper prefix that already exhausts  $X$  leaves no unused label for the longer enumeration. Thus the first-disagreement comparison is independent of an end-marker convention in this case.

| Interpretation                   | Mathematical representation                                | Size and comparison issue                                                                    |
|----------------------------------|------------------------------------------------------------|----------------------------------------------------------------------------------------------|
| A fixed set, fixed order type    | $\mathcal{W}_\alpha(X) = \{e : \alpha \simeq X\}$          | A set; numerical first disagreement.                                                         |
| A fixed set, all order types     | All well-order relations on $X$                            | A set; varying exhaustive enumeration lengths cause no prefix ambiguity.                     |
| Varying set-sized carriers       | Injective ordinal-length words in <b>No</b>                | An ordinary proper class; a termination convention is needed.                                |
| Numerically well-ordered subsets | Strictly increasing words, or class well-ordered suborders | Not arbitrary labelled well-orders; variable carriers again require a convention.            |
| Set-like global well-orders      | Class bijections $\text{Ord} \rightarrow \mathbf{No}$      | A predicate on class variables, not an ordinary class of objects.                            |
| Unrestricted global well-orders  | Class relations on <b>No</b>                               | Proper-class predecessor segments may occur; compare common labelled initial parts directly. |
| Unlabelled order types           | Quotient by order isomorphism                              | Lexicography of labels does not descend to this quotient.                                    |
| Relation-code or shortlex orders | Bit strings, or length first and then labels               | Different orders depending on the coding or primary key.                                     |

### 61.8.2 Words, repetitions, and terminal markers

All set-length words, injective words, and strictly increasing words are three different carriers. A word with repeated entries is not an exhaustive enumeration of a well-order on its range. It can instead describe a well-ordered family with repeated labels.

If lengths vary, an end-first convention declares a proper prefix smaller than its proper extensions. The empty word is then a least element. End-last gives a greatest element. A central terminal marker, placed between negative and positive labels after reserving 0, produces a different order. The earlier continuation [41] proves surreal-line isomorphism results for this central convention under its stated class foundations ([merge] section 36.4). They must not be transferred to end-first lexicography.

Even when the empty word is deleted, the convention matters. Under end-first comparison, a word  $p$  of nonzero limit length  $\lambda$  can be approached from below by its proper prefixes. Any word below  $p$  either is such a prefix or has a first smaller label, and then lies below a sufficiently long prefix. Hence its left character is  $\text{cf } \lambda$ . The full surreal line has no set-sized cofinal family below a point: the set cut between such a family and that point would be fillable. This is an explicit obstruction to identifying these word orders.

Restricting to numerically increasing words does not restore well-foundedness of the lexicographic order: singleton words already contain a copy of **No**. A numerically increasing enumeration of the *whole* surreal class cannot exist, since it would provide a numerically least surreal. Proper subclasses can, of course, be numerically well-ordered; the ordinal surreals are a basic example.

### 61.8.3 Quotients and alternative codes

If labels are forgotten, set well-orders are represented by ordinal order types. All set-like global well-orders of the whole surreal class have order type  $\text{Ord}$ , so their unlabelled quotient has one type, even though their labelled lexicographic comparison is highly nontrivial. An order on relations obtained by reading membership bits according to a chosen well-order of pairs is another legitimate construction. Its first differing bit need not correspond to the first differing element in the two exhaustive enumerations.

These distinctions are structural, not merely notational. There are indefinitely many possible coding conventions, but the table separates the independent choices responsible for the principal mathematical interpretations.

### 61.8.4 The Kanovei–Shelah connection

Kanovei and Shelah’s definable nonstandard-model construction [16] uses a lexicographically ordered set of maps from the continuum cardinal to  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters. The maps need not be injective, and the index set is not itself a well-order. Thus “the lexicographic order of all well-orders of the reals” is not a literal description of that construction. The relevant methodological connection is to retain presentations and order them definably, rather than select one presentation of each object. Their construction is set-sized; a proposed surreal analogue must state separately where its functions and index families live.

## 61.9 Source 23: scope, provenance, and the new results

[merge] Source 23’s Section 1, printed whole; its taxonomy (Section 2) is printed in Part XII with the word orders (section 80.1). Its marker  $\mathbf{e}$  is printed  $\varepsilon$ , as source 16’s marker at a cut (Part XII), and its word classes  $\mathcal{W}_{\mathbf{e}}(A)$ ,  $\mathcal{I}_{\mathbf{e}}(A)$ ,  $\mathcal{U}_{\mathbf{e}}(A)$  (all, injective and strictly increasing set-length words)

are printed  $\mathcal{T}_\varepsilon(A)$ ,  $\mathcal{I}_\varepsilon(A)$ ,  $\mathcal{T}_\varepsilon^{\text{inc}}(A)$ ; its polynomial order  $P(\Gamma)$  is printed  $P(\Gamma)$ , as Part IX prints source 15's  $P(J)$ ; its  $\mathfrak{E}$  and  $\mathfrak{W}$  are  $\mathfrak{W}_{\text{sl}}$  and  $\mathfrak{W}_{\text{all}}$ ; its character symbol  $\text{On}$  is printed  $\text{Ord}$ , as in Part VIII.

The numerical order on the surreal numbers is a dense class linear order, not a well-order. A *well-order of surreals* is therefore usually an additional ordering of some carrier of surreal labels. It can also mean a subset already well-ordered by the numerical order. These readings lead to different mathematics. Even after choosing one, the words “all” and “lexicographic” leave significant choices unresolved.

The ProveIt repository's merged report [39] treats set approximations, the singular birthday transition, set-length words, direct comparison of raw class well-orders, and the bounded-support core of the set-like global order. Its guide distinguishes written arguments from checked prerequisites; it does not claim a Lean formalization of that report. We inspected the guide and the relevant sign-sequence interfaces at revision 109aaca1505c12d70ae169bdc2011f40bd476f7d. The branch moved during the investigation; this is a pinned source, not a claim about the latest branch tip.

The subsequent manuscript [41] asks, in its Question 15.9, for a classification of termination cuts, including markers adjacent to existing labels. Its Question 15.11 asks how far residual decomposition can be iterated safely. Those two questions motivate the main developments below.<sup>7</sup> Earlier continuation material also studies cut recognition, support bounds, and automorphism extension [45]; we do not present those results again as new.

### 61.9.1 What this article adds

Write  $A$  for a class order having the small-cut property of **No**, and let  $A = L \sqcup R$  be a class cut determining the position of a new termination symbol  $\varepsilon$ . All letters in  $L$  precede  $\varepsilon$ , and  $\varepsilon$  precedes all letters in  $R$ . Both arbitrary and injective words are allowed to have any set ordinal length, including zero.

**Termination criterion.** The word order is set-cut saturated if and only if  $L, R$  are nonempty and

$L$  has a greatest element, or no set is cofinal in  $L$ ,  
 $R$  has a least element, or no set is coinital in  $R$ .

This holds for arbitrary words and for injective words separately. Under global choice, either saturated order is isomorphic to **No**.

[merge] This is source 16's [theorem 36.1](#) for an abstract alphabet with the set-cut property; the condensation hierarchy below is source 15's (Part IX).

The endpoint exceptions in this statement are essential. An immediate neighbor of  $\varepsilon$  can be replaced by a whole continuation cylinder, which has room above and below every set of its elements. A mere “the augmented alphabet must itself be saturated” criterion is false. Theorem 81.12 supplies exact point characters, not merely a sufficiency argument.

Strictly increasing words behave differently. Once an increasing word has entered the region above the marker, it cannot extend downward relative to its termination point. A countable

<sup>7</sup>[merge] The manuscript cited is source 13 of this report. Its question 15.9 was answered by source 16 before source 23 was placed ([theorems 36.1 and 36.2](#), Part VII); source 23's termination criterion is therefore a second route to that theorem, for an abstract set-cut-saturated alphabet. Source 23 read this report at 109aaca15, before Parts VI–VIII were written.

increasing word then yields an explicit unfilled countable cut. Theorem 82.1 proves this for every fixed marker placement.

The second development concerns the order *being encoded*, not merely its code. For a raw class well-order  $H$ , identify two points when the closed interval between them is a set. Every equivalence class has a least element, so the quotient is representable by an ordinary class of set objects. For a given class well-order  $\Gamma$ , let  $P(\Gamma)$  consist of finitely supported functions from  $\Gamma$  to the ordinals, compared at their greatest coordinate of disagreement. The functions are represented by finite graphs; we never turn a proper-class total function into a set.

**Prescribed condensation hierarchy.** For  $t \in \Gamma$ , put

$$p \equiv_t q \iff p(\gamma) = q(\gamma) \text{ for all } \gamma \geq_\Gamma t.$$

Adjoin a final stage  $\top$  with universal equivalence. This is exactly the set-interval condensation hierarchy of  $P(\Gamma)$ : successor stages condense set intervals and limit stages are unions. Every stage before  $\top$  is nontrivial. The whole family is given by one elementary definition in GBC.

For example, deleting the first  $n$  coordinates gives a quotient of  $P(\omega)$  isomorphic to itself for every finite  $n$ , yet the limit stage  $\omega$  collapses it to a point. For  $\Gamma = \text{Ord}$ , every set stage has the original quotient order type, but the union of all those stages collapses. Thus repeated isomorphism of successive quotients does not imply that a limit stage has stabilized.

The lexicographic relevance is concrete: between any two distinct set-like exhaustive enumerations of **No**, there is a raw well-order isomorphic to  $P(\Gamma)$  for any prescribed nonempty  $\Gamma$  (Theorem 108.23). This asserts arbitrary *internal well-order complexity* in those intervals. It does not assert that the complexity is recoverable from the bare outer linear order.

### 61.9.2 Conventions about size and proofs

Our default class theory is  $\text{GBC} = \text{GB} + \text{GC}$ , with ordinary set Foundation and Power Set. The name GB itself is not used to imply choice. All members of classes are sets. An “ordinary class” below is a class of set objects. A “virtual order” is a predicate on class variables with a definable comparison; it is not a same-level class whose members are proper classes.

A class well-order means a class linear order in which every nonempty admitted subclass has a least element. We use the global-choice consequences needed for class enumerations and for producing a descending sequence from a nonempty subclass with no minimum. No arbitrary class-valued recursion is silently included in GBC.

The symbol  $\text{Ord}$  in a character pair means “no set-sized cofinal family” or its dual. It is not an additional cardinal. Under global choice, the relevant nonempty class orders have cofinal or cointial sequences indexed by  $\text{Ord}$ , so this notation also records their class-sized character.

### 61.10 Source 24: the continuation and its main results

[merge] Source 24’s Sections 1 and 2, printed whole. Its  $\mathcal{P}_\mu(X)$  and  $\mathcal{I}_\mu(X)$  are printed  $\mathcal{W}_\mu(X)$  and  $\mathcal{L}_\mu(X)$  (the length- $\mu$  layer of this report’s  $\mathcal{I}(X)$ ; this  $\mathcal{P}$  is not  $\mathcal{P}_s$ ), its core  $\mathcal{C}_b$  (normalized permutation codes) is printed  $\mathcal{P}_{\text{bd}}(b)$ , and its  $\mathfrak{E}, \mathfrak{J}$  are  $\mathfrak{W}_{\text{sl}}, \mathfrak{J}$ .

There is no unique object denoted by “the lexicographic ordering of all well-orders of the surreal numbers.” Even after the size level is fixed, one must choose whether labels matter, whether the carrier is fixed, whether the enumeration length is prescribed, and how termination is compared

with the next label. At the class level, there is the additional distinction between a well-order whose every proper initial segment is a set and a well-order that has a proper-class initial segment.

The merged ProveIt report [39] develops the foundational taxonomy, embedding spectra, finite-tail adjacency, and a set-coded dense core of the global enumeration order. Three subsequent research drafts [45, 41, 42]<sup>8</sup> study cut reconstruction, automorphisms, asymmetric products, support thresholds, and model dependence. The present article does not count these as new results. Instead, it addresses a different question: *what exactly converges when longer and longer initial parts of an enumeration stabilize?*

For a set  $X$  of infinite cardinality  $\mu$ , regarded as an initial ordinal, write

$$\mathcal{W}_\mu(X) = \text{Bij}(\mu, X), \quad \mathcal{I}_\mu(X) = \text{Inj}(\mu, X).$$

The first is the minimal-length slice of the labelled well-ordering space. The second allows a well-order of a proper subset whose cardinality is still  $\mu$ . Both carry the topology generated by initial-segment cylinders. For the surreal alphabets treated below, this is also their lexicographic order topology.

### 61.10.1 A precise statement of the advances

**Theorem 61.2** (Main results, with hypotheses explicit). *Let  $|X| = \mu$  be infinite.*

- (i) *The Hausdorff completion of  $\mathcal{W}_\mu(X)$  for agreement on bounded initial segments is  $\mathcal{I}_\mu(X)$ . Surjectivity is the intersection of the  $\mu$  open dense requirements that each label occur.*
- (ii) *If  $\mu$  is regular and  $\lambda = \mu^{<\mu}$ , then*

$$\mathcal{W}_\mu(X) \cong_{\text{top}} \lambda^\mu,$$

*where the right side has the bounded topology. This is a homeomorphism, not an asserted order isomorphism or a forward-uniform isomorphism.*

- (iii) *If  $X$  is countable and densely ordered without endpoints, the lexicographic order on  $\mathcal{W}_\omega(X)$  has a complete compatible metric and is homeomorphic to  $\omega^\omega$ . Its Dedekind completion is  $\mathbb{R}$ , and its complement there is a dense meager  $F_\sigma$  set of cardinality  $2^{\aleph_0}$ . In particular, this order is not isomorphic to  $\mathbb{R} \setminus \mathbb{Q}$ .*
- (iv) *In the bounded-prefix topology on  $\text{Sym}(\mu)$ , right translation by  $\sigma$  is continuous exactly when  $\sigma$  takes bounded subsets of  $\mu$  to bounded subsets. Inversion is continuous at  $\pi$  exactly when  $\pi^{-1}$  has that property. These conditions hold automatically for regular  $\mu$  and can fail for singular  $\mu$ .*
- (v) *In GBC, every uniformly set-indexed prefix-Cauchy net of global enumerations is eventually constant. The coherent class-length prefix completion, formulated as a scheme about individual class parameters, consists of injective Ord-words. Requiring inverse stabilization as well yields exhaustive enumerations.*

*For (i), (ii), and (iv), the topology depends only on the alphabet as a set. To identify it with a lexicographic order topology at uncountable sizes, we use the thickness hypothesis in Definition 62.1.*

The proof of (ii) is constructive in the order-theoretic sense: a node is extended until the least still-unused label, relative to a fixed baseline enumeration, first appears. This produces a full tree with  $\mu^{<\mu}$  successors at every node. Regularity keeps all intermediate prefixes short. The very step that makes this construction work identifies its singular-cardinal obstruction.

<sup>8</sup>[merge] Sources 17, 13 and 14 of this report.

Part (iii) answers the complete-metrizability question in [45] for the countable-size case. It does *not* settle that question for uncountable singular  $\mu$  with  $\text{cf } \mu = \omega$ . Those spaces are metrizable, but the incompleteness of their most obvious metric is not a proof that every compatible metric is incomplete.<sup>9</sup>

### 61.10.2 How to read the article

Sections 61.11–62.1 provide the interpretations and reusable elementary order theory. Sections 65.1–69.1 contain the principal set-sized results and their proofs. Sections 71.1–71.2 treat the class problem, including non-set-like orders and universe-sensitive interpretations. The formalization plan and research agenda are in Sections 111.23 and 113.18.

Set-sized arguments use ZFC. For class arguments, GB means Gödel–Bernays theory without a choice convention silently built into the abbreviation, and GBC means GB with Global Choice. A statement about a family of classes always specifies a uniform coding relation; it never means that proper classes have become elements of an ordinary class.

## 61.11 The interpretations that must remain distinct

### 61.11.1 Fixed carriers, labels, and enumeration length

Let  $X$  be a linearly ordered set. A *labelled well-ordering of  $X$*  is a well-order relation  $R$  on that very carrier. It has a unique exhaustive enumeration

$$f_R : \alpha_R \longrightarrow X$$

that is an order isomorphism from the ordinal  $\alpha_R$  to  $(X, R)$ . Its enumeration is not usually increasing in the given numerical order of  $X$ . The external well-order  $R$  says when a label is listed; the original order of  $X$  says which first differing label is smaller.

If  $R \neq S$ , neither exhaustive enumeration can be a proper initial segment of the other. Once one has listed every element of  $X$ , an injective continuation on the same carrier is impossible. Thus there is a first index  $\delta$  at which they differ, and

$$R <_{\text{lex}} S \iff f_R(\delta) <_X f_S(\delta).$$

There is no termination convention to choose in this fixed-carrier comparison.

The full order  $\mathcal{W}(X)$  allows all ordinal lengths  $\alpha$  of cardinality  $|X|$ . Its fixed-length slice is  $\mathcal{W}_\alpha(X) = \text{Bij}(\alpha, X)$ . The minimal slice  $\mathcal{W}_\mu(X)$ , where  $\mu = |X|$  is initial, is especially uniform: after every prefix of length less than  $\mu$ , the remaining domain still has order type  $\mu$  and the remaining labels still have cardinality  $\mu$ . Several conclusions below fail without this qualification. In particular, the full order can have adjacent pairs produced by finite residual permutation tails [39].

### 61.11.2 Varying set carriers and the end marker

An arbitrary set-sized labelled well-order of a set of surreals is represented by an injective word  $p : \alpha \rightarrow \mathbf{No}$ , with both  $\alpha$  and the word's graph sets. Two such words can stand in the proper-prefix relation. Three natural conventions are genuinely different:

<sup>9</sup>[merge] Source 26, which read source 24, settles it negatively in ZFC: for uncountable  $\mu$  of countable cofinality  $\mathcal{W}_\mu(X)$  is not Borel in  $\mathcal{I}_\mu(X)$ , hence not completely metrizable (theorem 69.18; note 69.7).

| Convention          | Comparison at termination                            | Immediate consequence                                  |
|---------------------|------------------------------------------------------|--------------------------------------------------------|
| End first           | Termination precedes every actual label.             | A proper prefix is smaller; the empty word is least.   |
| End last            | Termination follows every actual label.              | A proper prefix is larger; the empty word is greatest. |
| Central termination | Termination lies at a specified cut of the alphabet. | Extending a word can move either left or right.        |

For example, on a nonzero ordered alphabet with negative and positive letters, a termination symbol placed at zero gives

$$p \frown (-1) < p < p \frown (1).$$

The sign-sequence presentation of a surreal uses precisely a central convention on the *sign* alphabet:  $- < \text{termination} < +$ . This should not be confused with end-first dictionary comparison of *surreal-valued* words. Length-first comparison, or shortlex, is yet another order. Allowing repeated labels produces an arbitrary word space rather than a space of labelled well-orders.

### 61.11.3 Numerically increasing well-orders

One may instead ask that a subset of **No** be well-ordered by the *inherited numerical order*. Its increasing enumeration is then a special injective word. This is a far smaller and more constrained problem than arbitrarily well-ordering its labels. The whole numerical order of **No** is not a well-order: it contains  $0 > -1 > -2 > \dots$ .

At the class level, even a numerically increasing well-ordered subclass need not be set-like. Ordinal surreals give a copy of Ord. The ordered-field identity

$$\frac{v}{v+1} - \frac{u}{u+1} = \frac{v-u}{(u+1)(v+1)} > 0 \quad (0 \leq u < v)$$

shows that  $\{\alpha/(\alpha+1) : \alpha \in \text{Ord}\}$  is an increasing, numerically bounded copy of Ord. Appending the surreal 1 gives a well-ordered subclass of type  $\text{Ord} + 1$ . The final point has a proper-class predecessor collection. Numerical boundedness is therefore not a substitute for set-likeness.

### 61.11.4 The whole surreal class

A *set-like* class well-order is one in which each element has only a set of predecessors. A set-like well-order on a proper class has a canonical enumeration of type Ord: the index of an element is the ordinal order type of its predecessor set. In GBC, fix a baseline class bijection

$$b : \text{Ord} \longrightarrow \mathbf{No}.$$

We write  $\mathfrak{W}_{\text{sl}}$  for the *virtual domain* of all class bijections  $f : \text{Ord} \rightarrow \mathbf{No}$ , ordered by numerical first disagreement. Each  $f$  is a class;  $\mathfrak{W}_{\text{sl}}$  is not declared to be a class whose members are those classes.

An *arbitrary* class well-order of **No** can have type  $\text{Ord} + 1$ ,  $\text{Ord} + \text{Ord}$ , or more complicated class-order types. These are not covered by  $\mathfrak{W}_{\text{sl}}$ . Their lexicographic comparison requires a largest common labelled initial segment that may itself be a proper class; Section 71.2 supplies an elementary formula.

### 61.11.5 Codes and quotients are different constructions

Fixing a class enumeration of  $\mathbf{No} \times \mathbf{No}$  permits comparison of the characteristic functions of two well-order relations at the first differing *relation bit*. This relation-code order is legitimate, but it depends on that chosen enumeration and need not agree with numerical first-disagreement comparison of the exhaustive label lists.

Quotienting by unlabelled order isomorphism is more drastic. All set-like global well-orders have the same type  $\mathbf{Ord}$ , so their quotient has one element. The rich order  $\mathfrak{W}_{\mathbf{sl}}$  is a structure of labelled presentations, not a structure of those unlabelled types. Numerical lexicographic order generally does not descend to the quotient.

The same caution applies to the Kanovei-Shelah construction of a definable nonstandard model [16]. Their published index set consists of functions from the continuum cardinal into  $\mathcal{P}(\mathbf{N})$  whose ranges are ultrafilters, ordered lexicographically. The functions need not be injective. This motivates definable fixed-length indexing, but it is not literally the present order of all well-order relations on  $\mathbb{R}$  or  $\mathbf{No}$ .

## 61.12 Source 25: the continuation and its main conclusions

[merge] Source 25's Sections 1 and 2, printed whole. Its core  $\mathcal{D}_b$  (support codes) is printed  $\mathcal{P}_s(b)$ , its node class  $\mathcal{T}$  of injective set-length words is  $\mathcal{I}$ , and its two-sorted reduct  $\mathcal{C}_b$  is printed  $\mathbf{C}_b$ , as in Part XIII (sources 20, 24 and 26 write  $\mathcal{C}_b$  for the core itself).

The phrase “the lexicographic ordering of all well-orders of surreal numbers” leaves several independent choices unspecified. The word *well-order* may describe an additional relation on a fixed carrier or the numerical order inherited by an increasing subset. The carrier may be a set or the whole proper class  $\mathbf{No}$ . A representation may be an enumeration, a relation code, or an unlabelled order type. Finally, the word *all* must be interpreted at an explicit logical size level. These distinctions are mathematical, not merely notational.

The maintained ProveIt report [39, 40] develops these layers and the set-supported dense core of the global enumeration order. Subsequent continuation manuscripts investigate cut reconstruction, prefix completion, termination conventions, residual geometry, and condensation [41, 50, 51].<sup>10</sup> In particular, the residual-geometry continuation recovers prefix heights from unranked cylinder inclusion but explicitly leaves open whether the label information used to recognize exhaustiveness can be discarded. The present article answers that question negatively, in a stronger form that still preserves the entire core and all its cylinders.

Our new arguments are concentrated in Sections 89–95. The supporting material is re-established where it enters those proofs. The preliminary fixed-set spectrum and raw-class comparison are included to make clear which interpretation each conclusion concerns; they are not presented as new discoveries.

### 61.12.1 The principal objects

Fix, in GBC, a class bijection

$$b : \mathbf{Ord} \longrightarrow \mathbf{No}.$$

<sup>10</sup>[merge] Sources 13, 22 and 23 of this report; source 25 also read source 17. It saw this report at 7ff7736ec, with Parts I–VIII.

Let  $\mathcal{P}_s(b)$  be the ordinary class of normalized *set codes* for set-supported permutations of this enumeration. Its evaluated branches are exhaustive, but the codes themselves are sets. Let

$$\mathcal{I} = \bigcup_{\alpha \in \text{Ord}} \text{Inj}(\alpha, \mathbf{No})$$

be the ordinary class of set-length injective words. A node  $p \in \mathcal{I}$  determines a cylinder

$$C_p = \{d \in \mathcal{P}_s(b) : p \sqsubseteq d\}.$$

Here and below a core code is identified notationally with its evaluated class word; the coding distinction is maintained in the proofs.

Write  $\mathfrak{J}$  for the *virtual domain* of admitted class injections  $\text{Ord} \rightarrow \mathbf{No}$ , and  $\mathfrak{W}_{\text{sl}}$  for the subdomain of bijections. These are predicates on class variables, not ordinary classes whose members are themselves classes. An automorphism of the core-and-cylinder structure acts on its ordinary classes of set codes and induces an elementary transformation of any supplied class branch.

### 61.12.2 The main result in one statement

**Theorem 61.3** (Configuration classification; precise version in Section 90). *Let  $(f_i)_{i \in I}$  and  $(g_i)_{i \in I}$  be uniformly set-indexed families of pairwise distinct members of  $\mathfrak{J}$ . There is an order automorphism of  $\mathcal{P}_s(b)$  preserving the entire unranked cylinder family and carrying every  $f_i$  to  $g_i$  on the induced branch action if and only if, for all applicable indices,*

$$\begin{aligned} f_i \in \mathcal{P}_s(b) &\iff g_i \in \mathcal{P}_s(b), \\ \delta(f_i, f_j) &= \delta(g_i, g_j), \\ f_i <_{\text{lex}} f_j &\iff g_i <_{\text{lex}} g_j. \end{aligned}$$

Here  $\delta(f, g)$  is the least ordinal at which distinct branches disagree.

Several consequences are worth distinguishing. An arbitrary noncore exhaustive branch and an arbitrary nonexhaustive injective branch lie in the same orbit. Thus exhaustiveness is not invariant under the unlabelled cylinder structure. This also produces cylinder-preserving core automorphisms with no order-automorphism extension to  $\mathfrak{W}_{\text{sl}}$ . On the other hand, preserving the equality of labels across different extension edges forces a single alphabet automorphism. Requiring that automorphism to preserve  $\mathcal{P}_s(b)$  forces it to be the identity.

These are statements about particular reducts and expansions. They do not say that the original, fully labelled definition of a global enumeration is ambiguous. They identify exactly which information was lost when labels were forgotten.

### 61.12.3 What is not claimed

The word “new” means an extension relative to the inspected repository and continuation material, not established historical priority. We do not classify all automorphisms of the *bare* order  $\mathfrak{W}_{\text{sl}}$ , nor all automorphisms of  $\mathcal{P}_s(b)$  after forgetting cylinders. We do not transfer the regular-cardinal theorem to arbitrary singular birthday fragments. We do not infer a proper-class theorem from finite experiments. Every such stronger question is separated from the proofs below.

### 61.13 A taxonomy of the interpretations

#### 61.13.1 Fixed carriers and canonical ordinal enumerations

For a linearly ordered set  $X$ , a well-order  $R$  on the labelled carrier  $X$  has a unique increasing enumeration with respect to  $R$ ,

$$e_R : \alpha_R \longrightarrow X.$$

The word “increasing” here refers to  $R$ , not to the pre-existing numerical order on  $X$ . For distinct well-orders on the same carrier, neither enumeration can be a proper prefix of the other: an exhaustive proper prefix leaves no new label available for an injective extension. Consequently there is a first disagreement, and one may define

$$R <_{\text{lex}} S \iff e_R(\delta) <_X e_S(\delta).$$

Different ordinal lengths are allowed; no termination convention is needed for two exhaustive words on the same carrier.

We use  $\mathcal{W}(X)$  for all such well-orders and  $\mathcal{W}_\alpha(X)$  for those of enumeration type  $\alpha$ . The latter is nonempty exactly when  $|\alpha| = |X|$ . In particular, “all well-orders on  $X$ ” and “all bijections  $|X| \rightarrow X$ ” need not be the same domain.

#### 61.13.2 Varying the carrier or allowing repetitions

An arbitrary injective set-length word represents a well-order on its range. If the ranges can differ, a word can be a proper prefix of another. An extra convention is then indispensable. Placing termination before every letter gives end-first dictionary order. Placing it after every letter gives the opposite prefix convention. Placing it inside an alphabet cut gives a third family of orders. Equal words are, of course, compared as equal.

Allowing repetitions produces all ordinal-length words, but these are no longer enumerations of well-orders on their ranges. They are still useful as comparison and coding spaces. The recent termination manuscript [51] studies how different termination cuts affect set-cut saturation ([merge] as source 16 does, section 36). Its results do not make those conventions interchangeable.

Shortlex orders compare length before letters and change the construction again. A right-to-left or “last disagreement” comparison is generally undefined on infinite words: the disagreement positions need not have a largest element. Sign expansions of individual surreal numbers have their own central termination convention,  $- < 0 < +$ ; that order must not be confused with an end-first order on words whose letters are themselves surreals.

#### 61.13.3 Numerically increasing words

A set  $A \subseteq \mathbf{No}$  can already be well-ordered by the numerical order. Its increasing enumeration is then an injective, numerically increasing ordinal word. This is a much smaller domain than arbitrary labelled well-orders on  $A$ : for a given  $A$  there is only one inherited numerical order.

For example, the finite list  $(3, -1, 2)$  specifies a perfectly good additional well-order of three surreal labels, but it is not numerically increasing. Our principal homogeneous structure contains all injective prefixes; restricting it to increasing prefixes removes the freedom that makes the one-point extension argument work. Section 103 returns to this distinction for class-sized increasing subsets.

#### 61.13.4 Global set-like and unrestricted class well-orders

A class well-order is *set-like* when every proper initial segment below an element is a set. On the proper class **No**, a set-like class well-order has type **Ord** and is equivalent to a class bijection  $\mathbf{Ord} \rightarrow \mathbf{No}$ . This is the interpretation represented by  $\mathfrak{W}_{sl}$ .

An unrestricted class well-order can have proper-class initial segments. A copy of  $\mathbf{Ord} + \mathbf{Ord}$  illustrates the difference. Such a well-order has no exhaustive ordinal-class enumeration of type **Ord**, so it is not an element of  $\mathfrak{W}_{sl}$ . It can nevertheless be compared directly with another labelled class well-order through their largest common labelled initial part; the definition is recalled in Section 103.

#### 61.13.5 Relation codes and unlabelled order types

A relation can instead be encoded as a binary characteristic word using a chosen well-order of the ordered pairs of labels. The resulting lexicographic order depends on that auxiliary coding and need not agree with enumeration lexicography. It is a valid but different construction.

Quotienting by order isomorphism discards labels. For a fixed infinite set  $X$  of cardinality  $\mu$ , the possible unlabelled types are the ordinals  $\alpha$  with  $|\alpha| = \mu$ . Ordering these types by ordinal comparison is not the labelled lexicographic order. For global set-like well-orders, the unlabelled type is always **Ord**, so this quotient has only one type. Arbitrary class well-order types require additional care: a class of proper-class isomorphism classes cannot simply be formed as an ordinary class in GBC.

| Interpretation      | Objects compared                                        | Logical size in the stated setting               |
|---------------------|---------------------------------------------------------|--------------------------------------------------|
| Fixed set $X$       | Well-order relations or exhaustive ordinal words        | An ordinary set in ZFC                           |
| Variable set ranges | Injective set-length surreal words                      | An ordinary class of sets                        |
| Repeated words      | All set-length surreal words                            | An ordinary class, but not all are well-orders   |
| Inherited order     | Numerically increasing words or subsets                 | Set/class distinction still applies              |
| Global set-like     | Class bijections $\mathbf{Ord} \rightarrow \mathbf{No}$ | A predicate on class variables                   |
| Global unrestricted | Class well-order relations on <b>No</b>                 | A predicate on class variables                   |
| Relation-code order | Binary codes under a selected pair order                | Set or higher-level domain, depending on carrier |
| Unlabelled types    | Isomorphism types rather than labels                    | A different quotient problem                     |

#### 61.13.6 The Kanovei–Shelah motivation, accurately scoped

The construction in Kanovei and Shelah [16, Section 1] uses lexicographically ordered maps  $a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters; those maps may repeat values. It is not literally the order of all well-order relations on  $\mathbb{R}$ , and it is not a construction involving the proper class of all surreal labels. Its relevant methodological idea is to order presentations even when selecting one distinguished presentation would be undesirable. We retain that motivation without conflating the index spaces.

### 61.14 Source 26: the continuation and its principal results

[merge] Source 26’s Sections 1 and 2, printed whole. Source 26 writes  $\kappa$  for the cardinality of the alphabet and  $\theta$  for a birthday cutoff; they are printed  $\mu$  and  $\kappa$ , as for source 16 (section 1.3.1), so its  $\mu = 2^{<\theta}$  reads  $\mu = 2^{<\kappa}$ . Its  $\mathcal{P}_\kappa(X)$ ,  $\mathcal{I}_\kappa(X)$  are printed  $\mathcal{W}_\mu(X)$ ,  $\mathcal{I}_\mu(X)$ .

The phrase “the lexicographic ordering of all well-orders of surreal numbers” does not determine a single object. A well-ordering of a fixed set of surreal labels is a set relation. A well-ordering of the entire surreal class is a class relation. Its totality is not an ordinary class of objects in a two-sorted set/class theory. Moreover, a numerical increasing enumeration and an arbitrary enumeration carrying a different well-order are different constructions, even before these size issues arise.

The repository report [39] already develops much of this foundational separation, together with embedding spectra, birthday-cutoff phenomena, global support cores, and comparison of non-set-like class well-orders. The subsequent manuscript [52]<sup>11</sup> identifies the forward-prefix completion with injective words and asks, in its Question 13.1, whether an uncountable minimal-length permutation space of countable cofinality might nevertheless admit some other compatible complete metric. Incompleteness of the displayed prefix metric did not decide that question. Neither did the construction of a finer complete two-sided uniformity.

Here that question is answered negatively, by a stronger descriptive obstruction. Throughout the set-sized part, cardinals are identified with initial ordinals, and set choice is available. Write

$$\mathcal{W}_\mu(X) = \text{Bij}(\mu, X), \quad \mathcal{I}_\mu(X) = \text{Inj}(\mu, X), \quad |X| = \mu \geq \aleph_0.$$

The topology has basic neighborhoods prescribing a whole initial segment of length  $\alpha < \mu$ . It is not, at uncountable lengths, the usual finite-coordinate product topology.

**Main classification.** In the bounded-prefix topology,

$$\mathcal{W}_\mu(X) \text{ is metrizable} \iff \text{cf } \mu = \omega,$$

whereas

$$\mathcal{W}_\mu(X) \text{ is completely metrizable} \iff \mu = \omega.$$

If  $\mu > \omega$  and  $\text{cf } \mu = \omega$ , the stronger assertion

$$\mathcal{W}_\mu(X) \notin \text{Borel}(\mathcal{I}_\mu(X))$$

holds in ZFC, without a continuum-hypothesis assumption.

The classification concerns the *minimal* ordinal enumeration length  $\mu$ . It does not silently include all other ordinals of cardinality  $\mu$ . The distinction is essential: at a successor enumeration length, fixing the entire proper prefix can leave a unique final label and isolate a point.

The second main result is a closed-subspace universality theorem. If additionally  $\mu > \mathfrak{c} = 2^{\aleph_0}$ , then every zero-dimensional separable metrizable space is homeomorphic to a closed subspace of  $\mathcal{W}_\mu(X)$ . For any prescribed subset of binary Cantor space, the construction can preserve binary lexicographic order when  $X$  is linearly ordered. Thus the missing boundary is not a technical nuisance that disappears after a simple completeness repair; it can carry arbitrary Cantor traces.

The surreal specialization uses two different cardinal parameters. For an infinite birthday cutoff  $\kappa$ ,

$$\mu = |\mathbf{No}_{<\kappa}| = 2^{<\kappa}.$$

The relevant permutation length is  $\mu$ , not automatically  $\kappa$ . Every interval and ray of  $\mathbf{No}_{<\kappa}$  has size  $\mu$ , so its minimal enumeration order has the prefix topology as its order topology. In particular,  $\kappa = \beth_\omega$  supplies an unconditional example with  $\mu = \kappa > \mathfrak{c}$  and  $\text{cf } \mu = \omega$ .

<sup>11</sup>[merge] Source 24 of this report.

### 61.14.1 What is inherited, and what is developed here

The interpretation taxonomy, the basic set-alphabet embedding results, the support-core framework, direct common-prefix comparison, and the earlier forward-completion theorem belong to the preceding reports [39, 52]. Their elementary mechanisms are reproved below when they are needed for a self-contained argument. The main developments of this continuation are the compact omitted-label coding theorem, its non-Borel consequence, the resulting exact complete-metrizability classification, closed universality, and their simultaneous application to singular surreal birthday fragments. The bounded-image refinement in Section 69.7 gives a further localization of the obstruction.

This is a statement of dependence and of what the present manuscript contributes relative to the inspected drafts, not a claim that no related result exists elsewhere. Classical descriptive set theory supplies the perfect-set property for uncountable Borel subsets of Cantor space [57]. The newer singular-cardinal descriptive-set-theoretic framework of Dimonte and Motto Ros [58] is relevant context, but its generalized Borel hierarchies are not identified with the ordinary Borel sigma-algebra used in our theorem.

### 61.14.2 Conventions and logical scope

The set-sized proofs take place in ZFC. In the class-sized part, GB denotes Gödel–Bernays theory without an included choice principle, and  $GBC = GB + GC$ . We explicitly distinguish a theorem about two class relations from an assertion that a collection of all such relations is itself a class. A uniformly coded family means one admitted class relation whose sections are the family members; it never means an arbitrary set whose members are proper classes.

The words “well-order” and “well-founded” in a class model are internal unless an external viewpoint is stated. “Borel” throughout the main theorems means generated from open sets by *countable* unions and complements. “Closed-universal” means that the specified spaces occur as closed subspaces; it does not mean that all of them admit complete metrics. “Equimorphic” means mutually order-embeddable and does not mean order-isomorphic.

## 61.15 An atlas of the main interpretations

There is no finite list of every artificial coding one could call lexicographic. The following axes isolate the standard mathematically distinct meanings. Their combinations cover the principal interpretations of the question without imposing a misleading single answer.

| Interpretation             | Objects and comparison                                                                       | Foundational level                    |
|----------------------------|----------------------------------------------------------------------------------------------|---------------------------------------|
| Fixed labelled carrier     | Well-orders of a set $X \subseteq \mathbf{No}$ , compared through their ordinal enumerations | A set in ZFC                          |
| Fixed enumeration length   | Bijections $\lambda \rightarrow X$ ; especially the minimal slice $\lambda =  X $            | A set in ZFC                          |
| Varying set carriers       | Injective ordinal-length surreal words; termination must be ordered                          | A class of set codes                  |
| Inherited numerical order  | Strictly increasing words, or subsets well-ordered by $<_{\mathbf{No}}$                      | A class of set codes                  |
| Relation-code order        | Characteristic functions of well-order relations, along a separately chosen coordinate order | Set codes, or virtual class relations |
| Order-type quotient        | Forget labels and retain ordinal or class order type                                         | Different quotient problem            |
| Set-like global orders     | Class bijections $\text{Ord} \rightarrow \mathbf{No}$                                        | A predicate on class variables        |
| Unrestricted global orders | Class well-orders, possibly with proper-class predecessor segments                           | A predicate on class variables        |
| Higher-universe version    | The preceding objects interpreted inside a specified smaller universe or class model         | Sets externally; size shift explicit  |

### 61.15.1 Fixed sets: arbitrary well-orders are not numerical increasing orders

Let  $X$  be a set of surreal numbers, equipped with its numerical linear order. A different relation  $R \subseteq X^2$  can well-order  $X$ . Its unique ordinal enumeration is

$$e_R : \text{otp}(X, R) \longrightarrow X.$$

The values need not increase numerically. For instance,  $\langle 1, 0 \rangle$  is a legitimate enumeration of a two-element labelled well-order, but is not increasing in surreal numerical order. Numerical order is used to compare *different enumerations*, not to constrain each enumeration.

Two unequal enumerations of the same carrier cannot be related by proper initial-segment extension. If one exhausted  $X$  before the other ended, the latter would have no unused label for its next position. Hence their first disagreement occurs at a coordinate belonging to both domains, and its two labels determine their lexicographic comparison. No end marker is needed on a fixed exhaustive carrier.

For an infinite  $X$  of cardinality  $\mu$ , the possible order types are exactly the ordinals  $\lambda$  with  $\mu \leq \lambda < \mu^+$ . Thus

$$\mathcal{W}(X) = \bigcup_{\mu \leq \lambda < \mu^+} \mathcal{W}_\lambda(X), \quad \mathcal{W}_\lambda(X) = \text{Bij}(\lambda, X).$$

These slices need not be convex in the full lexicographic order. First labels can already place members of different lengths on either side of each other. Our principal topological theorem is about the minimal slice  $\mathcal{W}_\mu(X)$ , not an assertion about this entire union.

### 61.15.2 Variable carriers and termination conventions

If the carrier is allowed to vary, one word can be a proper prefix of another. For an ordinary class of all set-length injective words, the most familiar convention puts a proper prefix first. Equivalently, the termination symbol is below every genuine label. The empty word is then least. Putting termination above every label reverses the prefix comparison and makes the empty word greatest. Inserting termination at a chosen cut in the alphabet gives further inequivalent orders.

The standard sign presentation of a surreal uses the special convention

$$- < \mathbf{end} < +.$$

It therefore cannot be identified without proof with a surreal-labelled word order using termination below all letters. With the three binary words  $\langle - \rangle$ ,  $\langle \rangle$ ,  $\langle + \rangle$ , the central-termination order places the empty word in the middle, whereas prefix-first puts it before both nonempty words.

Allowing repeated labels changes injective words into arbitrary ordinal-length functions. Sorting by length before comparing labels is another construction, often called shortlex. A reverse-coordinate comparison at the *last* disagreement is not automatically defined for infinite words: two words may differ at all natural-number coordinates and have no last disagreement. These alternatives need their own definitions, rather than being treated as harmless notational changes.

### 61.15.3 Inherited well-orders, simplicity, and quotienting

A set  $A \subseteq \mathbf{No}$  well-ordered by numerical order has a unique increasing enumeration. This gives a natural restricted suborder of the varying-carrier word order. It excludes almost all arbitrary permutations. The numerical surreal order itself is not a well-order, as witnessed by

$$0 > -1 > -2 > -3 > \dots$$

The simplicity order on sign sequences, by proper prefix extension, is well-founded but partial. Birthday order is only a rank comparison, and equal birthdays require an additional tie-breaker to produce a linear well-order. None of these is the numerical lexicographic order on all well-order presentations.

Forgetting the labels removes the information on which enumeration lexicography depends. All bijections  $\mu \rightarrow X$  represent the same abstract order type  $\mu$ , although their first values can be arbitrary elements of  $X$ . Therefore the strict lex order does not descend to their order-isomorphism quotient. Ordering the resulting ordinal types in their usual ordinal order is legitimate, but it answers a different question. At the global level all proper-class set-like well-orders have type  $\mathbf{Ord}$ ; their type quotient collapses an especially rich labelled order to one type.

### 61.15.4 Relation-code lexicography

Choose a well-order  $q$  of the coordinate set  $X^2$ . A relation  $R$  is coded by its indicator function  $\chi_R : X^2 \rightarrow \{0, 1\}$ , and two relation codes can be compared at their  $q$ -least disagreement. Restricting to well-order relations produces another linear order. It depends on  $q$  and compares incidences, not next enumeration labels.

For example, let  $X = \{0, 1, 2\}$ , let  $R$  enumerate  $0, 1, 2$ , and let  $S$  enumerate  $1, 0, 2$ . Enumeration lexicography gives  $R < S$ . If the first differing coordinate in  $q$  is  $(0, 1)$  and  $0 < 1$  is the bit order, then  $\chi_R(0, 1) = 1$  and  $\chi_S(0, 1) = 0$ , so relation-code lexicography gives  $S < R$ . Both constructions are rigorous, but they are not the same construction.

The Kanovei–Shelah definable-hyperreal construction provides related motivation for lexicographically ordered presentations [16]. Its displayed indexing family consists of maps from the continuum into  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters, with lexicographic comparison of maps. That is not literally the set of all well-orders of  $\mathbb{R}$ . Repeated presentations there are part of a definability device; this distinction should be retained when transferring the idea to surreal labels.

### 61.16 Source 27: the question, its scope, and the audited starting point

[merge] Source 27’s Section 1, printed whole; its map of interpretations (Section 2) is printed in Part XII (section 80.2). Its birthday  $\ell(s)$  is printed  $\text{bd}(s)$  and its  $S_{<\theta}$  is printed  $\mathbf{No}_{<\theta}$ ; in its fixed-set paragraphs the cardinality  $\kappa$  of  $X$  is printed  $\mu$  and the cutoff  $\theta$  is printed  $\kappa$  (section 1.3.2). Its core  $\mathcal{D}_b$  (support codes) is printed  $\mathcal{P}_s(b)$  and its prefix tree  $\mathcal{T}$  of injective words is printed  $\mathcal{I}$ .

The numerical order on  $\mathbf{No}$  is not a well-order: already the finite surreals contain  $0 > -1 > -2 > \dots$ . A well-order of a set of surreal numbers therefore usually means an *additional* relation on those numbers, with their ordinary numerical order retained only for comparing labels. This distinction is the first decision in any rigorous formulation.

The second decision is the object to be compared. A well-order relation can be replaced by its increasing enumeration *in that well-order*, or by a binary table of its ordered pairs. These encodings carry different lexicographic orders. A third decision is size: a set of surreals is a set, the class of all surreals is a proper class, and a collection whose members are arbitrary proper-class relations is not an ordinary class of sets in two-sorted set theory.

The report in ProveIt already treats general-alphabet enumeration spectra, birthday cutoffs, set-length coding, direct comparison of class well-orders, bounded-support cores, represented cuts, several termination conventions, and nonextendible automorphisms of those cores [39, 1]. Re-proving the ordinal spectrum for a fixed set would not by itself constitute meaningful further study. Our main extensions instead concern information discarded by encodings and unlabelled prefix structure, sharper support optimization, and the difference between an ordinary class family and the whole raw order.

#### 61.16.1 What was actually inspected

We inspected the pinned surreal report’s `article.tex`, its README, the neighboring report on real well-orderings, and the Lean modules `SignSequence.lean`, `SignSequenceCut.lean`, `SignSequenceCutOperation.lean`, and `SizeObstructions.lean`. The merged surreal source has an important editorial limitation: it advertises a later Part IX, but its body at this pin contains Parts I–VIII.<sup>12</sup> Advertisements of the missing part are not used as proof evidence. Its dated October 3 status passages also supersede some questions retained from the October 2 question list.

This matters mathematically. The present source already contains the cardinal reserve theorem, the class-cut recognition theorem, and several word isomorphisms. We use those as established inputs of the research corpus, while supplying the arguments required to understand our extensions. We do not label them newly discovered. The exact least ordinal support bound is explicitly left unasserted there; relation-table scan dependence and exhaustive-branch failure for ordered prefix-tree automorphisms go beyond its recorded comparisons.

#### 61.16.2 Notation and conventions

A surreal number is represented by a sign sequence  $s : \alpha \rightarrow \{-, +\}$  for a set ordinal  $\alpha$ . Its birthday is  $\text{bd}(s) = \alpha$ . At the first disagreement we compare signs using  $- < \dagger < +$ , where  $\dagger$  means that the sequence has ended. Thus termination is distinct from both signs. We write

$$\mathbf{No}_{<\theta} = \{s \in \mathbf{No} : \text{bd}(s) < \theta\}.$$

This is a set for every set ordinal  $\theta$ .

<sup>12</sup>[merge] True at 7ff7736ec. Part IX was written before this addition, and the README is updated with it.

A word over a linearly ordered alphabet  $X$  is a function  $p : \alpha \rightarrow X$ . Unless stated otherwise, its length is a set ordinal. The notation  $p \smallfrown q$  denotes ordinal concatenation; ordinal multiplication in all scan and block lengths is genuine ordinal multiplication, not cardinal multiplication. The order  $L \times_{\text{lex}} M$  compares the  $L$  coordinate first. The sum  $\sum_{l \in L} M_l$  is the corresponding lexicographic sum. We write  $L \simeq_e M$  for mutual order embeddability; this never asserts  $L \cong M$ .

We use GB for Gödel–Bernays theory without a choice axiom, GBC for GB with Global Choice, and KM for Kelley–Morse class theory. A *uniformly class-indexed family*  $(R_i)_{i \in I}$  means that  $I$  is an ordinary class of sets and one class relation  $\mathcal{R}(i, x, y)$  gives every section  $R_i$ . The word “uniformly” is a mathematical requirement, not a convenience of notation.

### 61.17 Source 28: what is being continued

[merge] Source 28’s Sections 1 and 2, printed whole. Its  $\mathcal{P}_\mu(X)$ ,  $\mathcal{I}_\mu(X)$  are printed  $\mathcal{W}_\mu(X)$ ,  $\mathcal{I}_\mu(X)$ , and its  $\mathfrak{E}$  is  $\mathfrak{W}_{\text{sl}}$ ; its bounded ideal  $\mathcal{B}_\mu$  is printed  $\mathcal{J}_b$  and its coordinate ideals  $\mathcal{J}$  keep their letter, as in Part X (its macros `\BB` and `\JJ` name other objects here).

The phrase “the lexicographic ordering of all well-orders of surreal numbers” does not determine a unique mathematical structure. A well-order may have a fixed set of labels, a varying set of labels, or the entire surreal class as its carrier. It may be arbitrary or inherited from the numerical order. Labels may be retained or forgotten. A global well-order may or may not have only set-sized proper initial segments. A word may terminate, and the rule for comparing termination with a further label matters.

The ProveIt report [39] develops this taxonomy, set-sized embedding spectra, the singular birthday transition, global supported-permutation cores, and direct comparison of arbitrary class well-orders. The subsequent manuscript [52]<sup>13</sup> distinguishes forward prefix completion from Dedekind completion and derives exact continuity criteria for permutation operations. The present paper takes the latter criteria as a starting point, reproves them in a more general form, and answers several of that manuscript’s questions about the boundedness-preserving subgroup and natural topology refinements. It does not present the earlier completion or regular-cardinal Baire-space theorems as new discoveries.

#### 61.17.1 The principal developments

Let  $\mu$  be an infinite initial cardinal. On  $S_\mu = \text{Sym}(\mu)$ , let  $\tau_b$  be the topology of agreement on bounded initial segments. Put

$$H_\mu = \{p \in S_\mu : p \text{ and } p^{-1} \text{ send bounded sets to bounded sets}\}.$$

The following statements summarize the principal contributions relative to the inspected predecessor material.

**Main results.** For singular  $\mu$ :

- (i)  $H_\mu$  is the largest subgroup containing the finitary permutations on which the inherited  $\tau_b$  topology is a group topology. Its normalizer in  $S_\mu$  is exactly  $H_\mu$ .
- (ii) Its  $\tau_b$ -closure consists of all permutations preserving bounded sets in the forward direction. This closure is nowhere dense. Its forward uniform completion consists of all boundedness-preserving injections.
- (iii) The inverse-boundedness locus is dense and is an intersection of  $\text{cf } \mu$  explicit open sets in

<sup>13</sup>[merge] Source 24 of this report. Source 28 did not see source 26.

the injection completion. If  $\text{cf } \mu = \omega$ , it is a dense completely metrizable  $G_\delta$  subspace.

- (iv) The coarsest group topology containing  $\tau_b$  is  $\tau_{<\mu}$ , agreement on arbitrary subsets of  $\mu$  of cardinality less than  $\mu$ . Its character is

$$\chi(S_\mu, \tau_{<\mu}) = \text{cof}([\mu]^{<\mu}, \subseteq) > \mu.$$

- (v) The group  $(S_\mu, \tau_{<\mu})$  is complete for its two-sided group uniformity. This is a topology-changing repair, not a proof that the original lexicographic topology was already a group topology.

The numerical application uses  $\mathbf{No}_{<\kappa}$ , the surreals with sign-sequence length less than an infinite initial cardinal  $\kappa$ . Its cardinality is  $\mu = 2^{<\kappa}$ . The topology of its minimal exhaustive-enumeration slice  $\text{Bij}(\mu, \mathbf{No}_{<\kappa})$  is precisely the prefix topology. The singularity relevant to the main results is therefore the singularity of  $2^{<\kappa}$ , not merely that of  $\kappa$ .

### 61.17.2 Assumptions and limits

All set-sized results are proved in ZFC. We write GB for Gödel–Bernays class theory without building a choice principle into the abbreviation, and GBC for GB with Global Choice. Our global constructions use GBC and a specified baseline enumeration. An assertion about a family of proper classes is stated using one uniform class relation, or explicitly in an external metatheory. Neither GBC nor KM makes a proper class an element of another class.

The remaining complete-metrizability question for the *full* singular forward permutation space is not settled by the dense complete subspace constructed here. We state that question precisely in Section 113.22.<sup>14</sup> Likewise, self-normalization in the natural permutation action is not a classification of all abstract automorphisms of  $H_\mu$ .

## 61.18 The interpretations that must not be identified

### 61.18.1 Fixed sets of labels

Let  $(X, <)$  be a linearly ordered set. A labelled well-ordering  $R$  of  $X$  has a unique exhaustive ordinal enumeration

$$f_R : \alpha_R \longrightarrow X,$$

which is an isomorphism from the ordinal  $\alpha_R$  to  $(X, R)$ . There are two orders here:  $R$  tells us when a label is listed, whereas  $<$  tells us which differing label is numerically smaller. The enumeration need not be increasing for  $<$ .

Two different exhaustive enumerations of the same carrier cannot be proper prefixes of one another. A completed enumeration has already used every available label. Hence, for  $R \neq T$ , a first disagreement  $\delta$  exists and we define

$$R <_{\text{lex}} T \iff f_R(\delta) < f_T(\delta).$$

The standard least-disagreement argument proves a linear order. For example, in a comparison of three words, the smaller of the first-disagreement indices for the first two comparisons determines

<sup>14</sup>[merge] Answered negatively, in ZFC, by source 26, which source 28 did not see: for uncountable  $\mu$  of countable cofinality,  $\mathcal{W}_\mu(X)$  is not completely metrizable, and no nonempty open subspace of it is (theorem 69.18); see note 70.13 and the status of source 28's question 1 in section 113.12. The statement that source 28's own dense complete subspace does not settle it stays true.

the outer comparison; when those indices agree, transitivity of the alphabet order applies. No end-marker convention is required.

We distinguish the full order

$$\mathcal{W}(X) = \{R : R \text{ is a well-order on } X\}$$

from a fixed-length slice  $\mathcal{W}_\alpha(X) = \text{Bij}(\alpha, X)$ , and especially from the minimal slice

$$\mathcal{W}_\mu(X) = \text{Bij}(\mu, X), \quad \mu = |X| \text{ initial.}$$

The full carrier is a set: it is a subclass of the set  $\mathcal{P}(X \times X)$ . The apparent union over ordinal lengths does not make it a proper class. The minimal slice, however, has a uniform supply of unused labels after each proper prefix, which need not hold for other slices.

### 61.18.2 Varying set carriers and termination

A labelled well-order on some set of surreals is represented by an injective set-length word  $p : \alpha \rightarrow \mathbf{No}$ . Such words themselves have set codes, so the collection of all of them is an ordinary class. Now proper-prefix comparisons occur. End-first dictionary order places a word below every proper extension; end-last places it above every proper extension. In particular, the empty word is respectively least or greatest.

A central termination convention puts an end symbol at a chosen cut of the alphabet. On nonzero surreal labels, for example, one may place termination between the negative and positive labels. For fresh labels this gives

$$p \frown \langle -1 \rangle < p < p \frown \langle 1 \rangle.$$

The sign representation of an individual surreal uses the central convention  $- < \text{termination} < +$  on the *two-sign alphabet*. It is not the same as end-first dictionary order on *surreal-valued* words. Allowing repeated labels makes a word space rather than a space of labelled well-orders. Comparing length first makes a shortlex-type order rather than first-disagreement lexicography. These are legitimate alternatives, not interchangeable notations.

### 61.18.3 Inherited numerical well-orders

A different question asks for subsets that are already well-ordered by the numerical order of  $\mathbf{No}$ . Their increasing enumerations form a restricted collection of injective words. The full numerical surreal order is not well-founded, since it contains

$$0 > -1 > -2 > \dots$$

Even a numerically bounded class well-order can fail to be set-like. For nonnegative surreals  $u < v$ , ordered-field arithmetic gives

$$\frac{v}{v+1} - \frac{u}{u+1} = \frac{v-u}{(u+1)(v+1)} > 0.$$

Thus  $\{\alpha/(\alpha+1) : \alpha \in \text{Ord}\}$  has increasing type  $\text{Ord}$  and lies below 1. Appending 1 gives type  $\text{Ord} + 1$ ; the last point has a proper class of predecessors. Numerical boundedness does not imply set-likeness.

#### 61.18.4 Global class orders, codes, and quotients

A class order is *set-like* when every element has a set of predecessors. A set-like well-order of a proper class has an ordinal-class enumeration. For the whole surreal class, this produces the virtual domain of class bijections  $\text{Ord} \rightarrow \mathbf{No}$ . Arbitrary class well-orders can have proper-class initial segments and types such as  $\text{Ord} + 1$  or  $\text{Ord} + \text{Ord}$ ; ordinal-class words do not exhaust them.

There are also representation-dependent alternatives. After choosing an enumeration of pairs of labels, one can compare the characteristic functions of the well-order relations themselves. This compares the first differing *relation bit*, not the first differing label in an exhaustive list. Section 71.4 gives an explicit finite discrepancy.

Finally, forgetting labels and taking order-isomorphism types changes the problem drastically. All set-like global well-orders have type  $\text{Ord}$ , so their unlabelled quotient has one element. The rich lexicographic structure belongs to presentations. Lexicographic order generally does not descend to the quotient: differently labelled presentations of the same ordinal may occur on both sides of another presentation.

| Interpretation         | Objects                                               | Essential qualification                        |
|------------------------|-------------------------------------------------------|------------------------------------------------|
| Fixed set $X$          | Well-order relations or exhaustive ordinal lists      | No proper-prefix ambiguity.                    |
| Minimal slice          | Bijections $\mu \rightarrow X$ , $\mu =  X $          | The subject of the topology and group results. |
| Varying set carriers   | Injective set-length surreal words                    | A termination rule is needed.                  |
| Inherited order        | Numerically increasing enumerations                   | Not arbitrary labelled well-orders.            |
| Set-like global orders | Class bijections $\text{Ord} \rightarrow \mathbf{No}$ | A virtual higher-order domain.                 |
| All class well-orders  | Possibly non-set-like relations                       | Common prefixes can be proper classes.         |
| Relation-bit codes     | Characteristic functions of relations                 | Depends on a coordinate enumeration.           |
| Order-type quotient    | Unlabelled isomorphism types                          | Numerical lexicography is not inherited.       |

#### 61.19 Source 29: the question, the audit, and the new results

[merge] Source 29's Sections 1 and 3, printed whole except Subsection 3.3; its interpretations (Section 2) and Subsection 3.3 are printed in Part XII (sections 80.3 and 80.3.5). Its  $\mathbf{T}$  (the shorter-first order of all set-length surreal words, the type  $\mathbf{T}_{\min}$  of source 16's theorem 36.2) is printed  $\mathbf{T}_{\min}$  and its  $\mathbf{P} = \mathbf{T} \setminus \{\emptyset\}$  is printed  $\mathbf{T}_{\min}^+$ ; its  $\otimes_{\text{lex}}$  is printed  $\times_{\text{lex}}$ . Its internal labels  $\mathbf{gl}$ : stay under its own prefix ( $\mathbf{swo:bw:gl}$ ).

Lexicographic comparison combines two orders with different jobs. An auxiliary well-order says which label is visited first, second, and so on. The numerical order on the labels decides which of two visits comes earlier at their first disagreement. There is no reason for the resulting order on presentations to be a well-order. When the labels are surreal numbers, a further issue intervenes: all surreal numbers form a proper class. The well-orders of a fixed set of surreals and the well-orders of the entire surreal class therefore have fundamentally different logical sizes.

These observations do not prevent a substantial theory. They tell us which carriers, parameters, and axioms must be written into a theorem. The present continuation develops that theory in several directions that are not settled by the inspected merged article. Its main theme is the

amount of information that a chosen order or presentation keeps. The numerical birthday alphabet remembers its exact cutoff; some permutation-stratum embedding invariants forget it. An ordered prefix tree remembers every local numerical comparison but can still forget whether a class branch visits every label. A class condensation history has a finite description at each individual point, while its existence for all class well-orders has nontrivial foundational strength.

### 61.19.1 What was actually inspected

The source audit used the GitHub repository at a fixed commit, not a moving branch name. Sixteen source files were retrieved and their bytes checked against the Git blob hashes returned by GitHub. The central research file is

```
Algebra/SurrealNumbers/docs/foundations-and-computation/
surreal-well-orders/article.tex.
```

At the pin, its blob is `f3f69663cd63682ad2e1db808bcb3c6e8fd940ce` and its size is 903,287 bytes. The research README still describes an earlier 116-page, four-source merge.<sup>15</sup> The actual article already incorporates substantial additions from six further manuscripts, called sources 13–18 in its editorial apparatus. Its Parts VI–VIII supersede several entries in the older research-question list. The introduction also mentions an intended Part IX that is absent from the pinned body ([merge] Part IX was written before this addition). Accordingly we use actual theorem statements and proofs, together with explicitly identified earlier manuscripts, rather than infer established results from a roadmap or README [39, 47, 49, 48].<sup>16</sup>

This distinction changes what counts as further study. The pinned article already proves the general set-alphabet ordinal cutoff, substantial binary-cube spectra, fixed-stratum density and cellularity, minimal-stratum gap spectra, word-termination classifications, a raw comparison of arbitrary class well-orders, and a detailed represented-cut theory for a bounded-support core. Those results are recalled as background. We do not present them again as new discoveries.

### 61.19.2 A guide to the extensions

The following results organize the continuation.

1. **Exact numerical birthday spectra.** For every pair of set ordinals  $\beta, \theta$ ,

$$\mathbb{B}_\beta \hookrightarrow \mathbf{No}_{<\theta} \iff \beta < \theta.$$

This gives the exact numerical embeddability hierarchy and its least binary coding lengths, including noninitial ordinal cutoffs.

2. **Residual strata at noninitial birthdays.** We extend the earlier variable-residual analysis to every noninitial birthday cutoff. In particular, without the continuum hypothesis, all countable noninitial birthday alphabets have the same fixed-stratum equimorphism type at each common admissible enumeration length. This is a statement about mutual embeddings, not order isomorphism.
3. **An exact centered-word product.** Increasing words split at their termination cut. At a numerical threshold this yields  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ , and a small finite-fiber calculation classifies

<sup>15</sup>[merge] True at `7ff7736ec`; the README is updated with this addition.

<sup>16</sup>[merge] The three earlier manuscripts are sources 19, 21 and 20 of this report; source 29's manifest (`data/29-birthdays-source_manifest.json`) records their SHA-256, which equal the delivered texts. Source 29 did not see sources 22–28 or 30.

the zero conventions up to isomorphism. Translation disposes of thresholds at other actual surreal numbers; nonprincipal class cuts remain genuine parameters.

4. **New behavior at proper-class carriers.** Numerically well-ordered proper subclasses can have unattained surreal suprema. Exactly these create adjacent pairs under shorter-first comparison. This destroys a symmetry present for all set-length words and obstructs extending the set-prefix tree isomorphism to full class carriers.
5. **Topology and Borel structure after finite tails.** Over a countable dense alphabet, the types  $\omega$ ,  $\omega + 1$ ,  $\omega + 2$ , and  $\omega + n$  for  $n \geq 3$  exhibit different relations between native lexicographic topology and coordinate topology. The resulting distinction is measurable as well as topological.
6. **Prefix-tree and foundational limitations.** Uniform tree automorphisms can exchange exhaustive and nonexhaustive class branches. Separately, canonical terminating condensation histories are equivalent over GBC to strong class-well-order comparability. Neither statement conflates the existence of a class object with the existence of a class containing all such objects.

### 61.19.3 The Kanovei–Shelah connection

The historical motivation needs a precise formulation. In the preprint of Kanovei and Shelah, the relevant index set consists of maps

$$a : \mathfrak{c} \longrightarrow \mathcal{P}(\mathbb{N}) \quad \text{whose ranges are ultrafilters on } \mathbb{N}.$$

The maps are compared at their first unequal coordinate, using the characteristic-function order on  $\mathcal{P}(\mathbb{N})$ . Repeated values are allowed. These are redundant ultrafilter presentations, not literally all well-orders of the real line. The index order is linear but is not itself required to be well-founded. Its role is in the definable nonstandard-real construction [16, §1 of the preprint]. What transfers here is the method of comparing sufficiently rich presentations lexicographically. No identification of the present surreal orders with that index order is assumed.

### 61.20 Source 29: the fixed-set baseline and what it does not identify

[merge] Source 29’s Section 3, printed whole. Its fixed set has cardinality  $\kappa$ ; following [section 1.3.1](#) it is printed  $\mu$  in the first two subsections (the birthday-fragment formulas keep  $\kappa$  as a cutoff). Its Theorem 3.1 is [theorem 6.1](#) and is recorded as a note.

#### 61.20.1 Exhaustive enumerations

For a linearly ordered set  $(X, <)$ , let

$$\mathcal{W}_\alpha(X) = \{f : \alpha \longrightarrow X : f \text{ is a bijection}\}, \quad \mathcal{W}(X) = \bigcup_{\alpha \in \text{Ord}} \mathcal{W}_\alpha(X).$$

If  $|X| = \mu$  is infinite, only  $\mu \leq \alpha < \mu^+$  can occur, so this union is a set. No exhaustive enumeration can be a proper prefix of another. Thus for distinct  $f, g$  there is a least coordinate at which both are defined and differ, and

$$f <_{\text{lex}} g \iff f(\delta) < g(\delta) \quad \text{at that coordinate } \delta.$$

The termination convention is immaterial here. It becomes relevant as soon as incomplete words or different carriers are admitted.

*Note 61.4* (Source 29, Theorem 3.1, “Inherited fixed-set spectrum”). *For every infinite linearly ordered set  $X$  of cardinality  $\mu$ ,*

$$|\mathcal{W}(X)| = 2^\mu, \quad \beta \hookrightarrow \mathcal{W}(X) \iff \beta < \mu^+$$

*for set ordinals  $\beta$ . Every linear order of size at most  $\mu$  embeds in the minimal stratum  $\mathcal{W}_\mu(X)$ . The reverse of every ordinal below  $\mu^+$  embeds as well, while neither direction admits a monotone sequence of length  $\mu^+$ .* This is [theorem 6.1](#) (the reals report’s `two:thm:ordinal-spectrum` for every infinite alphabet), as source 29 says: “This is established in the repository [39, 1]; we include the main mechanism because it underlies the later distinctions.” Its summary of the mechanism follows; it is source 09’s stabilization route ([theorem 6.1](#) and the note after it), not a new proof.

Partition  $X$  into pairs  $\{a_\xi, b_\xi\}$ , with  $a_\xi < b_\xi$ , indexed by  $\xi < \mu$ . A binary word chooses whether each pair is listed as  $(a_\xi, b_\xi)$  or  $(b_\xi, a_\xi)$ . Their concatenation has length  $2 \cdot \mu = \mu$  and preserves first-difference comparison. Hence  $\mathbb{B}_\mu \hookrightarrow \mathcal{W}_\mu(X)$ .

If  $L$  is any linear order of size at most  $\mu$ , enumerate its points among  $\mu$  coordinates and map  $x \in L$  to the bits recording whether the corresponding point is strictly below  $x$ . Unused coordinates are fixed at zero. For  $x < y$  all changing bits move from zero to one, and the coordinate naming  $x$  changes. This embeds  $L$  into  $\mathbb{B}_\mu$ . It also gives the lower cardinality bound  $2^\mu$  for the minimal stratum. The upper bound follows because well-orders are relations on  $X$  and there are only  $2^\mu$  such relations.

For the upper ordinal bound, suppose a strictly increasing sequence  $(f_i)_{i < \mu^+}$  existed. The first coordinates form a nondecreasing sequence in a set of size  $\mu$  and therefore are eventually constant. Continue by transfinite induction: after a common prefix of length  $\gamma < \mu^+$  has been fixed on a tail, the next coordinates are eventually constant on that tail. At a limit, regularity of  $\mu^+$  allows the at most  $\mu$  preceding tail bounds to be combined. The chosen labels are distinct. If a common prefix exhausts  $X$ , all subsequent  $f_i$  are identical, a contradiction. If none does, the construction chooses  $\mu^+$  distinct elements of  $X$ , also a contradiction. Reverse all comparisons for descending sequences. The lower ordinal assertion follows by embedding any order of cardinality at most  $\mu$ .

### 61.20.2 Why cardinality and abstract types are insufficient

The same theorem applies to many numerically different alphabets. For birthday fragments,

$$|\mathbf{No}_{<\kappa}| = 2^{<\kappa} \quad (\kappa \text{ infinite initial}), \quad |\mathbf{No}_{<\theta}| = 2^\kappa \quad (\kappa < \theta < \kappa^+).$$

The second formula follows because the full sign level of length  $\kappa$  is present and there are at most  $\kappa$  levels, each of size at most  $2^\kappa$ . It does not imply that the numerical alphabets are equimorphic. The next section proves exactly the contrary ([\[merge\] section 76](#), Part XI).

Nor does enumeration lexicography descend to abstract well-order types. Two presentations of the same type can fall on opposite sides of a third presentation after a change in the early labels. Ordering the possible types themselves by ordinal comparison gives the interval of types  $\mu \leq \alpha < \mu^+$ , whose order type is  $\mu^+$ . By [Note 61.4](#), that type cannot embed in the labelled order. For set-like global well-orders, quotienting by abstract class-order isomorphism collapses all objects to the single type  $\text{Ord}$ .

[\[merge\]](#) Source 29’s Subsection 3.3, “Relation scans and inverse ranks”, is printed in Part XII with the scans ([section 80.3.5](#)).

### 61.21 Source 30: scope, results, and the audited starting point

[merge] Source 30's Section 1, printed whole; its interpretations (Section 2) are printed in Part XII (section 80.4). Its  $\mathfrak{W}_{\text{sl}}$ ,  $\mathfrak{W}_{\text{all}}$  (macros `\SL`, `\ALL`) are  $\mathfrak{W}_{\text{sl}}$ ,  $\mathfrak{W}_{\text{all}}$ ; its  $X_\kappa$  is printed  $\mathbf{No}_{<\kappa}$  and its countable strata  $P_n = \mathcal{W}_{\omega+n}(\mathbb{Q})$  are printed  $P_{\omega+n}$ , as in source 29 (section 1.3.2).

Two choices precede every substantive question in this subject: *what objects are being ordered*, and *which representation is scanned*. A well-order of a fixed set can be represented by its ordinal enumeration, its relation table, or the ranks of labels in a previously fixed list. These representations give different comparisons. On the full surreal class, an individual well-order is itself a class relation, so the collection of all such relations is not an ordinary class of sets.

This article continues the merged ProveIt report *Lexicographic Orders of Well-Orderings of the Surreal Numbers* [39], inspected at the fixed revision

7ff7736ecf3a0adc8536b2d083cf819e1ba39ace.

Its location is

Algebra/SurrealNumbers/docs/foundations-and-computation/  
surreal-well-orders/article.tex.

We also inspected its guide and the four foundational Lean files listed in section 111.47. Some questions retained from the first wave are answered elsewhere in the merged text or in subsequent reports. Appearance in an old research list is therefore not, by itself, evidence that a problem remains open.

#### 61.21.1 The inherited baseline

The previous work develops fixed-set cardinalities and ordinal spectra; the singular strong-limit birthday transition; set-length words and termination conventions; the equivalence of global choice with the existence of any class well-order of  $\mathbf{No}$ ; direct comparison through proper-class common prefixes; and a bounded-support core, isomorphic to  $\mathbf{No}$  under global choice, together with cut recognition and automorphism-extension obstructions. Finite residual permutation blocks, non-monotone restrictions, class-model absoluteness, and countable external classifications have also already been studied. We do not present these as new findings.

#### 61.21.2 Four continuations

Throughout,  $\simeq_e$  means *equimorphism*: order embeddings exist in both directions. It does not mean isomorphism.

**Infinite remainders.** For an infinite cardinal  $\kappa$ , put

$$\mu = 2^{<\kappa}, \quad \rho_\kappa = \begin{cases} \kappa \cdot \kappa, & \kappa \text{ singular strong limit,} \\ \mu, & \text{otherwise.} \end{cases}$$

For every infinite regular  $\nu < \mu$ , every  $0 < \gamma < \mu^+$  and  $0 < \delta < \nu^+$ , and every finite  $n$ , we prove

$$\mathcal{W}_{\mu \cdot \gamma + \nu \cdot \delta + n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\rho_\kappa \cdot \gamma + \nu \cdot \delta} \times n!. \quad (\text{S30.1.1})$$

Here  $n!$  is a finite chain; products of orders are lexicographic; subscripts use ordinal arithmetic. In particular  $\nu = \omega$  handles every countably infinite remainder. The argument iterates through

finite descending sequences of residual cardinals. A singular strong-limit block of size  $\nu$  instead contributes  $\nu \cdot \nu$  per block. Mixing these two regimes gives a complete fixed-type equimorphism classification under GCH (note 64.18). The remaining unconditional boundary is a singular residual cardinal at most  $\kappa$  that is not strong limit. Residual cardinals above  $\kappa$  also have uninflated codes, even when singular. In particular, every fixed type is classified in ZFC whenever  $\kappa < \aleph_\omega$ , including  $\kappa = \omega_1$  without CH (corollary 64.20).

[merge] Source 19 proves the same classification independently and more generally (cube spectrum also at singular non-strong-limit layers): theorems 64.7 and 64.11. Source 30's explicit ZFC corollary for  $\kappa < \aleph_\omega$  is the one statement source 19 does not spell out (source 19 writes  $\mu \leq \aleph_\omega$ ). Neither source saw the other.

**Topological and measurable transitions.** For  $P_{\omega+n} = \mathcal{W}_{\omega+n}(\mathbb{Q})$ , the order topology is Polish and homeomorphic to Baire space at  $n = 0$ . At  $n = 1$  it is still second countable and metrizable but is meagre in itself. At  $n = 2$  it is separable and first countable, but nonmetrizable, and its Borel structure is not standard. At  $n \geq 3$  it has continuum many isolated points forming a dense open set and becomes a Baire space again. The maps between relation tables and enumerations have different, sharp measurability thresholds. Since  $\mathbf{No}_{<\omega}$  is a countable dense order without endpoints, the same results hold at the first infinite surreal stage  $\mathbf{No}_{<\omega}$ .

**Partial relation data and global type.** A set-sized partial table extends to a well-order of *any supplied proper-class well-order type* precisely when its forced orientations are well-founded, together with diagonal consistency. Each admitted global type is dense for set-supported relation observations. Finite observations approximate all linear orders; countable observations already detect ill-foundedness, but cannot detect set-likeness or the global class order type.

**Recovery of the class universe.** For GBC realizations of the same set model, inclusion of the admitted labelled global enumeration families is equivalent to inclusion of their whole class collections. Adjacent pair swaps along one common baseline already encode every class. The pure external order loses this information; the evaluation relation is essential.

### 61.21.3 The precise Kanovei–Shelah connection

Kanovei and Shelah lexicographically order maps  $a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters [16, Section 2] ([merge] Section 2 of the published paper; Section 1, page 2, of the preprint). Such maps can repeat values. Their index order is not literally the set of all bijective well-orderings of  $\mathbb{R}$ , or all class well-orders of  $\mathbf{No}$ . The common idea is a well-ordered coordinate domain and a linearly ordered alphabet. Keeping the actual indexing object straight prevents a misleading identification at the start of the surreal generalization.

*Note 61.5* ([merge]; what the twelve maps repeat). All twelve separate the carriers of the batch-80 and batch-81 sources (sections 2 and 4.3 and note 34.2): a fixed set with all types or one type, varying set carriers (injective words, with a termination convention), words with repetitions, numerically well-ordered subsets and subclasses, set-like and arbitrary class well-orders, relation codes, abstract types, and, in sources 20, 21, 26, 27, 29 and 30, the universe- or model-relative versions.

- *Fixed carriers.* That two exhaustive enumerations of one set are never proper prefixes of one another, so that no termination convention is needed there, is argued again by sources 20, 21, 22, 24, 25, 26, 27, 28 and 30, and stated as source 23's note 80.1; it is the prefix-freeness of section 6 and source 13's lemma 34.1.

- *Termination.* Sources 20–28 and 30 name the three placements of a terminator (first, last, inside the alphabet) and length-first order as a further choice; sources 21, 24, 25, 26, 28 and 30 repeat source 14’s warning that the Conway sign order  $- < \mathbf{end} < +$  is not prefix-first dictionary order (section 5). Source 19 and source 27 describe the centered terminator  $\dagger$  of source 18 (section 36.5).
- *Increasing subclasses.* Sources 19, 20, 21, 24, 27, 28 and 30 show that a numerically well-ordered subclass need not be set-like by a copy of Ord below a point, as source 12 did with  $\{-1/(\alpha + 1) : \alpha \in \text{Ord}\} \cup \{0\}$  (section 18); sources 21 and 30 use that example, sources 24 and 28 use  $\{\alpha/(\alpha + 1)\} \cup \{1\}$ , source 19  $\{1 - 1/(\alpha + 2)\} \cup \{1\}$ , source 20 the sign sequences  $s_\alpha$  below 0, and source 27 any increasing copy of Ord inside  $(0, 1)$  followed by 1; sources 23 and 29 state it.
- *Relation codes and inverse ranks.* The finite examples of sources 21, 26 and 30 make the point of source 12’s shipped example and of proposition 17.1; source 15 proves theorems about these orders (theorem 38.2 and corollary 38.3), and sources 27 and 30 prove further ones (Part XII). Source 30’s three scans of six objects are checked by its finite program (section 111).
- *Abstract types.* That enumeration lexicography does not descend to abstract order types (all twelve; source 19’s  $R < S < T$  and source 21’s example 61.1 are explicit non-convexity examples) is printed with source 15’s example in section 38.
- *Kanovei–Shelah.* All twelve make source 08’s point (section 4.4): the index there is a lexicographically ordered family of redundant ultrafilter codes, not a space of well-orders. Ten do so in their opening sections (printed here, or in Part XII for source 27); sources 23 and 28 do so in their audit and foundations sections (section 111 and Part X). Sources 19 and 30 cite Section 2 of the published paper; sources 20, 21, 25, 27 and 29 cite Section 1 of the preprint, and source 23 its second page, as this report’s bibliography does; sources 22, 24, 26 and 28 give no section.
- *Class levels.* All twelve fix GB without choice and  $\text{GBC} = \text{GB} + \text{GC}$  as in section 1.3, read “the class of all class well-orders” as a predicate on class variables, and require uniform families to be coded by one class relation; their foundations sections are printed in section 111.

## 62 Thick alphabets, prefix cylinders and the prefix topology (source 24; sources 26, 28, 21, 22 and 19)

[merge] Source 24’s Sections 3 and 4 are printed, with its re-proofs of results of this report as notes. Sources 26, 28, 21 and 22 open their set-sized parts with the same toolkit; their versions follow in notes, except source 26’s statement that every cylinder is homeomorphic to the whole space and source 21’s remark on descending chains, which are printed. Source 24’s  $\mathcal{P}_\mu(X)$  and  $\mathcal{T}_\mu(X)$  are printed  $\mathcal{W}_\mu(X)$  and  $\mathcal{I}_{<\mu}(X)$  (part X). The word *thick* is source 24’s; source 22 says  $\mu$ -rich, source 21 *uniformly large intervals*, for the same hypothesis.

A surreal can be represented by a set-length sign sequence; see also Ehrlich [15] for the broader arithmetic and foundational setting. Write  $\text{bd}(x)$  for its length, and for an infinite initial cardinal  $\kappa$  put

$$\mathbf{No}_{<\kappa} = \{x : \text{bd}(x) < \kappa\}, \quad \mu = 2^{<\kappa} = \sup_{\alpha < \kappa} 2^{|\alpha|}.$$

All cardinal arithmetic in this section is external ZFC arithmetic. There is no assumption that  $\kappa$  is regular, that  $\mu = \kappa$ , or that a birthday cutoff is a subfield.

**Definition 62.1** (Thickness). A linear order  $X$  of infinite cardinality  $\mu$  is  $\mu$ -thick if it is dense without endpoints and every nonempty open interval and every ray has cardinality  $\mu$ .

*Note 62.2* (Source 24, Lemma 3.2, “Cutoff size and thickness”). For every infinite initial cardinal  $\kappa$ , the alphabet  $\mathbf{No}_{<\kappa}$  has cardinality  $2^{<\kappa}$  and is  $2^{<\kappa}$ -thick. Removing fewer than  $\mu$  points from a  $\mu$ -thick alphabet leaves a  $\mu$ -thick alphabet of the same cardinality. This is lemma 29.2 (source 17), by the same sign-cone argument. Source 24 makes the cone explicit in three cases: if neither of  $a < b$  is a prefix of the other, or if  $b$  is a proper prefix of  $a$ , every extension of  $r = a \frown (+)$  lies in  $(a, b)$ ; if  $a$  is a proper prefix of  $b$ , the next sign of  $b$  is plus and  $r = a \frown (+) \frown (-)^{\text{bd}(b)+1}$  works, since “either a later plus of  $b$  gives the first strict comparison, or the negative tail extends past the end of  $b$ ”. It stresses that “finite ordinal sums of ordinals below an infinite initial cardinal remain below it; regularity is not needed here”, and obtains the deletion clause by applying the cardinality count inside each old interval and ray. Source 15’s three-case construction (note 29.8) uses  $b \frown -$  in the second case.

*Remark 62.3* (What the arithmetic parameters do and do not control). The previous cutoff study (source 17; lemma 29.3 and theorem 30.2) distinguishes  $\text{cf}(2^{<\kappa})$ , which controls several alphabet-side characters, from  $\text{cf}(2^{<\kappa})$ , which controls prefix-neighborhood characters in the minimal enumeration slice. The topology below uses  $\mu = |X|$  as its domain length. Replacing it by the birthday bound  $\kappa$  without checking equality would change the problem.

The proof also explains why the relevant formalization should begin with sign sequences and a linear-order interface, not with the whole surreal field. Addition, multiplication, normal forms, and real closedness are unnecessary for the main results.

## 62.1 The minimal slice: prefixes and elementary spectra (source 24)

[merge] Source 24’s Section 4. Its prefix lemmas hold for every infinite alphabet and, under thickness, for the order topology; for  $X = \mathbf{No}_{<\kappa}$  and the minimal slice they are lemma 30.1 (source 17). New are the injection space  $\mathcal{I}_\mu(X)$  beside  $\mathcal{W}_\mu(X)$ , the metrizable criterion and the relabelling corollary.

For an infinite  $\mu$  and a set  $X$  of size  $\mu$ , let

$$\mathcal{I}_{<\mu}(X) = \bigcup_{\alpha < \mu} \text{Inj}(\alpha, X).$$

For  $p \in \mathcal{I}_{<\mu}(X)$ , define its cylinders in the two spaces by

$$[p]_P = \{f \in \mathcal{W}_\mu(X) : p \subseteq f\}, \quad [p]_I = \{h \in \mathcal{I}_\mu(X) : p \subseteq h\}.$$

The subscript will be omitted when the ambient space is clear.

**Lemma 62.4** (Small-prefix extension). Every  $p : \alpha \rightarrow X$  in  $\mathcal{I}_{<\mu}(X)$  extends to a member of  $\mathcal{W}_\mu(X)$ . Moreover, if  $z \notin \text{ran } p$ , it extends to a bijection  $\mu \rightarrow X \setminus \{z\}$ , viewed as a nonexhaustive member of  $\mathcal{I}_\mu(X)$ .

*Proof.* The unused labels have cardinality  $\mu$ , even after the one additional deletion. The ordinal tail  $[\alpha, \mu)$  has order type  $\mu$ : its cardinality is  $\mu$ , its type is at most  $\mu$ , and  $\mu$  is initial. Choose a bijection between the tail and the required unused labels and append it to  $p$ .  $\square$

**Lemma 62.5** (Cylinders and order topology). Suppose  $X$  is  $\mu$ -thick. In both  $\mathcal{W}_\mu(X)$  and  $\mathcal{I}_\mu(X)$ , cylinders are nonempty convex clopen sets without endpoints and form a base for the lexicographic order topology. Both orders are dense without endpoints.

*Proof.* If a word lies lexicographically between two words sharing  $p$ , it shares  $p$ ; otherwise its first disagreement with  $p$  puts it on the same exterior side of both words. Thus cylinders are convex. The complement of a length- $\alpha$  cylinder is the union of the other length- $\alpha$  cylinders.

Let  $f$  extend  $p$ , where  $\text{dom } p = \alpha$ . Fewer than  $\mu$  labels have been used. Choose unused labels  $u < f(\alpha) < v$ , and complete  $p \frown (u)$  and  $p \frown (v)$  using Lemma 62.4. These give points of  $[p]$  on both sides of  $f$ . Hence  $[p]$  is open and has no endpoints; its complement is open as well.

If  $g < f < h$ , take a prefix of  $f$  extending beyond its first disagreements with  $g$  and  $h$ . Its cylinder is contained in  $(g, h)$ . Rays are handled using one disagreement. This proves the base assertion. Finally, at the first differing coordinate of any two words, an unused label strictly between their two labels gives an intermediate exhaustive completion. The same construction gives points above or below any given word.  $\square$

*Note 62.6* (Source 24, Proposition 4.3, “Cardinality and exact ordinal spectrum”). *For any infinite linearly ordered alphabet  $X$  of size  $\mu$ ,  $|\mathcal{W}_\mu(X)| = 2^\mu$ . Every linear order of cardinality at most  $\mu$  embeds into  $\mathcal{W}_\mu(X)$ . An ordinal  $\beta$  embeds into this lexicographic order exactly when  $\beta < \mu^+$ ; the same bound holds for reverse ordinal orders.* This is the set baseline (theorem 6.1; reals report `lwo:prop:cardinality`, `lwo:thm:ordinal-spectrum`) on the minimal slice, by the pair-orientation, initial-segment and coordinate-stabilization argument of section 6; it is note 30.4 without its interval clause. Source 24 adds: “For comparison, the predecessor report proves that the full fixed-carrier order  $\mathcal{W}(X)$  also has cardinality  $2^\mu$  and exact ordinal spectrum  $\{\beta : \beta < \mu^+\}$ . The positive embeddings already occur in the minimal slice. The upper-bound argument for the full varying-length space is a separate result, not an automatic consequence of the fixed-coordinate proof above. Equal cardinality and ordinal spectrum do not identify their topologies or their adjacency structure.”

[merge] The character assertion of the next proposition is theorem 30.2 (point character  $q = \text{cf } \mu$ ) for an arbitrary alphabet; the metrizable criterion is source 24’s.

**Proposition 62.7** (Local character and metrizable). *In the prefix topology on  $\mathcal{W}_\mu(X)$ , each point has neighborhood character  $\text{cf } \mu$ . The space is metrizable exactly when  $\text{cf } \mu = \omega$ . The same holds for  $\mathcal{I}_\mu(X)$ .*

*Proof.* Restrictions to any cofinal sequence of prefix lengths give a base of size  $\text{cf } \mu$ . Conversely, for every member  $U$  of a local base at  $f$ , choose a cylinder  $[f \upharpoonright \alpha_U] \subseteq U$ . If there were fewer than  $\text{cf } \mu$  members, the lengths would be bounded by some  $\gamma < \mu$ . Every such  $U$  would contain  $[f \upharpoonright \gamma]$ . No one of them could be contained in the strictly smaller neighborhood  $[f \upharpoonright (\gamma + 1)]$ , a contradiction. The strictness follows by changing coordinate  $\gamma$  and completing the resulting prefix.

When  $\text{cf } \mu = \omega$ , fix increasing cofinal lengths  $\alpha_n < \mu$ . Give two distinct words distance  $2^{-n}$ , where  $n$  is the least index at which their restrictions to  $\alpha_n$  differ. This is a compatible ultrametric. If  $\text{cf } \mu > \omega$ , the space is not first countable and hence not metrizable.  $\square$

**Corollary 62.8** (The topology forgets the numerical labels). *A bijection  $a : X \rightarrow Y$  induces a homeomorphism  $f \mapsto a \circ f$  of the corresponding prefix spaces. If both alphabets are  $\mu$ -thick, this is a homeomorphism of their lexicographic order topologies. It is an order isomorphism precisely when  $a$  is increasing.*

*Proof.* Relabelling carries cylinders to cylinders. An increasing relabelling preserves first disagreement. Conversely, use exhaustive enumerations with prescribed distinct first labels to see that an order-preserving relabelling must preserve the alphabet order.  $\square$

This is the first indication that a topological classification and an order classification answer different questions. Numerical comparison is indispensable for the order, but under thickness it is invisible to the topology of the minimal slice.

## 62.2 The same toolkit in sources 26, 28, 21, 22 and 19

[merge] The other sources' versions of the toolkit, in notes; source 26's Proposition 3.2 and source 21's remark on descending chains are printed.

*Note 62.9* (Source 26, Section 3: Lemma 3.1, Definition 3.3 and Theorem 3.4). Source 26 writes  $N_p$  for the cylinder  $[p]$  and works with  $|X| = \mu$  (its  $\kappa$ ). Its Lemma 3.1 (“Extension of a short prefix”): *every admissible short prefix extends to a bijection  $\mu \rightarrow X$ ; every cylinder  $N_p$  is nonempty and contains two extensions whose values at the next coordinate are any prescribed distinct unused labels*. Its Definition 3.3 is thickness, and its Theorem 3.4 (“When the two topologies agree”): *if  $X$  is  $\mu$ -thick, the bounded-prefix topology on both  $\mathcal{W}_\mu(X)$  and  $\mathcal{I}_\mu(X)$  is their lexicographic order topology; these orders have no endpoints and are dense*. These are [lemmas 62.4](#) and [62.5](#), by the same arguments; source 26 also verifies that least-disagreement comparison is a linear order (“the earlier coordinate decides the comparison of  $f, h$ , or the two coordinates coincide and transitivity in  $X$  applies. Every cylinder is convex”). It adds the reason why the tail has the right type: “The ordinal tail  $[\alpha, \mu)$  has order type  $\mu$ : otherwise its order type and  $\alpha$  would both have cardinality below  $\mu$ , contradicting  $\alpha + \text{otp}[\alpha, \mu) = \mu$ ”, and the warning: “A prefix of length  $\alpha$  leaves, after increasing reindexing, another full  $\mu$ -word problem over a remaining alphabet of size  $\mu$ . This is not a license to replace an arbitrary nonminimal ordinal length by its cardinality.”

[merge] Source 26's Proposition 3.2 adds that every cylinder is homeomorphic to the whole space; its complete-metrizability classification uses this ([theorem 69.18](#)).

**Proposition 62.10** (Basic topology). *The cylinders form a clopen base for a Hausdorff zero-dimensional topology on  $\mathcal{W}_\mu(X)$  and on  $\mathcal{I}_\mu(X)$ . The former is dense in the latter. Every permutation cylinder is homeomorphic to  $\mathcal{W}_\mu(X)$ , after an arbitrary bijective relabelling of its remaining alphabet.*

*Proof.* Two prefixes are either incompatible or one extends the other, so cylinder intersections have the required base property. The complement of  $N_p$  is a union of cylinders witnessing a disagreement before  $\text{dom } p$ . Distinct functions have a coordinate of disagreement and disjoint longer cylinders. Density is [note 62.9](#). For the final statement, remove the prescribed prefix, increasingly reindex the ordinal tail, and bijectively relabel  $X \setminus \text{ran } p$  by  $X$ . Both this map and its inverse carry bounded-prefix neighborhoods to bounded-prefix neighborhoods.  $\square$

*Note 62.11* (Source 26, Section 3.1, “Embedding information inherited from the repository”). Source 26 records the set baseline of this report ([theorem 6.1](#)) for the full order  $\mathcal{W}(X)$ , calling these “earlier written-proof results . . . not new claims of this continuation. The upper bound on increasing ordinal chains is a genuine order-theoretic assertion, not a consequence of the cardinality  $2^\mu$  alone. We do not use that upper bound in the proofs of our main theorems.” It then gives the pair-orientation embedding  $(2^\mu, <_{\text{lex}}) \hookrightarrow (\mathcal{W}_\mu(X), <_{\text{lex}})$  directly (pairs  $\{a_\xi < b_\xi\}$  listed  $a_\xi, b_\xi$  for bit 0 and  $b_\xi, a_\xi$  for bit 1; “the pair order of type  $2 \cdot \mu$  is order-isomorphic to  $\mu$  for infinite initial  $\mu$ ”), and notes that “the finite executable checks in this package verify the first-disagreement mechanism, not the transfinite cardinal assertions”.

*Note 62.12* (Source 28, Section 3: Definition 3.1, Lemmas 3.2 and 3.3, Propositions 3.4 and 3.5). Source 28 uses source 24's thickness (its Definition 3.1) and proves again: Lemma 3.2 (“Size and thickness of birthday cutoffs”) = [note 62.2](#), with the same three-case sign prefix; Lemma 3.3 (“Short-prefix extension”), *a short injective prefix extends to a bijection  $\mu \rightarrow X$ , and also to an injection omitting any specified label outside its range* = [lemma 62.4](#); Proposition 3.4 (“The prefix topology is the numerical order topology”) = [lemma 62.5](#); Proposition 3.5 (“Basic size and embedding spectra, recalled with proof”) = [note 62.6](#); each by the same argument. It uses “the sign-sequence order of

surreals, not their full arithmetic”, citing Ehrlich [15] and the repository’s universe-indexed sign sequences [10]. It adds a warning about the full order: its topology “must not be inferred from” the minimal slice’s. “For example, take a common prefix enumerating  $X \setminus \{a, b\}$ , where  $a < b$ . The two exhaustive continuations ending in  $(a, b)$  and  $(b, a)$  are adjacent: any word between them must share the prefix, and only those two residual enumerations are possible. No such finite residual tail occurs in the minimal infinite slice” (this report’s [theorem 16.2](#)).

*Note 62.13* (Source 21, Section 3: Proposition 3.1, Definition 3.3 and Proposition 3.4). Source 21’s Proposition 3.1 (“Cardinality and a uniform lower embedding”): *for every  $\alpha$  of cardinality  $\mu$ ,  $|\mathcal{W}_\alpha(X)| = |\mathcal{W}(X)| = 2^\mu$ ; the binary cube  $\mathbb{B}_\mu$  order-embeds into  $\mathcal{W}_\mu(X)$ ; consequently every linear order of cardinality at most  $\mu$  embeds into  $\mathcal{W}_\mu(X)$* . Its Definition 3.3:  $X$  has *uniformly large intervals* if it has no endpoints and  $|(a, b)_X| = |X| = \mu$  for  $a < b$ . Its Proposition 3.4: *if  $X$  has uniformly large intervals, the order topology of  $\mathcal{W}_\mu(X)$  equals its topology of agreement on bounded prefixes; at every point its left and right characters are both  $\text{cf}(\mu)$* . These are [note 62.6](#), [lemma 62.5](#) and [theorem 30.2](#), by the same arguments. Source 21 writes  $\mathcal{I}_\mu(X)$  for the injective  $\mu$ -words from the start: “An injective word need not be exhaustive. This small-looking difference will control both the fiber decomposition and the automorphism obstruction.” It adds: that the topology of agreement on bounded initial segments is, “at  $\mu = \omega \dots$  the usual product topology when  $X$  has the discrete topology; at an uncountable  $\mu$  it is generally finer than the ordinary product topology, which only fixes finitely many coordinates”; that “cardinality  $2^\mu$  does not imply an increasing copy of every ordinal of that cardinality” (the ordinal bound of [theorem 6.1](#) is “a structural restriction of the lexicographic presentation order. The corresponding theorem for arbitrary linear orders of cardinality  $2^\mu$  would be false”); that for birthday fragments “the cardinal parameter is  $\mu = 2^{<\kappa}$ , not necessarily  $\kappa$ ”, with the sharper equimorphism [theorem 8.3](#) (“we will not replace it by cardinal multiplication or use a regular-cardinal argument at a singular cutoff”); a direct check that every  $\mathbf{No}_{<\kappa}$  has uniformly large intervals (a sign cone between the endpoints, of size  $2^{<\kappa}$  because  $\gamma + \lambda < \kappa$ ), with the warning “Noncardinal cutoffs require a separate argument; they need not have uniformly large numerical intervals”; and “This explains why point characters depend on  $\text{cf}(\mu)$  even when the global cofinality is controlled by the much smaller birthday parameter.”

[merge] Source 21 also records, after its Proposition 3.1:

*Remark 62.14* (A well-order of presentations need not result). Even  $\mathbb{B}_\omega$  has an infinite descending sequence: let the  $n$ th word have a single 1 at coordinate  $n$ . The pair code above therefore exhibits descending chains in minimum-length permutation spaces. The objects being compared are well-orders; the lexicographic order on those objects is usually not a well-order.

*Note 62.15* (Source 22, Section 3: Definition 3.1, Lemmas 3.2 and 3.3, Theorem 3.4). Source 22 works in ZFC with  $\mathcal{W}_\alpha(X)$  for every ordinal  $\alpha$  with  $|\alpha| = |X|$ , and writes  $\mathcal{W}_0(\emptyset)$  for the one-element order containing the empty enumeration. It calls a thick alphabet  $\mu$ -rich: “dense without endpoints and every nonempty open interval has cardinality  $\mu$ . Its open rays then also have cardinality  $\mu \dots$  We do not assume that all cuts of size less than  $\mu$  are filled.” Its Lemma 3.2 (“Richness of cardinal birthday cutoffs”):  $\mathbf{No}_{<\kappa}$  is  $\mu$ -rich, and  $\text{cf } X = \text{ci } X = \text{cf } \kappa$ , which is [note 62.2](#) with [lemma 29.3](#); its proof takes the interval cone above a separator of birthday exactly  $\delta$ , “the sign-word cut lemma used in the repository; its complete-lattice proof and universe-relative formal statement occur in `exists_cut_separator_of_birthday_1t`” [8]. Its Lemma 3.3 (“Short prefixes remain flexible”): *if  $X$  is  $\mu$ -rich,  $|\alpha| = \mu$  and  $p : \beta \rightarrow X$  is injective with  $\beta < \mu$ , then  $p$  extends to an element of  $\mathcal{W}_\alpha(X)$ ; at any further coordinate below  $\mu$ , both a smaller and a larger unused label than a prescribed label are available; the cylinder of  $p$  is nonempty and open in the order topology*, which is [lemmas 62.4](#) and [62.5](#) for every length  $\alpha$  of cardinality  $\mu$ , with the warning: “The restriction  $\beta < \mu$  is essential. A prefix of length  $\mu$  can leave a finite, countable, or otherwise special residual alphabet. Its cylinder

is always convex but need not be open. This is the source of the transitions below.” Its Theorem 3.4 (“Size and embeddings”): *for every infinite linearly ordered  $X$  of cardinality  $\mu$  and every ordinal  $\alpha$  of cardinality  $\mu$ ,  $|\mathcal{W}_\alpha(X)| = 2^\mu$ ; every linear order of size at most  $\mu$  embeds in  $\mathcal{W}_\alpha(X)$ ; an ordinal  $\beta$  embeds in it if and only if  $\beta < \mu^+$ , which is [theorem 6.1](#) for each slice; writing  $\alpha = \mu + \nu$ , the lower embedding orients pairs of a set of size  $\mu$  and appends a fixed enumeration of length  $\nu$  of the remaining labels. “This recovers the fixed-stratum portion of the earlier general-alphabet theory. In particular, the topological changes below do not reflect a change in the ordinal embedding spectrum.”*

*Note 62.16* (Source 19, Section 3, “Elementary tools and the known spectrum”). Source 19 recalls “a small toolkit so that the later proofs are understandable without the earlier reports”, citing Gonshor [12], Ehrlich [15] and Hamkins’s class-universality formulation. Its Lemma 3.1 (“Surreal set cuts and avoidance”): *if  $A < B$  are sets of surreals, a surreal  $z$  with  $A < z < B$  exists and can be chosen outside any prescribed set  $F$ ; every nonempty open surreal interval is a proper class, which is [theorem 5.6](#) and [corollary 5.7](#). Its Lemma 3.2 (“A birthday-controlled insertion”): *every linear order of cardinality  $\lambda$ , an infinite initial cardinal, embeds into  $\mathbf{No}_{<\lambda}$ , without regularity of  $\lambda$* ; its proof enumerates the order as  $(x_i)_{i<\lambda}$  and maps  $x_i$  to the simplest surreal between the images of the earlier elements below and above it, so that “the image of  $x_j$  has birthday at most  $j$ ” and the stage- $i$  cut has a separator of birthday at most  $\sup_{j<i}(j+1) \leq i$ ; “it is an ordinary set recursion”. This is the forth construction of [proposition 5.13](#) with the birthday bound of [theorem 5.6](#). Its Lemma 3.3 (“Deletion and sign cones”) is [lemma 29.2](#), and its Proposition 3.4 (“Fixed-carrier baseline”) is [theorem 6.1](#); for the ordinal upper bound source 19 says “we take that upper bound as a cited input here” from this report’s general-alphabet spectrum theorem and the reals report, and “the new residual-coding and model theorems below have their own proofs and do not depend on an informal extension of that bound”.*

## 63 Fixed-length strata: residual cylinders, weight and point characters (source 22)

[merge] Source 22’s Sections 4–6, printed whole. They treat every stratum  $\mathcal{W}_\alpha(X)$ ,  $|\alpha| = \mu$ , of a thick (source 22:  $\mu$ -rich) alphabet. The density and cellularity column of its table is source 16’s [theorem 27.2](#) ([note 63.5](#)); new in source 22 are the residual-cylinder identity and the first-disagreement character formula, the weight column, the complete point-character classification of the finite tails  $\mu + n$  and of the tail  $\mu + \omega$ , and the one-step Cantor–Bendixson derivative. Source 22 writes  $\Delta = \mu^{<\mu}$  and  $\chi^\pm$  for the left and right characters. Source 30’s [corollary 63.12](#), which removes the richness hypothesis from the weight column, follows the table.

### 63.1 Residual cylinders and an exact character formula (source 22)

#### 63.1.1 The residual-fibre identity

For an injective prefix  $p : \beta \rightarrow X$  of a length- $\alpha$  enumeration, let

$$R_p = X \setminus \text{ran } p, \quad \gamma_p = \text{otp}([\beta, \alpha)).$$

The prefix is extendible exactly when  $|R_p| = |\gamma_p|$ .

**Theorem 63.1** (Residual-cylinder identity). *For every extendible prefix  $p$ , concatenation is an order isomorphism*

$$\mathcal{W}_{\gamma_p}(R_p) \cong \{e \in \mathcal{W}_\alpha(X) : e \restriction \beta = p\}.$$

The image is convex. In particular, if  $\alpha = \mu + \nu$  and  $R \subseteq X$  satisfies  $|R| = |\nu|$  and  $|X \setminus R| = \mu$ , every length- $\mu$  enumeration of  $X \setminus R$  determines a convex copy of  $\mathcal{W}_\nu(R)$ .

*Proof.* Restriction to the remaining coordinate interval and reindexing by its order type are inverse to concatenation. All initial coordinates are equal, so first disagreement occurs in the tail. An enumeration between two extensions of  $p$  cannot disagree with  $p$  earlier than  $\beta$ , since such a disagreement puts it on the same outside side of both extensions.  $\square$

The theorem is elementary, but its consequence is substantial: after  $\mu$  coordinates, the original birthday alphabet imposes no uniform residual-cardinality condition beyond the prescribed tail length. A proof valid only while fewer than  $\mu$  labels have been consumed cannot simply be reused.

### 63.1.2 Characters and disagreement fibres

For a point  $e$  in a linear order  $P$ , define

$$\chi^-(e; P) = \text{cf}(P_{<e}), \quad \chi^+(e; P) = \text{ci}(P_{>e}).$$

We assign character 0 to an empty side and character 1 to a side with a greatest, respectively least, element. Thus  $(1, 1)$  means an isolated non-endpoint.

For  $e \in \mathcal{W}_\alpha(X)$  put

$$X_\beta = X \setminus e[\beta], \quad A_e^- = \{\beta < \alpha : (X_\beta)_{<e(\beta)} \neq \emptyset\},$$

with  $A_e^+$  defined similarly. These are the coordinates at which a smaller or larger first disagreement is possible. Let  $H_\beta^-$  and  $H_\beta^+$  be the corresponding fibres.

**Theorem 63.2** (General first-disagreement formula). *For any infinite set alphabet and any enumeration length,*

$$P_{<e} \cong \sum_{\beta \in A_e^-} H_\beta^-,$$

where the index set has its increasing ordinal order. The upper side is the analogous sum in reverse coordinate order. Consequently:

- (i) If  $A_e^-$  is empty,  $\chi^-(e; P) = 0$ .
- (ii) If  $A_e^-$  has no greatest member,  $\chi^-(e; P) = \text{cf}(A_e^-)$ .
- (iii) If  $A_e^-$  has greatest member  $\beta_*$ , then  $\chi^-(e; P) = \text{cf}(H_{\beta_*}^-)$ .

The dual statements hold on the right. More explicitly, with  $\gamma = \text{otp}([\beta + 1, \alpha))$ ,

$$H_\beta^- \cong \sum_{a \in (X_\beta)_{<e(\beta)}} \mathcal{W}_\gamma(X_\beta \setminus \{a\}).$$

Thus, if the next-label index order has no greatest element, its cofinality is the cofinality of the fibre; if it has greatest element  $a_*$ , the last residual enumeration order supplies the cofinality.

*Proof.* Every  $f < e$  has one first-disagreement coordinate. If this coordinate is  $\beta < \delta$ , and  $g < e$  first disagrees at  $\delta$ , then  $f < g$ , because  $g(\beta) = e(\beta) > f(\beta)$ . For fixed  $\beta$ , varying the label  $a < e(\beta)$  gives the displayed lexicographic sum, and the remainder is exactly the residual cylinder. Every allowed label has a completion: deleting any one member of the same residual set leaves the required cardinality.

For a sum of nonempty orders indexed by a limit well-order, choosing one point on a cofinal collection of indices yields a cofinal set. Conversely, every cofinal set projects to cofinally many indices. If there is a last index, the last summand is cofinal. Applying these facts twice proves the formula. Reverse the order for the upper side.  $\square$

This is an exact reduction, not an assertion that arbitrary residual endpoint cofinalities already have a simple closed formula. Limit prefixes can fail to be extendible even when every shorter prefix is extendible. For example, the decreasing enumeration of  $\omega^*$  has length  $\omega$ ; its finite prefixes extend to length  $\omega \cdot 2$  enumerations of that alphabet, but their union exhausts the alphabet too early.

### 63.1.3 Endpoint replacement after the first cardinal block

**Theorem 63.3** (Character transfer). *Let  $X$  be  $\mu$ -rich,  $q = \text{cf } \mu$ , and  $\alpha = \mu + \nu$ . Write  $e = p \frown t$ , where  $p$  has length  $\mu$ ,  $R = X \setminus \text{ran } p$ , and  $t \in \mathcal{W}_\nu(R)$ . Then*

$$\chi^\pm(e; \mathcal{W}_\alpha(X)) = \begin{cases} \chi^\pm(t; \mathcal{W}_\nu(R)), & \text{if that intrinsic side is nonempty,} \\ q, & \text{if that intrinsic side is empty.} \end{cases}$$

*Proof.* A nonempty part of the cylinder below  $e$  is cofinal in the entire lower side of  $e$ : every point below  $e$  outside the cylinder lies below all its points. This proves the first case. If  $t$  is the cylinder minimum, all lower first disagreements occur before  $\mu$ . At every  $\beta < \mu$ , richness supplies an unused smaller label, so the active coordinate set is exactly  $\mu$ . Theorem 63.2 gives  $q$ . The right side is dual. The proof also covers  $\nu = 0$ , when the cylinder is a singleton.  $\square$

## 63.2 The finite-tail transition and all fixed-length cardinal invariants (source 22)

The order topology is always intended. Density  $\text{d } P$  is the least cardinality of a dense subset, weight  $\text{w } P$  the least cardinality of a base, and cellularity  $\text{cell } P$  the supremum of the sizes of families of pairwise disjoint nonempty open sets. A  $\pi$ -base need only contain a nonempty open subset of each nonempty open set; it need not provide neighborhoods of every individual point.

**Theorem 63.4** (Topological classification of every fixed-length stratum). *Let  $X$  be  $\mu$ -rich, let  $\Delta = \mu^{<\mu}$ , and let  $|\alpha| = \mu$ . Then*

| <i>enumeration length</i> | $\text{d } \mathcal{W}_\alpha(X)$ | $\text{cell } \mathcal{W}_\alpha(X)$ | $\text{w } \mathcal{W}_\alpha(X)$ |
|---------------------------|-----------------------------------|--------------------------------------|-----------------------------------|
| $\mu$ or $\mu + 1$        | $\Delta$                          | $\Delta$                             | $\Delta$                          |
| $\mu + 2$                 | $\Delta$                          | $\Delta$                             | $2^\mu$                           |
| $\alpha \geq \mu + 3$     | $2^\mu$                           | $2^\mu$                              | $2^\mu$                           |

*Thus this table applies to every ordinal length of cardinality  $\mu$ , not merely to finite extensions of  $\mu$ .*

*Proof.* *The common lower bound.* For each  $\beta < \mu$ , there are  $\mu^{|\beta|}$  injective prefixes of length  $\beta$ . To verify the lower estimate, partition  $X$  into  $|\beta|$  disjoint sets of size  $\mu$  and choose the  $\xi$ th entry from the  $\xi$ th set; the finite and empty cases are immediate. Distinct prefixes of that length have disjoint, nonempty open cylinders by note 62.15. Consequently

$$\text{cell } \mathcal{W}_\alpha(X) \geq \sup_{\beta < \mu} \mu^{|\beta|} = \Delta.$$

There are altogether  $\Delta$  short prefixes, since  $\Delta \geq \mu$ .

*The first three lengths.* Suppose  $\alpha = \mu + n$  with  $n \leq 2$ . If two distinct enumerations have the same length- $\mu$  prefix, they lie in a fibre of size  $n! \leq 2$ . Their open interval is therefore empty. Hence the endpoints  $e < f$  of any nonempty open interval must first disagree at some  $\beta < \mu$ . Choose an unused label

$$e(\beta) < a < f(\beta)$$

above the common prefix, and extend that prefix by  $a$ . Richness ensures that deleting the fewer than  $\mu$  earlier labels does not exhaust this interval. The resulting short cylinder is contained in  $(e, f)$ .

The orders have no endpoints, because their first labels can always be moved down or up. Thus every nonempty open set contains such an interval, and the short cylinders form a  $\pi$ -base. Choose one point from each cylinder. This gives a dense subset of size at most  $\Delta$ . Since disjoint nonempty open sets require different points of a dense set,

$$\Delta \leq \text{cell } P \leq \text{d } P \leq \Delta.$$

For  $n = 0, 1$ , any two distinct enumerations differ before  $\mu$ , so the same interpolation argument shows that  $P$  is dense as an order. In a dense order without endpoints, intervals with endpoints in a dense subset form a base. Therefore  $\text{w } P = \Delta$  in these two cases.

For  $n = 2$ , fix a two-element subset  $R \subset X$ . There are  $2^\mu$  bijections  $p : \mu \rightarrow X \setminus R$ . Each cylinder of such a  $p$  consists of two adjacent points, say  $a_p < b_p$ . These are pairwise disjoint jumps. For each jump, a base must contain an element  $B_p$  with

$$b_p \in B_p \subseteq (a_p, \infty).$$

Different jumps require different base elements: if the  $p$ -jump precedes the  $p'$ -jump, then  $b_p \leq a_{p'}$ , so  $B_{p'}$  cannot contain  $b_p$ . Thus  $\text{w } P \geq 2^\mu$ . Every order of size  $2^\mu$  has an interval base of size at most  $2^\mu$ , proving equality.

*Every remaining length.* Write  $\alpha = \mu + \nu$ , where  $\nu \geq 3$ . Choose  $R \subset X$  with  $|R| = |\nu|$  and  $|X \setminus R| = \mu$ . There are  $2^\mu$  length- $\mu$  enumerations of  $X \setminus R$ . Their cylinders are pairwise disjoint convex copies of  $\mathcal{W}_\nu(R)$  by [theorem 63.1](#). This residual order has at least three points. Choose  $u_p < v_p < w_p$  in each cylinder. Then  $(u_p, w_p)$  is a nonempty open interval, contained in that cylinder. We have obtained  $2^\mu$  pairwise disjoint nonempty open sets. The inequalities

$$2^\mu \leq \text{cell } P \leq \text{d } P \leq \text{w } P \leq |P|^2 = 2^\mu$$

finish the proof. □

*Note 63.5* ([merge]; credits for [theorem 63.4](#)). The density and cellularity columns of the table are [theorem 27.2](#) (source 16; source 18's route in [section 27.1](#)), proved there for every infinite alphabet without the richness hypothesis; source 22's proof of them is a second route, by the same short-prefix  $\pi$ -base and the same  $2^\mu$  disjoint residual intervals. The weight column is new in source 22: weight  $\Delta$  at lengths  $\mu$  and  $\mu + 1$  and  $2^\mu$  from  $\mu + 2$  on, so that weight changes at the second terminal coordinate and density and cellularity at the third. For  $X = \mathbb{R}$  the table is the reals report's `two:prop:finite-topology`; source 30's [corollary 63.12](#) below removes the richness hypothesis from the weight column. Source 22 states that “the fixed-length density/cellularity/weight table and the redundancy of cylinder heights are now treated as proved results rather than left open”; for density and cellularity this is source 16's theorem, placed in the repository before source 22 was written (commit f0cd7032d) and printed in Part VI. The cofinality clause of [corollary 63.7](#) is source 16's [proposition 28.2](#).

*Remark 63.6* (Why the distinction between a base and a  $\pi$ -base matters). At length  $\mu + 2$ , short cylinders still detect every nonempty open set, but they cannot refine a neighborhood of an upper jump point which excludes its lower partner. Treating the short-prefix  $\pi$ -base as a neighborhood base would give the false conclusion  $wP = \Delta$  whenever  $\Delta < 2^\mu$ . Conversely, a length- $\mu$  cylinder is convex, but its two-point endpoints prevent it from being open. Both distinctions are essential.

**Corollary 63.7** (Birthday-cutoff form). *For every infinite cardinal  $\kappa$ , put  $\mu = 2^{<\kappa}$  and  $\Delta = \mu^{<\mu}$ . The table in [theorem 63.4](#) holds for  $X = \mathbf{No}_{<\kappa}$  without assuming that  $\kappa$  or  $\mu$  is regular. Moreover, for every  $\alpha$  of cardinality  $\mu$ ,*

$$\text{cf } \mathcal{W}_\alpha(X) = \text{ci } \mathcal{W}_\alpha(X) = \text{cf } \kappa.$$

*Proof.* Apply [note 62.15](#). For the last assertion, the first-label projection expresses the order as a lexicographic sum of nonempty fibres indexed by  $X$ . Since  $X$  has neither endpoint, the cofinality and coinitality are those of the indexing order.  $\square$

### 63.3 Finite fibres and exact point characters

Let

$$Q_n(X) = \{p : \mu \hookrightarrow X : |X \setminus \text{ran } p| = n\},$$

with first-disagreement order. Sorting each finite residual set identifies its permutation order with the finite chain of size  $n!$ .

**Proposition 63.8** (Finite-tail normal form). *For each finite  $n$ , there is an order isomorphism*

$$\mathcal{W}_{\mu+n}(X) \cong Q_n(X) \times_{\text{lex}} n!.$$

*The order  $Q_n(X)$  is dense without endpoints, has cardinality  $2^\mu$ , and every point has character  $(\text{cf } \mu, \text{cf } \mu)$ . Its density, cellularity, and weight are  $\mu^{<\mu}$ .*

*Proof.* The residual-cylinder identity gives the displayed lexicographic sum and hence the isomorphism. Distinct elements of  $Q_n(X)$  differ at a coordinate below  $\mu$ . At that coordinate one can insert an unused label strictly between their labels, then complete a length- $\mu$  injection leaving exactly  $n$  labels. This proves density; changing the first label proves the absence of endpoints.

For a fixed  $p$ , smaller and larger first disagreements are possible at every  $\beta < \mu$ . The argument of [theorem 63.2](#), applied directly to these prefixes, gives characters  $(\text{cf } \mu, \text{cf } \mu)$ . The cardinality is  $2^\mu$  by fixing a residual set of size  $n$ . The short-cylinder counting and  $\pi$ -base argument from [theorem 63.4](#) applies to  $Q_n(X)$  as well. Density of its order then converts the dense subset into a base of the same size.  $\square$

**Theorem 63.9** (All finite-tail point characters). *Let  $q = \text{cf } \mu$ . The complete character classification for  $\mathcal{W}_{\mu+n}(X)$  is*

| $n$        | characters and positions within each $n!$ -point block                      |
|------------|-----------------------------------------------------------------------------|
| 0, 1       | $(q, q)$ at every point                                                     |
| 2          | $(q, 1)$ at the first point; $(1, q)$ at the last point                     |
| $n \geq 3$ | $(q, 1)$ first; $(1, 1)$ at the $n! - 2$ interior points;<br>$(1, q)$ last. |

*For  $n \geq 3$ , there are exactly  $2^\mu$  isolated points, and they form a dense subset.*

*Proof.* Inside a finite chain, each nonempty side has character one. At a block endpoint, the missing intrinsic side acquires character  $q$  by [theorem 63.3](#). Singleton blocks acquire  $q$  on both sides.

A point with both an immediate predecessor and an immediate successor is isolated. Hence exactly the interior points of the finite blocks are isolated. There are  $2^\mu$  blocks and a fixed positive finite number of interior points per block. To see density, take a nonempty interval. If it lies within a single block, it contains an interior block point. If its endpoints have different blocks, density of  $Q_n(X)$  supplies a whole intervening block, which has an interior point.  $\square$

**Corollary 63.10** (One-step derivative). *For  $n \geq 3$ , the first Cantor–Bendixson derivative of  $\mathcal{W}_{\mu+n}(X)$  consists exactly of the first and last points of each finite block. The derivative has no isolated points in its subspace topology, so the derivatives stabilize at this stage. For  $n \leq 2$ , the original space has no isolated points.*

*Proof.* The first assertion is the isolated-point classification. Between distinct blocks there are further blocks arbitrarily close in the relevant direction. Consequently each retained first point is accumulated from below by retained endpoints, and each retained last point is accumulated from above. No retained endpoint is isolated after the interior points are removed. For singleton blocks both sides have character  $q \geq \omega$ ; for two-point blocks one side still has that character.  $\square$

**Example 63.11** (A countable alphabet). Take  $\kappa = \omega$ , so  $\mu = \omega$ ,  $q = \omega$ , and  $\Delta = \omega$ . The orders at lengths  $\omega$  and  $\omega + 1$  are second-countable. At length  $\omega + 2$  the order is separable and first-countable but not second-countable: it has  $2^{\aleph_0}$  distinct jumps. At length  $\omega + 3$  it has  $2^{\aleph_0}$  isolated points, densely distributed in six-point blocks. Thus extending an exhaustive enumeration by only two or three ordinal positions changes its topology sharply, although the alphabet cardinality and ordinal embedding spectrum have not changed.

[merge] Source 30 proves the weight column for every infinite alphabet, with no density, regularity, saturation or endpoint hypothesis. Its “established” inputs are the finite-residual decomposition ([proposition 63.8](#), whose proof does not use richness) and the density theorem [theorem 27.2](#).

**Corollary 63.12** (Weight for arbitrary infinite alphabets). *Let  $X$  be any infinite linearly ordered set of cardinality  $\mu$ , and let  $n < \omega$ . Then*

$$w(\text{Bij}(\mu + n, X)) = \begin{cases} \mu^{<\mu}, & n = 0, 1, \\ 2^\mu, & n \geq 2. \end{cases}$$

*No density, regularity, saturation or endpoint hypothesis on  $X$  is needed.*

*Proof.* Use the established finite-residual decomposition and dense-quotient lemma for arbitrary infinite alphabets. For  $n = 0, 1$  the fibers have one point, so the order is dense. In an infinite dense linear order, a dense subset gives a base of intervals and endpoint rays; thus weight equals density. The established density calculation is  $\mu^{<\mu}$  in these two cases.

For  $n = 2$ , fix an omitted pair. There are  $2^\mu$  bijections from  $\mu$  to its complement, producing  $2^\mu$  distinct adjacent pairs in the full order. The base-set argument in the preceding proof gives weight at least  $2^\mu$ . For  $n \geq 3$ , the same argument with a fixed omitted  $n$ -element set gives  $2^\mu$  isolated interior points of finite fibers. In all cases the whole order has cardinality  $2^\mu$ , which bounds its weight above.  $\square$

This refines the density and cellularity threshold in the existing fixed-type analysis. Weight changes at the *second* terminal coordinate, whereas density and cellularity change at the third. The numerical values can coincide when  $\mu^{<\mu} = 2^\mu$ ; the finite-fiber geometry still distinguishes the mechanisms.

### 63.4 Infinite tails and the general adjacency mechanism (source 22)

[merge] [Lemma 63.13](#) is the fixed-stratum form of this report's adjacency theorems ([theorems 16.2](#) and [16.6](#)); source 22's proof is printed because the next lemma uses its tail argument.

#### 63.4.1 Why infinite residuals cannot make jumps

The finite-tail origin of adjacency was established in the earlier reports for more general enumeration comparisons ([theorem 16.2](#); source 17). The following fixed-stratum form is useful here.

**Lemma 63.13** (Adjacency forces a finite residual). *Let  $X$  be an infinite linearly ordered set and write an infinite ordinal  $\alpha$  uniquely as  $\alpha = \lambda + n$ , where  $\lambda$  is a nonzero limit ordinal and  $n < \omega$ . The adjacent pairs in  $\mathcal{W}_\alpha(X)$  are precisely the consecutive permutations in a common length- $\lambda$  prefix cylinder. Its maximal finite adjacency components are therefore the  $n!$ -point cylinders, with singleton components when  $n = 0$  or  $1$ .*

*Proof.* Suppose  $e < f$  are adjacent, and let  $\beta$  be their first disagreement. Fixing the prefix through  $e(\beta)$ , the remaining tail of  $e$  must be lexicographically greatest among all exhaustive permutations of its residual labels. Otherwise a larger such tail would produce a point strictly between  $e$  and  $f$ . Swapping entries at an increasing pair of tail positions shows that this greatest tail is numerically strictly decreasing. Dually, the tail of  $f$  after its first differing label must be numerically strictly increasing.

Let  $R$  be the common set of unused labels before coordinate  $\beta$ . The inherited numerical order on

$$R \setminus \{e(\beta), f(\beta)\}$$

is both well-ordered and reverse well-ordered. Such a set is finite: if infinite, its first  $\omega$  increasing elements have no greatest member, contradicting reverse well-ordering. Hence  $R$  is finite, and the remaining coordinate interval  $[\beta, \alpha]$  is finite. Therefore  $\beta \geq \lambda$ .

Conversely, the common length- $\lambda$  prefix cylinder is a finite convex chain of  $n!$  permutations. Consecutive points in it are adjacent in the whole order. No adjacency crosses between these cylinders, proving the component assertion.  $\square$

#### 63.4.2 The tail of order type $\omega$

**Lemma 63.14** (Countable residual enumeration orders). *For a countably infinite linearly ordered set  $R$ , the order  $\mathcal{W}_\omega(R)$  has no adjacent pair and is separable. Each nonempty side of a point has character  $\omega$ . A minimum exists exactly when the numerical order type of  $R$  is  $\omega$ , and a maximum exists exactly when its order type is  $\omega^*$ .*

*Proof.* There are no jumps by [lemma 63.13](#). There are countably many finite injective prefixes. Choose one exhaustive completion of each. Given a nonempty interval, choose an interior enumeration  $h$ . Its comparisons with the endpoints are both decided at finite coordinates. A sufficiently long finite prefix of  $h$  has its entire cylinder in the interval. Therefore the chosen completions form a countable dense set. A nonempty side has no extremal point, because there are no jumps; its cofinality or coinitality is at most  $\omega$  by separability and cannot be finite. It is therefore  $\omega$ .

If an enumeration is the minimum, every pair of its entries must be numerically increasing; otherwise swapping an inversion produces a smaller enumeration. Thus it is a strictly increasing exhaustive enumeration of length  $\omega$ , and  $R$  has order type  $\omega$ . Conversely, that enumeration always chooses the least unused label, so is lexicographically least. The maximum assertion is dual.  $\square$

**Theorem 63.15** (Exact  $\mu + \omega$  character spectrum). *For a  $\mu$ -rich alphabet  $X$  and  $q = \text{cf } \mu$ , the complete set of point characters in  $\mathcal{W}_{\mu+\omega}(X)$  is*

$$\{(q, \omega), (\omega, q), (\omega, \omega)\}.$$

*Repeated pairs are counted only once. The order is dense without endpoints, has no isolated points, and has density, cellularity, and weight  $2^\mu$ .*

*Proof.* The length- $\mu$  prefix leaves a countably infinite residual set  $R$ . Apply [lemma 63.14](#) and [theorem 63.3](#). A countably infinite order cannot have both an increasing and a decreasing exhaustive  $\omega$ -enumeration, so its permutation order cannot have both endpoints. This gives exactly the three displayed possibilities.

Each possibility occurs. A rich alphabet contains a countable increasing sequence of type  $\omega$ , a decreasing one of type  $\omega^*$ , and a countable dense suborder without endpoints. These can be chosen inside a fixed interval with an outside complement of size  $\mu$ . Leaving one of these sets as the residual alphabet realizes the first, second, and third cases, respectively. For the dense suborder, recursively satisfy all rational-order requirements inside the interval, using density to place each new point. This requires only countably many choices.

The length  $\mu + \omega$  is a limit ordinal, so there are no adjacent pairs by [lemma 63.13](#). There are no global endpoints, since the first label can be changed in either direction. The last assertion is [theorem 63.4](#).  $\square$

*Remark 63.16* (A sharp contrast even when cardinal invariants coincide). If  $\text{cf } \mu > \omega$ , the minimal stratum has character  $(\text{cf } \mu, \text{cf } \mu)$  everywhere, while the  $\mu + \omega$  stratum does not have that character anywhere. Thus local characters can distinguish these strata even in cardinal-arithmetic situations in which their densities and weights happen to coincide. At  $\mu = \omega$ , the  $\omega + \omega$  stratum is first-countable but has continuum many disjoint nonempty open intervals. Unlike the  $\omega + 3$  stratum, it has no isolated points.

### 63.4.3 What remains for longer infinite tails

For  $\alpha = \mu + \nu$  with general  $\nu$ , [theorem 63.4](#) settles the three cardinal invariants, while [theorems 63.2](#) and [63.3](#) reduce local characters to residual enumeration orders. At  $\nu = \mu$ , the residual can be any subset  $R \subseteq X$  of cardinality  $\mu$  with complement of cardinality  $\mu$ . Its order need not resemble the original birthday fragment. A further classification of point characters or cuts must therefore analyze the actual residual order and not just substitute  $\text{cf } \mu$  into the minimal-stratum formulas.

The same distinction controls ordinal-tail refinements. For example, at  $\alpha = \mu + \omega + n$ , finite adjacency blocks have size  $n!$ , but the geometry between them is governed by the preceding countable residual enumeration. The residual-cylinder identity provides a recursive description; it is not, by itself, an order-isomorphism classification of all such strata.

## 64 Fixed types with infinite residual tails: the exact binary-cube spectrum (source 19; route of source 30)

[merge] Source 19's Section 5, printed whole. It continues Part VI's block-type theorem ([theorem 31.2](#), source 15), whose boundary ([section 31.3](#)) left every type  $\mu \cdot \gamma + \zeta$  with an infinite remainder  $\zeta < \mu$  open, and it answers source 12's question on all fixed enumeration types ([research question 113.11](#)) for the embedded binary cubes in every case and for the coding length except at singular non-strong-limit residual layers at most  $\kappa$  ([section 72](#)). Source 19 read source 15 as an unplaced manuscript;

“the previous continuation” and “the prior theorem” below are source 15’s [theorem 31.2](#), and the display (5) is that theorem. Its entry code and main-prefix lemma extend source 15’s [lemma 31.1](#), [lemma 31.3](#) and [lemma 31.4](#) from finite to small deletions; its finite-capacity lemma is [lemma 31.5](#) and is recorded as a note. Source 19’s  $r_\kappa$  is printed  $\rho_\kappa$ , its  $D_{\rho,m}$  is printed  $\mathbb{B}_\rho \times_{\text{lex}} m$ , and its residual weights  $r(\lambda)$ ,  $u_\kappa(\lambda)$  and their sums  $R$ ,  $U$  are printed  $\text{wt}(\lambda)$ ,  $\text{wt}_\kappa^+(\lambda)$ ,  $\varrho_{\text{lo}}$ ,  $\varrho_{\text{up}}$  ([part X](#)). Source 30 proves the equality cases again by a different organization, block by block; its statements follow in [section 64.7](#).

The finite-tail theorem in the previous continuation leaves a specific obstruction: a long initial enumeration can leave a smaller, variably ordered alphabet for its final infinite tail. We now control that variation. The result is an exact binary-cube spectrum for every fixed enumeration type, together with exact equimorphisms for a broad family that includes every type at alphabet cardinality at most  $\aleph_\omega$ .

Throughout this section  $\kappa$  is an infinite initial cardinal and

$$X = \mathbf{No}_{<\kappa}, \quad \mu = 2^{<\kappa}, \quad \rho_\kappa = \begin{cases} \kappa \cdot \kappa, & \kappa \text{ is singular strong limit,} \\ \mu, & \text{otherwise.} \end{cases} \quad (4)$$

For a positive finite integer  $m$  put

$$(\mathbb{B}_\rho \times_{\text{lex}} m) = \mathbb{B}_\rho \times_{\text{lex}} \{0, \dots, m-1\}, \quad \mathbb{B}_\rho = (\{0, 1\}^\rho, <_{\text{lex}}).$$

The notation  $\simeq_e$  always means an order embedding in each direction. It does not mean order isomorphism. All arithmetic on enumeration types and binary lengths is ordinal arithmetic.

Write an admissible type as

$$\alpha = \mu \cdot \gamma + \zeta, \quad 0 < \gamma < \mu^+, \quad \zeta < \mu, \quad \sigma = \rho_\kappa \cdot \gamma.$$

The previously proved finite-tail result is

$$\mathcal{W}_{\mu \cdot \gamma + n}(X) \simeq_e (\mathbb{B}_\sigma \times_{\text{lex}} n!) \quad (n < \omega). \quad (5)$$

Its proof uses a sign-sequence code and, at singular strong limits, a first-varying-row scheduler (source 15, [lemma 31.3](#); [lemma 8.1](#)). We first record exactly which parts continue to apply when infinitely many labels are reserved.

## 64.1 Uniform prefix codes and deletion of a small alphabet

**Lemma 64.1** (A prefix-free code for any small alphabet). *Every linear order  $Y$  of infinite cardinality  $\lambda$  admits an order-preserving prefix-free binary entry code whose code lengths are positive and strictly less than  $\lambda$ . This assertion does not require regularity of  $\lambda$ .*

*Proof.* By [note 62.16](#), insert  $Y$  into  $\mathbf{No}_{<\lambda}$ , with the element inserted at stage  $\xi$  having birthday at most  $\xi < \lambda$ . Replace each minus sign by 00, each plus sign by 11, and append 01. The three blocks express exactly minus  $<$  termination  $<$  plus. Distinct completed codes cannot be proper prefixes of one another, and their lexicographic comparison agrees with the comparison of the surreal labels. The code length is  $2 \cdot \text{bd}(y) + 2 < \lambda$ . Padding any completed code with zeros therefore preserves its comparison with every other completed code.  $\square$

**Lemma 64.2** (The main prefix and its small-deletion counterpart). *Every lexicographically ordered family of injective prefixes  $p : \mu \cdot \gamma \rightarrow X$  embeds into  $\mathbb{B}_\sigma$ . Moreover, for every  $Y \subseteq X$  with  $|Y| < \mu$ ,*

$$\mathbb{B}_\sigma \hookrightarrow \mathcal{W}_{\mu \cdot \gamma}(X \setminus Y).$$

*Proof.* Use the prefix-free sign code of Lemma 64.1 for the labels of  $X$ , of length less than  $\kappa$ . If  $\mu > \kappa$ , pad each entry to length  $\kappa$ . A block of  $\mu$  entries then has length  $\kappa \cdot \mu = \mu$ . If  $\mu = \kappa$  is regular, concatenate the unpadding codes. Every proper partial sum within a  $\kappa$ -entry block is below  $\kappa$ , and its full sum is  $\kappa$ . If  $\mu = \kappa$  is singular, it is a strong limit: otherwise an attained equality  $2^\rho = \kappa$ ,  $\rho < \kappa$ , would also hold at  $\max(\rho, \text{cf } \kappa)$ , contradicting König's inequality. In this last case pad entries to length  $\kappa$ ; each  $\kappa$ -entry block has length  $\kappa \cdot \kappa$ . Applying the appropriate construction to the  $\gamma$  consecutive blocks gives length exactly  $\sigma$ . Exhaustiveness of the prefix is never used.

For the lower embedding in the nonexceptional cases, partition  $X \setminus Y$  into pairs indexed by  $\mu \cdot \gamma$ . Orient each pair by its corresponding bit. Since  $2 \cdot (\mu \cdot \gamma) = \mu \cdot \gamma$ , this has exactly the required enumeration type and preserves first disagreement.

Suppose now  $\mu = \kappa$  is singular strong limit. The sign cones with prefixes  $+\xi \frown -$ ,  $\xi < \kappa$ , are disjoint copies of  $X$ . At most  $|Y| < \kappa$  of them meet  $Y$ . Choose  $\kappa$  unaffected cones and index them by  $\kappa \cdot \gamma$ . Their complement in  $X \setminus Y$  still has size  $\kappa$ : it contains all but fewer than  $\kappa$  of the all-plus sequences. Thus the row scheduler used in the prior theorem still applies.

For completeness, its relevant property is the following. Inside a  $\kappa$ -row block, schedule row-column pairs  $(i, j)$  first by  $\max(i, j)$  and then lexicographically within each level. Every pair has fewer than  $\kappa$  predecessors, so the schedule has type  $\kappa$ , including when  $\kappa$  is singular. The first occurrence of row  $i$  is  $(i, 0)$ , and these occurrences increase with  $i$ . Choose the first entry of each row by an input parameter and enumerate the rest of that cone in a fixed way depending on that parameter. Include the complement as a fixed filler row in the first block. This embeds  $X_{\text{lex}}^{\kappa \cdot \gamma}$  in the required permutation order.

Finally let  $\delta = \text{cf } \kappa$  and choose positive lengths  $(\tau_j)_{j < \delta}$  with sum  $\kappa$ . Since  $\delta \cdot (\kappa \cdot \gamma) = \kappa \cdot \gamma$ , group the input coordinates into  $\kappa \cdot \gamma$  successive blocks of  $\delta$  coordinates. In each group restrict coordinate  $j$  to surreals of sign length exactly  $\tau_j$ . This realizes the cube of length  $\kappa \cdot \kappa \cdot \gamma = \sigma$  inside the product, completing the proof.  $\square$

The small-deletion assertion is necessary: the independent residual alphabet can have any cardinality below  $\mu$ . Removing it is not being treated as if only finitely many cones were affected.

## 64.2 Extracting an arbitrary tail factor from one residual fiber

Let  $P$  be the order of injective prefixes  $p : \mu \cdot \gamma \rightarrow X$  whose omitted set has cardinality  $|\zeta|$ . There is an actual lexicographic-sum isomorphism

$$\mathcal{W}_{\mu \cdot \gamma + \zeta}(X) \cong \sum_{p \in P} \mathcal{W}_{\zeta}(X \setminus \text{ran } p). \quad (6)$$

The next result shows why this decomposition controls embeddings that need not initially respect the displayed fibers.

**Lemma 64.3** (Fusion into one fiber). *If  $Q \hookrightarrow \mathbb{B}_\rho$  and  $L = \sum_{q \in Q} F_q$ , then for every nonempty linear order  $K$ ,*

$$\mathbb{B}_\rho \times_{\text{lex}} K \hookrightarrow L \implies K \hookrightarrow F_q \text{ for some } q \in Q.$$

*Proof.* Compose an asserted embedding with the nondecreasing projection to  $Q$  and its binary code. At stage  $\xi < \rho$ , retain a full source cylinder with its first  $\xi$  bits fixed and with the first  $\xi$  target bits fixed. The next target bit makes an ordered split. If the lower full source child lies entirely on the lower side, retain it. Otherwise it contains a point on the upper side, and the upper full source child lies entirely on the upper side; retain that child. At limits take unions of prefixes. The whole  $K$  factor survives. After  $\rho$  stages it has one target binary code and therefore lies inside a single  $F_q$ . Restrict the original injective map to that factor.  $\square$

**Theorem 64.4** (Exact residual embedding reduction). *For every nonempty linear order  $K$ ,*

$$\begin{aligned} \mathbb{B}_\sigma \times_{\text{lex}} K &\hookrightarrow \mathcal{W}_{\mu \cdot \gamma + \zeta}(X) \\ \iff \exists Y \subseteq X (|Y| = |\zeta| \text{ and } K &\hookrightarrow \mathcal{W}_\zeta(Y)). \end{aligned}$$

*In particular, replacing  $K$  by  $\mathbb{B}_\tau$  gives the exact test for whether  $\mathbb{B}_{\sigma+\tau}$  embeds into the total order.*

*Proof.* Forwards, combine the prefix code from Lemma 64.2, the sum (6), and Lemma 64.3. Conversely fix  $Y$  and apply the small-deletion embedding to  $X \setminus Y$ . Append the chosen  $K$ -indexed permutations of  $Y$ . Every main prefix exhausts the same complement, so the residual alphabet is independent of its binary parameter.  $\square$

**Proposition 64.5** (Which small orders can occur as residual alphabets). *For an infinite cardinal  $\lambda < \mu$ , every linear order of cardinality  $\lambda$  embeds numerically into  $X$  if and only if  $\lambda \leq \kappa$ .*

*Proof.* If  $\lambda \leq \kappa$ , note 62.16 embeds the order into  $\mathbf{No}_{<\lambda} \subseteq X$ . If  $\lambda > \kappa$ , the padded sign code embeds  $X$  into  $\mathbb{B}_\kappa$ . This cube has no increasing sequence of type  $\kappa^+$ : successive stabilization of its bits, with bounds taken at the regular cardinal  $\kappa^+$ , would make every coordinate constant on a tail of such a sequence. But the  $\lambda$ -sized ordinal  $\lambda$  contains a  $\kappa^+$ -sequence. It cannot embed into  $X$ .  $\square$

Thus residual alphabets at or below  $\kappa$  include all small linear orders, not just a special family of surreal order types. Above  $\kappa$ , the inherited global sign code is a real restriction.

### 64.3 Finite cardinal layers and the coding sandwich

Repeated left division by the current infinite cardinal gives

$$\zeta = \lambda_0 \cdot \eta_0 + \cdots + \lambda_{k-1} \cdot \eta_{k-1} + n, \quad (7)$$

where

$$\mu > \lambda_0 > \cdots > \lambda_{k-1} \geq \omega, \quad 0 < \eta_i < \lambda_i^+, \quad n < \omega.$$

There are only finitely many layers: otherwise the successive remainders would give an infinite strictly decreasing sequence of initial ordinals. Finite  $\zeta$  means  $k = 0$ .

Define two weights on infinite cardinals:

$$\text{wt}(\lambda) = \begin{cases} \lambda \cdot \lambda, & \lambda \text{ singular strong limit,} \\ \lambda, & \text{otherwise,} \end{cases} \quad (8)$$

$$\text{wt}_\kappa^+(\lambda) = \begin{cases} \lambda \cdot \lambda, & \lambda \leq \kappa \text{ and } \lambda \text{ singular,} \\ \lambda, & \text{otherwise.} \end{cases} \quad (9)$$

Finally put

$$\varrho_{\text{lo}} = \sigma + \sum_{i < k} \text{wt}(\lambda_i) \cdot \eta_i, \quad \varrho_{\text{up}} = \sigma + \sum_{i < k} \text{wt}_\kappa^+(\lambda_i) \cdot \eta_i. \quad (10)$$

Both are nonzero limit ordinals and  $\varrho_{\text{lo}} \leq \varrho_{\text{up}}$ .

**Lemma 64.6** (Regular-cardinal blocks over any alphabet). *Let  $\lambda$  be an infinite regular cardinal,  $|Y| = \lambda$ , and  $0 < \eta < \lambda^+$ . Injective prefixes of length  $\lambda \cdot \eta$  in  $Y$  admit an order embedding into  $\mathbb{B}_{\lambda \cdot \eta}$ . For every  $n < \omega$ ,*

$$\mathcal{W}_{\lambda \cdot \eta + n}(Y) \simeq_e (\mathbb{B}_{\lambda \cdot \eta} \times_{\text{lex}} n!).$$

*Proof.* Use Lemma 64.1. Regularity makes every proper partial sum of entry-code lengths within a  $\lambda$ -entry block less than  $\lambda$ , while positivity makes the full sum exactly  $\lambda$ . Code the  $\eta$  consecutive blocks separately. In an exhaustive enumeration the last  $n$  labels are determined by the preceding prefix, so append their finite permutation rank. This gives the upper embedding. For the lower embedding reserve a fixed  $n$ -element set, orient pairs of the complement indexed by  $\lambda \cdot \eta$ , and append its selected terminal permutation.  $\square$

**Theorem 64.7** (Uniform coding bounds for every fixed type). *With the parameters above,*

$$(\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} n!) \hookrightarrow \mathcal{W}_\alpha(X) \hookrightarrow (\mathbb{B}_{\varrho_{\text{up}}} \times_{\text{lex}} n!). \quad (11)$$

*In particular, if  $\varrho_{\text{lo}} = \varrho_{\text{up}}$ , then  $\mathcal{W}_\alpha(X) \simeq_e (\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} n!)$ . Equality holds whenever every residual cardinal is regular, singular strong limit, or strictly larger than  $\kappa$ .*

*Proof.* For the upper embedding, code the main prefix in length  $\sigma$ . At the beginning of residual layer  $i$ , the remaining alphabet has cardinality  $\lambda_i$ . If it is regular use Lemma 64.6. If it is singular and at most  $\kappa$ , pad the entry code from Lemma 64.1 to length  $\lambda_i$ . The next  $\lambda_i \cdot \eta_i$  entries then use length  $\lambda_i \cdot \lambda_i \cdot \eta_i$ . If  $\lambda_i > \kappa$ , use the fixed global  $\kappa$ -bit sign code instead; its length for this block is  $\kappa \cdot \lambda_i \cdot \eta_i = \lambda_i \cdot \eta_i$ .

Choose an entry code for each possible residual alphabet. Such choices are indexed by a set. Two enumerations that have agreed up to a layer boundary have the same residual alphabet and use the same code; if they disagree before that boundary, their comparison is already decided. Consequently these conditional codes combine to an order-preserving code of length  $\varrho_{\text{up}}$ . Append the finite permutation rank, obtaining the upper embedding.

For the lower embedding choose fixed, pairwise disjoint alphabets for the finitely many residual layers. A singular strong-limit  $\lambda < \mu$  necessarily satisfies  $\lambda < \kappa$ , for otherwise  $\mu = 2^{<\kappa} \leq 2^{<\lambda} = \lambda$ . At such a layer choose an ordered copy of  $\mathbf{No}_{<\lambda}$ , which has cardinality  $\lambda$ , inside a sign cone of  $X$ . Finitely many distinct finite prefixes, such as  $+^i \frown -$ , make these copies disjoint. The singular scheduler in Lemma 64.2, applied at cutoff  $\lambda$ , realizes the factor  $\mathbb{B}_{\lambda \cdot \lambda \cdot \eta}$  there. For all other layers choose arbitrary disjoint sets of the requisite cardinality and realize  $\mathbb{B}_{\lambda \cdot \eta}$  by pair orientation. Also reserve a fixed  $n$ -element terminal set.

Their union has cardinality less than  $\mu$ . Its complement realizes  $\mathbb{B}_\sigma$  by Lemma 64.2. Concatenate all the independent block enumerations and the selected terminal permutation. The first changed source factor supplies the first changed target block. This gives the lower embedding in (11).  $\square$

**Corollary 64.8** (All regular residual layers). *If every  $\lambda_i$  in (7) is regular, and  $\tau = \sum_{i < \kappa} \lambda_i \cdot \eta_i$ , then*

$$\mathcal{W}_{\mu \cdot \gamma + \tau + n}(X) \simeq_e (\mathbb{B}_{\sigma + \tau} \times_{\text{lex}} n!).$$

*In particular every countably infinite residual is classified. Every admissible enumeration type is classified whenever  $\mu \leq \aleph_\omega$ .*

*Proof.* The first assertion is  $\varrho_{\text{lo}} = \varrho_{\text{up}} = \sigma + \tau$ . A countable ordinal is of the form  $\omega \cdot \eta + n$ . If  $\mu \leq \aleph_\omega$ , every smaller infinite cardinal is one of the regular cardinals  $\aleph_j$ ,  $j < \omega$ .  $\square$

Even with a singular non-strong-limit residual, ordinal absorption inside a coefficient  $\eta_i$  can occasionally make  $\varrho_{\text{lo}} = \varrho_{\text{up}}$ . The criterion is the equality of the computed ordinals, not merely the absence of one label in a list of cardinal cases. When they differ, Theorem 64.7 leaves a binary coding-length problem. The next argument nevertheless determines all embedded binary cubes exactly.

#### 64.4 A cardinality fusion lemma and the complete cube spectrum

**Lemma 64.9** (A constant subcylinder from a small range). *Let  $\chi$  be an infinite cardinal and  $A$  a linear order with  $|A| < 2^\chi$ . A nondecreasing map from a binary cylinder with at least  $\chi$  free initial bits, followed by any nonempty factor, into  $A$  is constant on a full subcylinder obtained by fixing fewer than  $\chi$  of those bits.*

*Proof.* Fix all later bits and choose one point in the final factor. This gives  $2^\chi$  ordered test points. Some value has at least three test preimages  $x_0 < x_1 < x_2$ , since a union of  $|A|$  sets of at most two elements has cardinality at most  $|A|$ . Choose  $\delta < \chi$  strictly beyond the first disagreements of  $x_1$  with both outer points. The entire source cylinder determined by the first  $\delta$  bits of  $x_1$  lies strictly between  $x_0$  and  $x_2$ , regardless of its later bits and final factor. Monotonicity forces the same value throughout it.  $\square$

**Lemma 64.10** (The singular non-strong-limit block). *Suppose  $\lambda$  is singular and not strong limit, and  $0 < \eta < \lambda^+$ . Consider a putative order embedding whose target enumerations share their earlier prefix, leaving an alphabet of cardinality  $\lambda$ , and whose source has a free initial block  $\mathbb{B}_{\lambda \cdot \eta}$  followed by a nonempty factor  $K$ . One can fix the source binary block so that the next  $\lambda \cdot \eta$  target entries are constant on the surviving whole  $K$  factor.*

*Proof.* Choose an exponent  $\theta < \lambda$  with  $2^\theta \geq \lambda$ , and put  $\chi = \max(|\theta|, \text{cf } \lambda) < \lambda$ . Then  $2^\chi \geq \lambda$ , and equality would contradict  $\text{cf}(2^\chi) > \chi \geq \text{cf } \lambda$ . Thus  $2^\chi > \lambda$ .

Process target coordinates  $j < \lambda \cdot \eta$ . All earlier target coordinates have been fixed. The current coordinate is therefore a nondecreasing map on the remaining source cylinder into a  $\lambda$ -element order. Lemma 64.9 makes it constant after fewer than  $\chi$  additional source bits. Before coordinate  $j$ , the total bits fixed are at most  $\chi \cdot j$ . There are still  $\chi$  free bits available:

$$\chi \cdot (j+1) < \lambda \cdot \eta \quad (j+1 < \lambda \cdot \eta).$$

Indeed, writing  $j = \lambda \cdot \beta + \delta$  with  $\delta < \lambda$  gives  $\chi \cdot j = \lambda \cdot \beta + \chi \cdot \delta$ , and  $\chi \cdot (\delta+1) < \lambda$ . The ordinal  $\lambda \cdot \eta$  is a limit, so  $j+1$  stays below it at every stage.

At limits take unions of the chosen prefixes. The total cost at the end is at most

$$\chi \cdot (\lambda \cdot \eta) = \lambda \cdot \eta.$$

If fewer bits were used, fix arbitrary additional bits to the exact block boundary. All target entries in the stated block are now fixed, and the entire subsequent factor  $K$  remains.  $\square$

**Theorem 64.11** (Exact binary-cube spectrum for every fixed type). *For every positive finite integer  $m$ ,*

$$(\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} m) \hookrightarrow \mathcal{W}_\alpha(X) \iff m \leq n!. \quad (12)$$

*Consequently, for every ordinal  $\theta$ ,*

$$\boxed{\mathbb{B}_\theta \hookrightarrow \mathcal{W}_\alpha(X) \iff \theta \leq \varrho_{\text{lo}} + \lfloor \log_2(n!) \rfloor.} \quad (13)$$

*This includes all singular non-strong-limit residual layers.*

*Proof.* The lower embedding in Theorem 64.7 proves the forward constructions in (12). Conversely suppose an embedding of  $(\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} m)$  is given. Fuse through the target's main prefix code, using Lemma 64.3; this fixes  $\sigma$  source bits and the entire main target prefix while preserving the later source factor.

At each regular residual layer fuse through the prefix code of length  $\lambda_i \cdot \eta_i$ . At each singular strong-limit layer fuse through the padded code of length  $\lambda_i \cdot \lambda_i \cdot \eta_i$ . At a singular non-strong-limit layer use Lemma 64.10, whose cost is only  $\lambda_i \cdot \eta_i$ . These are exactly the successive summands defining  $\varrho_{\text{lo}}$ . After finitely many layers, all target positions before the last  $n$  are fixed. The surviving  $m$  source points must inject into the  $n!$  permutations of one fixed residual  $n$ -element set. Thus  $m \leq n!$ .

Put  $j = \lfloor \log_2(n!) \rfloor$ . The lower construction contains  $\mathbb{B}_{\varrho_{\text{lo}}+j} = (\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} 2^j)$ , whereas (12) excludes  $\mathbb{B}_{\varrho_{\text{lo}}+j+1} = (\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} 2^{j+1})$ . Every larger cube contains this forbidden cube, and every smaller cube embeds into  $\mathbb{B}_{\varrho_{\text{lo}}+j}$  by padding zeros.  $\square$

The small-range argument concerns a map on a full binary cylinder, not merely on the chosen test points. Fixing a prefix of the middle test point puts every extension between the two outer points. This is what permits the fusion to retain an arbitrary subsequent source factor and to pass through limit stages.

## 64.5 Exact coding lengths, comparisons, and examples

Define the binary coding length  $\ell_2(L)$  to be the least ordinal  $\rho$  for which  $L \hookrightarrow \mathbb{B}_\rho$ . The finite-capacity argument has the following familiar consequence, recalled with its obstruction.

*Note 64.12* (Source 19, Lemma 5.12, “Finite factors over a limit-length cube”). *For nonzero limit ordinals  $\rho, \tau$  and positive finite integers  $m, n$ ,  $(\mathbb{B}_\rho \times_{\text{lex}} m) \hookrightarrow (\mathbb{B}_\tau \times_{\text{lex}} n)$  if and only if  $\rho < \tau$  or  $(\rho = \tau \text{ and } m \leq n)$ ; and  $\ell_2(\mathbb{B}_\rho \times_{\text{lex}} m) = \rho + \lceil \log_2 m \rceil$ . This is source 15’s lemma 31.5, by the same equal-length fusion; source 19 adds that the one-bit fusion also gives  $\mathbb{B}_\beta \hookrightarrow \mathbb{B}_\xi$  exactly when  $\beta \leq \xi$  (“if  $\beta > \xi$ , fixing  $\xi$  source bits to match all target bits leaves at least two source points”), which is lemma 6.4. Source 19 calls it “the familiar consequence ... recalled with its obstruction”. Source 29 proves it a third time (its Lemma 4.1 and Corollary 4.2).*

**Corollary 64.13** (Coding bounds and exact classifications). *For every type in this section,*

$$\varrho_{\text{lo}} + \lceil \log_2(n!) \rceil \leq \ell_2(\mathcal{W}_\alpha(X)) \leq \varrho_{\text{up}} + \lceil \log_2(n!) \rceil. \quad (14)$$

*If  $\varrho_{\text{lo}} = \varrho_{\text{up}}$ , both inequalities are equalities. Two such classified orders with parameters  $(\varrho_{\text{lo}}, n!)$  and  $(\varrho'_{\text{lo}}, m!)$  embed in the indicated direction exactly when*

$$\varrho_{\text{lo}} < \varrho'_{\text{lo}} \quad \text{or} \quad (\varrho_{\text{lo}} = \varrho'_{\text{lo}} \text{ and } n! \leq m!).$$

*Proof.* Apply note 64.12 to the sandwich (11). When its two outer orders coincide up to notation, use the resulting equimorphisms on both sides of a proposed embedding.  $\square$

Under CH,  $\kappa = \mu = \omega_1$  and every admissible type has the form

$$\alpha = \omega_1 \cdot \gamma + \omega \cdot \eta + n.$$

It follows that

$$\begin{aligned} \mathcal{W}_\alpha(\mathbf{No}_{<\omega_1}) &\simeq_e (\mathbb{B}_{\omega_1 \cdot \gamma + \omega \cdot \eta} \times_{\text{lex}} n!), \\ \ell_2(\mathcal{W}_\alpha(\mathbf{No}_{<\omega_1})) &= \omega_1 \cdot \gamma + \omega \cdot \eta + \lceil \log_2(n!) \rceil. \end{aligned}$$

For  $n = 3$ , the largest embedded cube has length  $\omega_1 \cdot \gamma + \omega \cdot \eta + 2$ , while the least coding length is that limit part plus 3. The difference follows from finite-capacity nonembedding, not from cardinality.

For an example with an infinite singular residual, let  $\lambda$  be singular strong limit, put  $\kappa = \lambda^+$  and  $\mu = 2^\lambda$ . Then

$$\mathcal{W}_{\mu \cdot \gamma + \lambda \cdot \eta + n}(\mathbf{No}_{<\lambda^+}) \simeq_e (\mathbb{B}_{\mu \cdot \gamma + \lambda \cdot \lambda \cdot \eta} \times_{\text{lex}} n!).$$

The singular residual contributes an additional ordinal factor  $\lambda$ , despite having smaller cardinality than the main alphabet.

## 64.6 What is settled and what remains

The arbitrary variable residual has now been controlled well enough to determine the complete embedded binary-cube spectrum for every fixed type. Exact equimorphism and coding length are also determined whenever the two computable bounds  $\varrho_{\text{lo}}, \varrho_{\text{up}}$  agree. This includes every type when  $\mu \leq \aleph_\omega$ , every countable residual at any cutoff, and the singular strong-limit residuals described above.

The remaining coding question occurs when singular non-strong-limit residual layers at or below  $\kappa$  make  $\varrho_{\text{lo}} < \varrho_{\text{up}}$ . Does the lower coding bound in (14) always hold with equality? A stronger formulation asks whether the whole order embeds into  $(\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} n!)$ . The simplest general-alphabet instance asks whether

$$\mathcal{W}_\lambda(Y) \hookrightarrow \mathbb{B}_\lambda$$

for every ordered  $Y$  of singular non-strong-limit cardinality  $\lambda$ . The argument above proves that its embedded cube spectrum is exactly  $\theta \leq \lambda$ , but the direct entry code only gives an embedding into  $\mathbb{B}_{\lambda \cdot \lambda}$ . One must not infer a coding embedding from the absence of the next larger cube.

Further refinements concern isomorphism instead of equimorphism, residual gap spectra, and which fiber structures can be recovered from the pure order. The exact residual reduction Theorem 64.4 supplies a useful test: an arbitrary product embedding with the full main binary factor must already realize its remaining factor on a single allowed residual alphabet.

## 64.7 Source 30's route to the residual codes

[merge] Source 30's Sections 4 and 5 classify the same fixed types again, independently: source 30 read this report at pin 7ff7736ec and cites no batch-81 or batch-83 manuscript. It builds the classification block by block (one smaller regular block, one singular strong-limit block, a finite descent through both, residual cardinals above  $\kappa$ ), where source 19 proves the coding sandwich for every type at once and adds the cube spectrum at singular non-strong-limit layers. Every statement of source 30 in these sections is a case of theorem 64.7 with corollary 64.13, or of its equality clause, proved with the same entry codes, padded codes, schedulers and reserved alphabets; they are recorded in notes. Source 30 states one consequence that source 19 does not state, printed as corollary 64.20, and an unconditional mixed example. Its weight  $r(\nu)$  is printed  $\text{wt}(\nu)$  and its bl is  $\ell_2$ .

*Note 64.14* (Source 30, opening of Section 4; dated correction). Source 30 opens: “The repository’s cardinal-block theorem treats  $\mathcal{W}_{\mu \gamma + n}(\mathbf{No}_{<\kappa})$ , where  $\mu = 2^{<\kappa}$  and  $n < \omega$ , but explicitly leaves infinite remainders  $\zeta < \mu$  untreated. See source label `swo:cb:new:thm:block-types`, lines 9200–9367, and the boundary discussion `swo:vi:sub:cb-boundary`, lines 9561–9580, at the source pin recorded above. The first new instance proved here is  $\mu + \omega$ . In fact the argument handles every countable remainder, and more generally a block of any smaller regular cardinal followed by a finite remainder.” [merge] (3 October 2026.) This was true of this report at source 30’s pin 7ff7736ec (the cited line numbers are those of theorem 31.2 and section 31.3). Within batch 83, source 19, written earlier at pin d5bd4a67b, treats every infinite remainder (theorems 64.7 and 64.11); the two treatments are independent.

*Note 64.15* (Source 30, Lemmas 4.1–4.3: entry codes, the long prefix, small deletion). Lemma 4.1 (“Short codes for arbitrary regular-cardinality alphabets”): *let  $\nu$  be an infinite regular cardinal and  $Y$  an arbitrary linear order of cardinality  $\nu$ ; there is an order-preserving, prefix-free binary code  $c_Y$  for  $Y$  with  $0 < \text{lh}(c_Y(y)) < \nu$ ; consequently  $\mathcal{W}_{\nu\delta+n}(Y) \simeq_e \mathbb{B}_{\nu\delta} \times_{\text{lex}} n!$  for every  $0 < \delta < \nu^+$  and  $n < \omega$ ; for  $\nu = \omega$  the codes are finite binary words, and the conclusion holds “for every countable linear alphabet, regardless of density, endpoints, jumps, or scatteredness”.* This is lemma 64.1 with lemma 64.6, by the same stage-controlled insertion into  $\mathbf{No}_{<\nu}$  (“regularity is not needed for this embedding step”) and the same  $00 < 01 < 11$  sign code; for  $\nu = \omega$  source 30 notes the alternative embedding into the dyadic rationals. Lemma 4.2 (“Exact coding length of an arbitrary long prefix”): *for  $0 < \gamma < \mu^+$  there is an order embedding  $X_{\text{lex}}^{\mu\gamma} \rightarrow \mathbb{B}_{\rho_\kappa\gamma}$ , in particular for all injective prefixes of that length; no exhaustiveness hypothesis is used, which is the first half of lemma 64.2 and the upper construction of theorem 31.2 (“This proves the asserted order embedding even for functions with repeated entries”).* Lemma 4.3 (“Small deletion in the singular scheduler”): *let  $\kappa$  be singular strong limit and  $D \subseteq \mathbf{No}_{<\kappa}$  with  $|D| < \kappa$ ; for  $0 < \gamma < \kappa^+$  and  $\lambda = \kappa\gamma$ ,  $\mathbb{B}_{\kappa\lambda}$  order-embeds into  $\mathcal{W}_\lambda(\mathbf{No}_{<\kappa} \setminus D)$ .* This is the second half of lemma 64.2: it “extends the repository’s finite-deletion lemma” lemma 31.4 “from finite deletion to deletion of cardinality below  $\kappa$ ”, and it prints the row scheduler of lemma 31.3 in full “to expose the order, rather than merely cardinal, requirements”: the sign cones  $+\xi \frown -$ ,  $\xi < \kappa$ , of which fewer than  $\kappa$  meet  $D$ ; a filler row for the unselected labels; rows split into blocks of  $\kappa$  and scheduled by  $\max(\xi, j)$ ; and the regrouping of coordinates into blocks of cf  $\kappa$  restricted to sign words of lengths  $\eta_j$  with  $\sum_j \eta_j = \kappa$ .

*Note 64.16* (Source 30, Theorem 4.4 and Corollaries 4.5, 4.6 and 4.8; Remark 4.7). Theorem 4.4 (“A smaller regular-cardinal block after the long prefix”): *for an infinite regular  $\nu < \mu$ ,  $0 < \gamma < \mu^+$ ,  $0 < \delta < \nu^+$  and  $n < \omega$ ,  $\mathcal{W}_{\mu\gamma+\nu\delta+n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\rho_\kappa\gamma+\nu\delta} \times_{\text{lex}} n!$ ; all constructions are set constructions in ZFC, with no global choice or class comprehension.* Corollary 4.5 (“Every countable remainder”): *if  $\mu > \omega$ , then  $\mathcal{W}_{\mu\gamma+\omega\delta+n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\rho_\kappa\gamma+\omega\delta} \times_{\text{lex}} n!$  for  $0 < \gamma < \mu^+$ ,  $0 < \delta < \omega_1$ ,  $n < \omega$ ;* “Together with the repository’s finite-remainder theorem, this covers every  $\alpha = \mu\gamma + \zeta$  with  $\zeta < \omega_1$ . For a countable alphabet itself, Lemma 4.1 already treats every admissible ordinal length.” Corollary 4.6 (“Exact coding and cube spectrum”): *with  $\sigma = \rho_\kappa\gamma + \nu\delta$ , the least binary coding length is  $\sigma + \lceil \log_2(n!) \rceil$ ,  $\mathbb{B}_\theta$  embeds exactly when  $\theta \leq \sigma + \lceil \log_2(n!) \rceil$ , and two instances embed exactly when  $\sigma < \sigma'$  or ( $\sigma = \sigma'$  and  $n! \leq m!$ ), by lemma 31.5.* Remark 4.7: “At  $\kappa = \omega_1$ , the countable-remainder corollary already classifies every fixed type under CH: divide  $\alpha$  by  $\omega_1$  and apply the corollary to the countable remainder. Corollary 5.6 below removes CH entirely.” Corollary 4.8 (“Finite descent through regular residual cardinals”): *for regular  $\mu > \nu_1 > \dots > \nu_t$ ,  $\mathcal{W}_{\mu\gamma+\zeta+n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_\sigma \times_{\text{lex}} n!$  with  $\zeta = \nu_1\delta_1 + \dots + \nu_t\delta_t$  and  $\sigma = \rho_\kappa\gamma + \zeta$ , with the coding-rank, cube-spectrum and comparison conclusions of Corollary 4.6.* These are corollary 64.8 and corollary 64.13, by the same upper codes (“ordinary set choice suffices” to choose one code for each possible residual alphabet; “equal earlier prefixes determine the same code”) and the same reserved alphabets with pair orientations. Source 30’s closing paragraph of its Section 4, “The remaining boundary”, observes that every remainder has a finite decomposition into blocks of strictly decreasing infinite cardinalities followed by a finite term, that “regularity is the exact step used to make a block of short entry codes have precisely the cardinal’s ordinal length, and the residual alphabet need not contain all of  $\mathbf{No}_{<\nu}$ ”, and that after its Section 5 “the remaining uncontrolled regime is therefore singular, not strong limit, and at most  $\kappa$ ”, as for source 19.

*Note 64.17* (Source 30, Theorem 5.1 and Corollary 5.2). Theorem 5.1 (“A singular strong-limit residual block”): *if  $\nu < \mu$  is a singular strong-limit cardinal,  $0 < \gamma < \mu^+$ ,  $0 < \delta < \nu^+$  and  $n < \omega$ , then  $\mathcal{W}_{\mu\gamma+\nu\delta+n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\rho_\kappa\gamma+\nu\cdot\nu\cdot\delta} \times_{\text{lex}} n!$ .* Corollary 5.2 (“A strict obstruction to the uninflated residual formula”): *with  $n = 0$  and  $\delta = 1$ ,  $\ell_2(\mathcal{W}_{\mu\gamma+\nu}(\mathbf{No}_{<\kappa})) = \rho_\kappa\gamma + \nu \cdot \nu$ , so*

$\mathcal{W}_{\mu\gamma+\nu}(\mathbf{No}_{<\kappa}) \not\rightarrow \mathbb{B}_{\rho_\kappa\gamma+\nu}$ ; “Thus the smaller regular-cardinal formula cannot be extended to all singular residual cardinals with the same uninflated tail length.” These are the singular strong-limit layer of [theorem 64.7](#), where  $\text{wt}(\nu) = \text{wt}_\kappa^+(\nu) = \nu \cdot \nu$ , and its coding consequence [corollary 64.13](#); source 30’s proof is source 19’s:  $\nu < \kappa$  because  $\mu = 2^{<\kappa} \leq 2^{<\nu} = \nu$  otherwise, every residual alphabet of size  $\nu$  embeds into  $\mathbf{No}_{<\nu}$  with codes of length below  $\nu$ , padded to length  $\nu$ , and the lower embedding reserves the full smaller cutoff  $\mathbf{No}_{<\nu}$  and runs the singular scheduler at cutoff  $\nu$ . Source 30 adds: “The explicit strict contrast above uses  $\delta = 1$ ; for arbitrary  $\delta$ , ordinal absorption can make  $\nu \cdot \nu \cdot \delta = \nu \cdot \delta$ . The smaller-cutoff argument alone does not classify a residual singular cardinal which is not strong limit. The padded upper bound remains available, but the smaller full surreal cutoff may have more than  $\nu$  labels, so it cannot be reserved as a residual alphabet of size  $\nu$ .”

*Note 64.18* (Source 30, Corollaries 5.3 and 5.4). For an infinite cardinal  $\nu$  that is regular or singular strong limit, source 30 puts  $\text{wt}(\nu) = \nu$  or  $\nu \cdot \nu$  respectively. Corollary 5.3 (“Finite descent through both controlled cardinal regimes”): *if  $\mu > \nu_0 > \dots > \nu_k$  are infinite cardinals, each regular or singular strong limit, then  $\mathcal{W}_\alpha(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_\sigma \times_{\text{lex}} n!$  for  $\alpha = \mu\gamma + \sum_{i \leq k} \nu_i \delta_i + n$  and  $\sigma = \rho_\kappa\gamma + \sum_{i \leq k} \text{wt}(\nu_i) \delta_i$ .* Corollary 5.4 (“All fixed types when smaller cardinals are controlled”): *if every infinite cardinal below  $\mu$  is regular or singular strong limit, every fixed type of cardinality  $\mu$  is covered by this formula; in particular this yields a complete isomorphism classification of all fixed types under GCH*, because under GCH every singular cardinal is a strong limit. Under GCH, with the canonical decomposition  $\alpha = \sum_{i \leq k} \kappa_i \delta_i + n$ ,  $\kappa = \kappa_0 > \kappa_1 > \dots > \kappa_k \geq \omega$ , the complete formula reads

$$\mathcal{W}_\alpha(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\sum_{i \leq k} \text{wt}(\kappa_i) \cdot \delta_i} \times_{\text{lex}} n!,$$

and “every product and sum here is ordinal; replacing a term  $\kappa_i \cdot \kappa_i$  by its cardinality would destroy the claimed classification”. These are the equality clause of [theorem 64.7](#) in the regular and singular strong-limit cases; the GCH classification follows from that clause, and source 19 leaves it implicit. The one point source 30 checks separately is that the reserved alphabets of the singular strong-limit blocks (copies of  $\mathbf{No}_{<\nu_i}$  behind distinct prefixes  $+^j \frown -$ ) are disjoint, as in source 19’s lower embedding.

[merge] Source 30’s unconditional example, with a singular residual inflation, a subsequent countable block and a non-power-of-two finite factor in one type:

**An unconditional mixed example.** Let  $\nu = \beth_\omega$ , let  $\kappa = \nu^+$ , and put  $\mu = 2^\nu = 2^{<\kappa}$ . Then  $\nu$  is singular strong limit, whereas the successor cutoff  $\kappa$  is not singular strong limit, so  $\rho_\kappa = \mu$ . For

$$\alpha = \mu + \nu + \omega + 3, \quad \sigma = \mu + \nu \cdot \nu + \omega,$$

the mixed theorem gives

$$\mathcal{W}_\alpha(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_\sigma \times_{\text{lex}} 6.$$

Its exact binary coding length is  $\sigma + 3$ , while its largest embedded binary cube has length  $\sigma + 2$ . This example needs no continuum hypothesis: it displays a singular residual inflation, a subsequent countable block, and a non-power-of-two finite factor in one fixed enumeration type.

*Note 64.19* (Source 30, Proposition 5.5, “Residual cardinals above the birthday cutoff”). *If  $\kappa < \nu < \mu$  is any infinite cardinal, with no regularity assumption, then  $\mathcal{W}_{\mu\gamma+\nu\delta+n}(\mathbf{No}_{<\kappa}) \simeq_e \mathbb{B}_{\mu\gamma+\nu\delta} \times_{\text{lex}} n!$  for  $0 < \gamma < \mu^+$ ,  $0 < \delta < \nu^+$  and  $n < \omega$ .* This is the clause  $\text{wt}_\kappa^+(\nu) = \nu$  for  $\nu > \kappa$  of [theorem 64.7](#), by the same padded native code: “since  $\mu$  and  $\nu$  are initial cardinals strictly larger than  $\kappa$ ,  $\kappa \cdot \mu = \mu$ ,  $\kappa \cdot \nu = \nu$ ”, with no regularity of either. Source 30 then combines the three admitted regimes into one cost per block,  $\nu$  when  $\nu$  is regular or larger than  $\kappa$  and  $\nu \cdot \nu$  when  $\nu$  is singular strong

limit (“a singular strong-limit  $\nu < \mu$  is necessarily below  $\kappa$ ”), and concludes: “The remaining unresolved residual-cardinal regime is therefore *singular, not strong limit, and at most  $\kappa$* , with  $\nu < \mu$ . Singularity by itself is not an obstruction to an uninflated residual code: the available uniform birthday bound must also be taken into account.” Source 19 proves more in that regime: the cube spectrum (theorem 64.11) and the coding bounds corollary 64.13.

[merge] Source 30’s Corollary 5.6 is a consequence of the equality clause of theorem 64.7 that source 19 does not state: source 19 states the classification of every type when  $\mu \leq \aleph_\omega$  (corollary 64.8) and at  $\kappa = \omega_1$  only under CH. It is printed whole.

**Corollary 64.20** (The first uncountable cutoff needs no continuum hypothesis). *Put  $X = \mathbf{No}_{<\omega_1}$  and  $\mu = 2^{\aleph_0}$ . For every ordinal  $\alpha$  of cardinality  $\mu$ , write  $\alpha = \lambda + n$ , where  $\lambda$  is a nonzero limit ordinal and  $n < \omega$ . Then, in ZFC,*

$$\mathcal{W}_\alpha(X) \simeq_e \mathbb{B}_\lambda \times_{\text{lex}} n!.$$

*More generally the same conclusion holds for  $X = \mathbf{No}_{<\kappa}$  at every infinite initial cutoff  $\kappa < \aleph_\omega$ , with  $\mu = 2^{<\kappa}$  and  $|\alpha| = \mu$ .*

*Proof.* For such a  $\kappa$ , every infinite cardinal at most  $\kappa$  is regular. Any larger residual cardinal has the uninflated native code from note 64.19. Thus every cardinal in the canonical finite residual decomposition is covered and has cost equal to itself. The main cutoff is regular, so  $\rho_\kappa = \mu$  as well. The mixed formula therefore has binary length equal to the entire limit part  $\lambda$  of  $\alpha$ . For  $\kappa = \omega_1$ , its alphabet cardinal is  $2^{\aleph_0}$ , with no condition on the value of that cardinal. For  $\kappa = \omega$ , there are no smaller infinite residual cardinals, and the existing cardinal-block theorem supplies the same conclusion.  $\square$

## 65 Completions of the minimal slice (sources 24, 21 and 19)

[merge] Three different completions of the minimal slice are printed here: the Hausdorff completion for agreement on bounded initial segments (source 24’s Section 5), the closure of the minimal stratum inside the full order  $\mathcal{W}(X)$  (source 21’s Section 4), and normal forms for the Dedekind completion (source 19’s Section 7). Source 24’s own summary of the difference: “Forward stabilization preserves injectivity but can lose labels. Inverse stabilization prevents that loss. Dedekind completion is larger again: it also fills cylinder edges and numerical gaps.” Sources 26 and 28 prove the forward completion again; source 28 extends it to every admissible coordinate ideal (theorem 70.25).

### 65.1 Forward prefix completion and the missing-label boundary (source 24)

#### 65.1.1 The uniformity that remembers only initial segments

For  $\alpha < \mu$ , put

$$E_\alpha = \{(f, g) : f \restriction \alpha = g \restriction \alpha\}.$$

These equivalence relations form a base of entourages for a Hausdorff uniformity on either  $\mathcal{W}_\mu(X)$  or  $\mathcal{I}_\mu(X)$ . We call it the *forward prefix uniformity*. Its topology is the cylinder topology. No ordering of  $X$  is needed to define it.

A net is Cauchy for this uniformity when, for every  $\alpha < \mu$ , all sufficiently late terms have exactly the same restriction to  $\alpha$ . The requirement is stronger than merely having many pairwise agreements, and at a singular  $\mu$  it must still be stated for every bounded initial segment, not merely for arbitrary finite sets of coordinates.

**Theorem 65.1** (Exact forward completion). *The uniform space  $\mathcal{I}_\mu(X)$  is complete. The inclusion*

$$\mathcal{W}_\mu(X) \hookrightarrow \mathcal{I}_\mu(X)$$

*is a dense uniform embedding and exhibits  $\mathcal{I}_\mu(X)$  as the Hausdorff completion of  $\mathcal{W}_\mu(X)$ .*

*Proof.* Let  $\mathcal{F}$  be a Cauchy filter on  $\mathcal{I}_\mu(X)$ . For each  $\alpha < \mu$  it contains a nonempty  $E_\alpha$ -small set, hence contains a cylinder  $[p_\alpha]$  of length  $\alpha$ . It cannot contain two distinct cylinders of that length, since they are disjoint. These unique prefixes are coherent: if  $\alpha < \beta$ , the two cylinders in the filter intersect, so  $p_\alpha = p_\beta \upharpoonright \alpha$ .

Their union  $h = \bigcup_{\alpha < \mu} p_\alpha$  is a function with domain  $\mu$ . It is injective, because any two proposed equal values occur in a common sufficiently long injective prefix. The filter contains every cylinder neighborhood of  $h$  and therefore converges to  $h$ . This proves completeness.

The entourages on  $\mathcal{W}_\mu(X)$  are the restrictions of the same entourages on  $\mathcal{I}_\mu(X)$ . Every cylinder of the latter meets  $\mathcal{W}_\mu(X)$  by Lemma 62.4. Completeness, density, and Hausdorffness give the claimed completion, including its uniqueness up to the usual uniform isomorphism fixing the dense subspace.  $\square$

**Theorem 65.2** (Exhaustion is an intersection of dense open requirements). *For each  $x \in X$ , let*

$$U_x = \{h \in \mathcal{I}_\mu(X) : x \in \text{ran } h\}, \quad F_x = \mathcal{I}_\mu(X) \setminus U_x.$$

*Then  $U_x$  is open dense and  $F_x$  is closed nowhere dense. Moreover,*

$$\mathcal{W}_\mu(X) = \bigcap_{x \in X} U_x, \quad \mathcal{I}_\mu(X) \setminus \mathcal{W}_\mu(X) = \bigcup_{x \in X} F_x.$$

*Both  $\mathcal{W}_\mu(X)$  and its complement are dense in  $\mathcal{I}_\mu(X)$ .*

*Proof.* Once  $x$  occurs, a prefix extending past that occurrence witnesses membership in  $U_x$ , so  $U_x$  is open. Any prefix can be extended to include  $x$ , if it does not already include it; then complete the new prefix. Hence  $U_x$  is dense, and  $F_x$  has the stated properties. The displayed equalities express surjectivity exactly.

Density of  $\mathcal{W}_\mu(X)$  was proved above. Given any short prefix, choose an unused label  $z$  and extend to an enumeration of  $X \setminus \{z\}$ . This gives a nonexhaustive point in the cylinder and proves density of the complement.  $\square$

The last result is a generalized dense-intersection description, not automatically an ordinary  $G_\delta$  statement. It becomes a  $G_\delta$  statement when  $X$  is countable. At larger cardinalities, the number of exhaustion requirements matters.

### 65.1.2 A concrete failure of forward completeness

**Example 65.3** (A label escaping to later and later positions). On  $\mathbb{N}$ , define

$$\pi_n(k) = \begin{cases} k+1, & k < n, \\ 0, & k = n, \\ k, & k > n. \end{cases}$$

Each  $\pi_n$  is the cycle  $(0 \ 1 \ \cdots \ n)$ . For every fixed  $k$ , eventually  $\pi_n(k) = k+1$ , so the sequence is forward Cauchy and converges in  $\mathcal{I}_\omega(\mathbb{N})$  to  $h(k) = k+1$ . The limit omits 0. Equivalently,  $\pi_n^{-1}(0) = n$  never stabilizes. Forward stabilization records where each position goes, but not where each target label comes from.

For arbitrary infinite  $\mu$ , choose a nononto injection  $h : \mu \rightarrow X$  and, for every  $\alpha < \mu$ , an exhaustive extension  $f_\alpha$  of  $h \upharpoonright \alpha$ . The  $\mu$ -indexed net  $(f_\alpha)$  is forward Cauchy with limit  $h$  in  $\mathcal{I}_\mu(X)$  and no limit in  $\mathcal{W}_\mu(X)$ . Thus the forward uniformity is incomplete for every infinite  $\mu$ .

### 65.1.3 Why this is not Dedekind completion

Assume thickness. Let  $\hat{P}$  be the Dedekind completion of the dense order  $P = \mathcal{W}_\mu(X)$ , using nonempty proper lower sets without a greatest element as the cut convention. For  $h \in \mathcal{I}_\mu(X)$ , put

$$L_h = \{f \in P : f <_{\text{lex}} h\}.$$

**Proposition 65.4** (The injection space sits strictly inside order completion). *The map  $h \mapsto L_h$  is an order embedding of  $\mathcal{I}_\mu(X)$  into  $\hat{P}$  extending the canonical embedding of  $P$ . If  $h$  is nonexhaustive, its image is a nonprincipal cut of  $P$ . This map is not onto: even cylinder-edge cuts need not come from injective words.*

*Proof.* For  $h < k$  in  $\mathcal{I}_\mu(X)$ , choose an unused label strictly between their values at the first disagreement and complete the resulting prefix exhaustively. This gives  $f \in P$  with  $h < f < k$ . Repeating the same argument supplies exhaustive words on either side of any injection and between any injection and a strictly smaller or larger exhaustive word. It follows that  $L_h$  is a valid cut, that the map is strictly order preserving, and that a nonexhaustive  $h$  has neither a greatest exhaustive word below it nor a least exhaustive word above it. If its cut were the cut of an exhaustive  $g$ , the same separation argument between  $h$  and  $g$  would be a contradiction.

Fix  $x \in X$ . Consider the lower edge of the cylinder  $[\langle x \rangle]$ :

$$L = \{f \in P : f(0) < x\}.$$

This is a nonempty proper lower set with no greatest element. An injection beginning with a label below  $x$  is not cofinal in this lower side, by density of the alphabet. An injection beginning above  $x$  lies above the entire  $x$ -cylinder. An injection beginning exactly with  $x$  has exhaustive words with that same first label strictly below it. Its lower cut therefore contains words not in  $L$ . These three cases exhaust the possibilities, so  $L$  is not  $L_h$  for any injection  $h$ .  $\square$

Thus there are at least two qualitatively different boundaries. A *branch boundary* is an injective full-length word missing labels. A *prefix edge* ends a cylinder without selecting a full continuation. Alphabet gaps create further order-completion points. Earlier cut-classification results (sources 17 and 13; [section 30.2](#)) organize these possibilities more finely; [Theorem 65.1](#) identifies exactly the part visible to the forward uniformity.

*Note 65.5* (Source 26, [Theorem 4.1](#) and [Proposition 4.2](#)). Source 26's [Theorem 4.1](#) (“Forward completion; earlier result reproved”):  $\mathcal{I}_\mu(X)$  is complete for the forward-prefix uniformity, and the inclusion  $\mathcal{W}_\mu(X) \subseteq \mathcal{I}_\mu(X)$  exhibits it as the Hausdorff uniform completion of the permutation space. Its [Proposition 4.2](#) (“Exhaustion requirements”): each  $U_x = \{h \in \mathcal{I}_\mu(X) : x \in \text{ran } h\}$  is open dense,  $\mathcal{W}_\mu(X) = \bigcap_{x \in X} U_x$ , and the complement  $F_x$  is closed nowhere dense and nonempty. These are [theorems 65.1](#) and [65.2](#); source 26 says “This is the mechanism of the earlier completion theorem” (source 24), and stresses that at uncountable  $\mu$  “a Cauchy filter must eventually stabilize every bounded prefix; pointwise stabilization of isolated coordinates alone is not the definition”. It adds: “The missing points of the uniform completion are therefore precisely the nonexhaustive injections. This is not a Dedekind completion theorem. Order completion can add cylinder edges and gaps in the alphabet that are not represented by a full injective branch ... the non-Borel theorem below concerns the branch boundary already present in  $\mathcal{I}_\mu(X)$ ” ([theorem 69.17](#)).

## 65.2 First-cardinality fibres and the closure of the minimal stratum (source 21)

[merge] Source 21's Section 4, printed whole. Its first-cardinality decomposition is the set-level form of the fibre decomposition of class well-orders that source 16 proves in Part VIII (equation (S16.12)) and of source 22's residual-cylinder identity (theorem 63.1); the closure theorem is new. Source 21's  $\mathcal{I}_\mu(X)$  is this Part's.

The set-sized setting already contains a useful prototype of the proper-class residual-tail phenomenon. No higher-order foundation is needed for it.

**Theorem 65.6** (First-cardinality decomposition). *Let  $X$  be any infinite linearly ordered set of cardinality  $\mu$ . There is a canonical order isomorphism*

$$\mathcal{W}(X) \cong \sum_{f \in \mathcal{I}_\mu(X)} \mathcal{W}(X \setminus \text{ran}(f)), \quad (15)$$

where the index set has its numerical lexicographic order and the sum is a lexicographic sum. The fiber over an exhaustive  $f$  is a singleton; the set of these singleton points is exactly  $\mathcal{W}_\mu(X)$ .

*Proof.* Every well-order of  $X$  has an enumeration of ordinal length at least  $\mu$ . Take its first  $\mu$  entries, an injective word  $f$ . The rest of the relation is exactly a well-order of the unused set  $Y_f = X \setminus \text{ran}(f)$ . Conversely, concatenate  $f$  with the enumeration of any well-order of  $Y_f$ . This uses every label exactly once and produces a well-order of  $X$ . The two constructions are inverse.

If two first words differ, their first disagreement occurs below  $\mu$  and decides the comparison of all corresponding completions. If they agree, comparison reduces to the residual well-orders. This is precisely the lexicographic sum in (15). For  $Y_f = \emptyset$  there is one empty residual relation. For  $Y_f \neq \emptyset$ , the concatenation has length strictly greater than  $\mu$ , so it does not belong to the minimum stratum.  $\square$

One should not confuse a singleton fiber with an exhaustive word. A one-element residual set also has only one well-order. Thus the unlabelled size of a fiber cannot detect exhaustivity.

**Lemma 65.7** (Endpoints of a residual enumeration order). *For any set  $Y$  with a linear label order,  $\mathcal{W}(Y)$  has a least element if and only if the label order  $<$  well-orders  $Y$ . It then consists of listing  $Y$  in that order. It has a greatest element if and only if the reverse label order well-orders  $Y$ .*

*Proof.* If  $<$  is a well-order, its increasing enumeration chooses the least unused label at every stage. Every first disagreement in another enumeration is larger, so this is the lexicographic minimum. Conversely, if a lexicographic minimum ever chooses a label while a smaller unused label remains, interchange the chosen label with that later label. The resulting well-order is smaller. Hence a minimum always chooses the least unused label; its enumeration shows that the label order itself is a well-order. Reverse the inequalities for the greatest element.  $\square$

**Lemma 65.8** (Density of exhaustive branches in the index order). *If  $X$  has uniformly large intervals, the exhaustive words  $\mathcal{W}_\mu(X)$  are order-dense in  $\mathcal{I}_\mu(X)$ , and there are exhaustive words on both sides of every nonexhaustive word.*

*Proof.* For  $f < g$ , let  $\delta < \mu$  be their first disagreement. Fewer than  $\mu$  labels occur in the common prefix. Choose an unused label strictly between  $f(\delta)$  and  $g(\delta)$  and complete that prefix to an exhaustive  $\mu$ -word. It lies strictly between  $f$  and  $g$ . To obtain exhaustive words on both sides of a single branch, choose unused labels below and above its first label, respectively, and complete.  $\square$

**Theorem 65.9** (Closure theorem). *Assume  $X$  has uniformly large intervals. In the order topology of  $\mathcal{W}(X)$ , the closure of  $\mathcal{W}_\mu(X)$  consists of:*

1. every point of  $\mathcal{W}_\mu(X)$ ; and
2. the least and greatest point, when they exist, of each fiber over a nonexhaustive  $f \in \mathcal{I}_\mu(X)$ .

By [lemma 65.7](#), the added endpoints are exactly the orders obtained by following  $f$  with an increasing or decreasing numerical well-order of its unused set.

*Proof.* An interior point of a nonexhaustive fiber has a point of that fiber on each side. The open interval between those two points is disjoint from  $\mathcal{W}_\mu(X)$ , so the point is not in the closure.

Suppose  $R$  is the least point of its fiber over  $f$ . If  $A < R < B$ , then  $A$  cannot lie in the same fiber. Its first  $\mu$  entries form a word  $g < f$ . By [lemma 65.8](#) choose an exhaustive word  $h$  with  $g < h < f$ . Its singleton fiber gives a point of  $\mathcal{W}_\mu(X)$  between  $A$  and  $R$ , hence inside  $(A, B)$ . Thus every neighborhood of  $R$  meets the minimum stratum. The greatest-point case is symmetric. A singleton fiber satisfies both arguments.  $\square$

**Example 65.10** (Finite and infinite residuals). If  $f$  omits a finite set of size  $n$ , its fiber is an  $n!$ -element chain. For  $n = 1$  the unique point is in the closure; for  $n = 2$  both points are; for  $n \geq 3$  only the two extreme permutations are. If  $X = \mathbb{Q}$  and  $f : \omega \rightarrow \mathbb{Q} \setminus \mathbb{N}$  is a bijection, the residual  $\mathbb{N}$  has a numerical well-order but its reverse does not. Exactly the least point of this infinite fiber is in the closure. If the unused set has order type  $\mathbb{Q}$ , neither endpoint exists, and its entire fiber is disjoint from the closure.

The closure theorem describes the relative position of strata, not just their separate cardinalities. It also identifies the information lost by retaining only the first  $\mu$  entries: all residual well-order choices are compressed to a single index. At the class level the first Ord-block plays the analogous role, but its fibers are no longer automatically set-sized.

### 65.3 Normal forms for the Dedekind completion of the minimal slice (source 19)

[merge] Source 19's Section 7, printed whole. Its three kinds of cut are source 17's cut trichotomy ([lemma 30.8](#)): a branch, an edge at a last straddling prefix, a limit-prefix boundary. New in source 19 are the uniqueness of the codes, the order read directly from them, and the sign codes of the residual splits ([proposition 65.12](#)). "The gap spectrum in the preceding research" is [theorem 30.11](#) (source 17) with source 18's multiplicities [theorem 30.16](#). Its full-branch cuts  $L_f$  are source 24's trace cuts ([proposition 65.4](#)). Source 19's  $\text{Perm}_\mu(D)$  is printed  $\mathcal{W}_\mu(D)$ ; its alphabet  $D$  is thick.

The gap spectrum in the preceding research identifies possible characters and their multiplicities. The same prefix analysis gives more information: it describes the arrangement of the completion points through unique decorated-word codes. This construction is entirely set-sized and therefore takes place in ZFC.

Let  $D$  be a dense linear order without endpoints, of infinite cardinality  $\mu$ , and assume that every nonempty open interval of  $D$  has cardinality  $\mu$ . Put

$$P = \mathcal{W}_\mu(D) = \{e : \mu \longrightarrow D : e \text{ is bijective}\}.$$

The application is  $D = \mathbf{No}_{<\kappa}$  and  $\mu = 2^{<\kappa}$  for an infinite initial cardinal  $\kappa$ . For an injective prefix  $p : \delta \rightarrow D$ ,  $\delta < \mu$ , write

$$C_p = \{e \in P : e \restriction \delta = p\}, \quad D_p = D \setminus \text{ran}(p).$$

The cylinder  $C_p$  is nonempty and convex. Since fewer than  $\mu$  labels have been used,  $D_p$  still meets every nonempty interval and is unbounded in both directions. In particular, every cylinder has neither a first nor a last member.

Use the following convention for the Dedekind completion:  $\overline{P}$  consists of the nonempty proper initial subsets of  $P$  having no greatest element, ordered by inclusion. The point  $e \in P$  is represented by  $P_{<e}$ . The two external endpoints can be added separately when a compactified completion is wanted.

**Theorem 65.11** (Unique normal forms for the completion). *Every point of  $\overline{P}$  has exactly one code of one of the following three kinds.*

1. **A full branch.** An injection  $f : \mu \rightarrow D$ , representing

$$L_f = \{e \in P : e < f\}.$$

*If  $f$  is onto, this is the original point  $f$ ; otherwise it is an omitted-branch gap.*

2. **A numerical split.** A pair  $(p, I)$ , where  $p$  has length  $\delta < \mu$  and  $I$  is a nonempty proper initial subset of  $D_p$ , representing

$$L_{p,I} = \{e : e < C_p\} \cup \{e \in C_p : e(\delta) \in I\}.$$

*Here  $e < C_p$  means that  $e$  lies below every member of the cylinder. The set  $I$  may have a greatest member, and its complement may have a least member. This kind always represents a proper gap.*

3. **A limit-prefix boundary.** A pair  $(p, \varepsilon)$ , where  $p$  has nonzero limit length  $\delta < \mu$  and  $\varepsilon \in \{-, +\}$ , representing respectively

$$L_{p,-} = \{e : e < C_p\}, \quad L_{p,+} = \{e : e < C_p\} \cup C_p.$$

*Both are proper gaps.*

*The restrictions in this list eliminate all duplication. In particular, a successor-prefix boundary is already a numerical-split code at its predecessor; a principal point is represented only by its full surjective branch.*

*Proof.* Let  $L \in \overline{P}$ , and let  $K$  consist of the short injective prefixes whose cylinders meet both  $L$  and  $P \setminus L$ . Two incompatible cylinders are disjoint convex sets, so they cannot both straddle one cut. Thus  $K$  is a downward-closed chain under extension. It contains the empty prefix because both sides of the cut are nonempty.

If  $K$  has a greatest member  $p$ , no child cylinder straddles. Partition  $D_p$  according to whether its entire child cylinder is in  $L$  or in  $P \setminus L$ . Both parts are nonempty since  $C_p$  straddles. The lower digit part is an initial subset  $I$ , and the cut is precisely  $L_{p,I}$ . Both sides have no endpoint: if a digit side has an endpoint, its final or initial child cylinder still has no endpoint; otherwise the varying next digits themselves defeat an endpoint. The longest straddling prefix and its partition are intrinsic to  $L$ , proving uniqueness in this case.

Suppose that  $K$  has no greatest member and its lengths have supremum  $\delta < \mu$ . The union  $p = \bigcup K$  is injective and has nonzero limit length  $\delta$ . Its cylinder does not straddle, for then  $p$  would be a greatest member of  $K$ . If  $C_p \subseteq P \setminus L$ , the cut is the lower boundary of  $C_p$ : any point below  $C_p$  disagrees with  $p$  at an earlier coordinate, and a longer member of  $K$  has a point of  $L$  above it. Every point above or in  $C_p$  belongs to the upper side. The reverse argument gives the upper boundary when  $C_p \subseteq L$ . The union  $p$  and the side containing its cylinder are intrinsic.

In the remaining case the lengths in  $K$  are cofinal in  $\mu$ . Their union is an injection  $f : \mu \rightarrow D$ . Every permutation  $e$  different from  $f$  has a first disagreement with it. Looking at a longer straddling prefix shows that  $e \in L$  exactly when  $e < f$ . If  $f$  is onto, it belongs to  $P$  and cannot lie in  $L$ ,

because then it would be the greatest member of  $L$ . Consequently  $L = L_f$  in the onto case as well as the non-onto case. The word  $f$  is uniquely recovered as the union of  $K$ .

Conversely, the displayed codes have exactly their asserted straddling patterns. For a numerical split,  $p$  is the last straddling prefix. For a limit boundary, all proper prefixes of  $p$  straddle and  $p$  itself does not. To see straddling arbitrarily late, choose unused smaller and larger next digits and complete the resulting prefixes. For a full branch, every short prefix straddles by the same construction. The full-interval-size hypothesis ensures the requisite fresh digits, and each resulting short injection has a bijective completion. All displayed lower subsets are nonempty, proper, and have no greatest member. Their distinct patterns exclude duplication between the three kinds.  $\square$

### 65.3.1 How the normal forms are ordered

The order can be read directly from the codes; it need not be reconstructed from cofinality data. Compare actual entries up to their first disagreement. If there is such a disagreement, use the order of  $D$ . If one code ends at  $p$  while the other continues with next label  $x$ , a numerical-split token  $I$  lies above the continuing code exactly when  $x \in I$ , and below it exactly when  $x \notin I$ . A boundary token  $p^-$  lies below every code continuing  $p$ , and  $p^+$  lies above them all. Numerical-split tokens at the same prefix compare by inclusion of their initial subsets. At a limit prefix,  $p^-$  is below all numerical-split tokens and  $p^+$  is above all of them.

There is a necessary distinction at an available next letter  $x$ :

$$I_x^- = \{y \in D_p : y < x\}, \quad I_x^+ = \{y \in D_p : y \leq x\}.$$

These are different initial subsets and represent the two different boundaries of  $C_{p \smallfrown x}$ . Identifying them would collapse a whole nonempty interval of the completion. In contrast, a successor boundary must not be added again as a separate boundary code.

The theorem realizes the completion as an explicit decorated tree order. Every automorphism of  $P$  extends uniquely to it through its action on cuts. This alone does not say that the automorphism preserves the three kinds of code or the displayed prefix tree.

### 65.3.2 Surreal sign codes for the residual numerical splits

For the surreal cutoff, even the residual-cut parameter has a concrete sign description.

**Proposition 65.12** (The exact identifications after deleting labels). *For  $D = \mathbf{No}_{<\kappa}$ , initial subsets of  $D$ , including the two external ends and both principal cuts at a point, are in bijection with sign words of length  $\kappa$ . Initial subsets of  $D_p$  are obtained by restricting these cuts. This restriction identifies exactly the pair of principal cuts immediately below and immediately above each deleted point  $x \in \text{ran}(p)$ , and makes no other identifications.*

*Proof.* Given an initial subset  $A$  of  $D$ , recursively construct  $s : \kappa \rightarrow \{-, +\}$  by

$$s(\alpha) = + \iff s \restriction \alpha \in A.$$

Every proper prefix is a surreal in  $D$ . A first-disagreement comparison proves  $A = \{x \in D : x < s\}$ . If  $x$  is a proper prefix of  $s$ , its membership is exactly the defining condition at its length. At a genuine first disagreement, the membership of the common prefix and initiality of  $A$  give the same conclusion. Conversely, the cut induced by a length- $\kappa$  sign word reconstructs that word by this recursion, proving the bijection.

Restriction to  $D_p$  is surjective: for an initial subset  $I$  of  $D_p$ , its downward closure in  $D$  induces exactly  $I$ . Suppose  $A \subsetneq B$  are two initial subsets of  $D$  with the same restriction. If  $B \setminus A$  contained

$x < y$ , there would be  $z \in D_p$  strictly between them because  $D_p$  is dense in  $D$ . Initiality gives  $z \in B \setminus A$ , a contradiction. The difference therefore consists of one deleted point  $x$ . The two cuts must then be  $\{y : y < x\}$  and  $\{y : y \leq x\}$ . Each such pair plainly has equal restriction. This proves that there are no further identifications.  $\square$

Thus numerical-split tokens can be coded by length- $\kappa$  sign words modulo these precisely specified deleted-point pairs, with the two residual endpoints excluded. All branches, prefixes, quotients, and completion points in this construction are sets.

An unrestricted analogue for global surreal well-orders would require a collection of arbitrary class cuts. A higher sort, an external containing universe, or a supplied uniform family must be specified before forming it. Applying the same first-failure argument to individually supplied classes does not create a GB class whose elements are all such cuts, and does not turn the raw global well-order family into a completion of its core.

## 66 A generalized Baire model at every regular size (source 24)

[merge] Source 24's Section 6, printed whole. It determines the topology, not the order, of the minimal slice at every regular enumeration cardinal  $\mu$ : the slice is homeomorphic to the bounded-topology space  $(\mu^{<\mu})^\mu$ , with no hypothesis  $\mu^{<\mu} = \mu$  and no GCH. For  $X = \mathbf{No}_{<\kappa}$  this answers source 12's question "Classify the order topology" (research question 113.13) whenever  $\mu = 2^{<\kappa}$  is regular (section 72). Source 28 recalls the construction and its singular obstruction (section 70.7).

For a cardinal  $\lambda$  and an infinite cardinal  $\mu$ , the *bounded topology* on  $\lambda^\mu$  has basic open sets

$$N_s = \{a \in \lambda^\mu : s \subseteq a\}, \quad s \in \lambda^\alpha, \quad \alpha < \mu.$$

When  $\mu$  is uncountable this is usually finer than the ordinary product topology, which permits only finitely many coordinate restrictions. Generalized descriptive set theory systematically studies this distinction [61]. We keep the topology explicit rather than relying on an ambiguous use of "Baire space."

### 66.0.1 The exhaustion-adapted prefix tree

Fix a bijection  $e : \mu \rightarrow X$ . For a short injective prefix  $p$ , let

$$m(p) = \min\{\xi < \mu : e(\xi) \notin \text{ran } p\}.$$

This exists because  $|\text{dom } p| < \mu$ . A *child* of  $p$  is an extension in which the label  $e(m(p))$  first appears at the very end:

$$q = p \frown t \frown \langle e(m(p)) \rangle, \quad t \in \text{Inj}(\delta, X \setminus (\text{ran } p \cup \{e(m(p))\})), \quad \delta < \mu.$$

All these extensions are short. Different children are incompatible: neither is a proper prefix of the other, because the earlier one would already have used the distinguished label. Every exhaustive extension of  $p$  extends exactly one child, namely the prefix ending at its first occurrence of that label.

**Lemma 66.1** (Exact branching number). *Each node  $p$  has exactly  $\lambda = \mu^{<\mu}$  children.*

*Proof.* The available labels for  $t$  have size  $\mu$ . For each ordinal  $\delta < \mu$ , the number of injections from  $\delta$  into a set of size  $\mu$  is  $\mu^{|\delta|}$ . For nonzero  $\delta$ , the lower bound follows by coding an arbitrary function  $a : \delta \rightarrow \mu$  as the injection  $\xi \mapsto (\xi, a(\xi))$  and then using a fixed bijection from  $\delta \times \mu$  to  $\mu$ ; the upper bound is immediate. The zero-length case contributes one. Summing over  $\delta < \mu$  gives  $\mu^{<\mu}$ , since that cardinal is at least  $\mu$ .  $\square$

The rule uses a well-order of the *set of labels* only to decide which coverage requirement to enforce next. It is independent of their numerical order. This is why it can classify the topology without classifying the linear order.

**Theorem 66.2** (Regular-cardinal topological classification). *If  $\mu$  is infinite regular,  $|X| = \mu$ , and  $\lambda = \mu^{<\mu}$ , there is a homeomorphism*

$$\Phi : \lambda^\mu \longrightarrow \mathcal{W}_\mu(X)$$

*for the bounded topology and the prefix topology. If  $X$  is  $\mu$ -thick, the latter is its lexicographic order topology.*

*Proof.* Using Choice, label the children of every short injective prefix by  $\lambda$ . Define prefixes  $p_s$  for  $s \in \lambda^{<\mu}$  by recursion. Let  $p_\emptyset$  be empty. At a successor stage let  $p_{s \smallfrown \langle i \rangle}$  be the child of  $p_s$  labelled by  $i$ . At a limit  $\eta < \mu$ , define

$$p_s = \bigcup_{\xi < \eta} p_{s \upharpoonright \xi} \quad (\text{dom } s = \eta).$$

Regularity of  $\mu$  is used here: the supremum of fewer than  $\mu$  prefix lengths, each below  $\mu$ , is still below  $\mu$ . The union is injective and hence is a valid node.

For a branch  $a \in \lambda^\mu$ , put

$$\Phi(a) = \bigcup_{\xi < \mu} p_{a \upharpoonright \xi}.$$

Every successor step increases the prefix length. Thus these lengths are cofinal in  $\mu$ , and the union has domain  $\mu$ . It is injective. At stage  $\xi$ , the prefix contains every label  $e(\zeta)$  with  $\zeta < \xi$ : prove this by induction. At a successor, either  $e(\xi)$  is already present or it is exactly the least missing label and the child adds it. At a limit, take the union. Therefore  $\Phi(a)$  is exhaustive.

Conversely, an exhaustive  $f : \mu \rightarrow X$  chooses a unique child of the empty prefix, then a unique child of that child, and so on. At limit stages take the already-determined prefix union. All intermediate prefixes are short by regularity and remain restrictions of  $f$ . This defines a unique branch  $a$  with  $\Phi(a) = f$ .

The correspondence satisfies

$$\Phi[N_s] = [p_s]_P.$$

Indeed, a permutation extending  $p_s$  must have followed the unique distinguished-label choices along the path to  $s$ . Hence  $\Phi$  is an open bijection. To check continuity, take  $f = \Phi(a)$  and a prescribed prefix length  $\alpha < \mu$ . Some  $p_{a \upharpoonright \xi}$  has length at least  $\alpha$ , so its cylinder lies inside  $[f \upharpoonright \alpha]$ . The preimage of every cylinder is open. This proves the homeomorphism, and Lemma 62.5 supplies the final order-topological identification.  $\square$

**Corollary 66.3** (Size-matched regular cutoffs). *If  $\mu = 2^{<\kappa}$  is regular, then*

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \cong_{\text{top}} (\mu^{<\mu})^\mu.$$

*In particular, if  $\mu^{<\mu} = \mu$ , this is the usual bounded-topology generalized Baire space  $\mu^\mu$ .*

No continuum hypothesis or generalized continuum hypothesis has been used. The branching cardinal is retained as  $\mu^{<\mu}$  rather than being silently replaced by  $\mu$ . The regularity hypothesis is on the *enumeration cardinal*  $\mu$ ; regularity of the birthday parameter  $\kappa$  alone is not the statement of the theorem.

### 66.0.2 Why the construction does not contradict forward incompleteness

The full branch space  $\lambda^\mu$  is complete for its own prefix uniformity: a Cauchy filter stabilizes a unique prefix at every height, and the union is a branch. The homeomorphism  $\Phi$  transports this complete uniformity to a compatible complete uniformity on  $\mathcal{W}_\mu(X)$ .

This is not the forward uniformity of Section 65.1. A height in the exhaustion-adapted tree means that a prescribed list of labels has already been covered. The amount of ordinary enumeration needed to achieve that height varies from branch to branch and is not uniformly bounded. In the countable example, the place at which 0 first occurs can be arbitrarily late. Homeomorphisms preserve topology, not a chosen uniformity or the completeness of every compatible metric.

### 66.0.3 The exact point where singularity intervenes

If  $\mu$  is singular, a chain of fewer than  $\mu$  short prefixes can have union of length  $\mu$ . It can therefore reach a full injective word before all  $\mu$  coverage requirements have been visited. There is no short node at that limit stage to which the same child construction can be applied. This is a concrete obstruction to *this proof*, not a proof that no other generalized Baire presentation exists.

The distinction will recur in Section 69.1: at a singular cardinal a small-cardinality set of coordinates may be unbounded. Arguments that control finitely or cardinally few positions do not automatically control one bounded initial segment.

## 67 The countable cutoff (source 24; routes of sources 19, 20, 21, 26, 29 and 30)

*Note 67.1* ([merge]; one theorem, seven proofs). For every countable dense alphabet  $X$  without endpoints, in particular for the finite-birthday surreals  $\mathbf{No}_{<\omega}$ , the minimal slice  $\mathcal{W}_\omega(X)$  is homeomorphic to Baire space  $\omega^\omega$ , its Dedekind completion is the real line, every interval of the completion contains continuum many omitted points, and the slice is not order-isomorphic to the irrationals. Seven batch-83 sources prove this independently: source 24 (theorems 67.2 and 67.4, lemma 67.3, and corollary 67.5, printed below as the base: it alone gives both a complete compatible metric for the original topology and the exact descriptive form of the complement); source 19 (theorem 67.13, which adds that every interval also contains continuum many original points); source 20 (theorem 67.11, which adds that the slice is not  $F_\sigma$  in its completion); source 21 (theorems 67.6 and 67.10, which add a second mechanism of omitted cuts, and its homogeneity theorem theorem 67.8); source 26 (proposition 69.11, complete metrizability only); source 29 (theorem 68.2, case  $n = 0$ , set beside the slices with finitely many omitted labels); and source 30 (proposition 68.4 and note 68.5). Five build the homeomorphism with  $\omega^\omega$  by the same least-missing-label tree (sources 19, 20, 24, 30, and source 29 by citation); source 21 uses an even-odd back-and-forth coding. The  $G_\delta$  description through cylinder intervals and label requirements is common to sources 19, 20 and 24; source 26 obtains complete metrizability from the  $G_\delta$  criterion proposition 69.8. In this report the case was the example example 30.19 (“a Baire, zero-dimensional order”, with the warning that these facts do not identify it with the real line). No source has priority over another. The routes are printed after source 24’s text, each whole, because each adds a clause or a different proof.

[merge] Source 24’s Section 7, “The countable cutoff: a complete metric but a different order”.

Let  $X$  be countable, densely ordered, and without endpoints. This includes  $\mathbf{No}_{<\omega} = \mathbf{No}_{<\omega}$ , the finite sign sequences. Every nonempty interval and ray of such an  $X$  is infinite, so the thickness hypothesis holds with  $\mu = \omega$ .

### 67.0.1 An explicit complete compatible metric

Fix  $e : \omega \rightarrow X$  and identify  $f \in \mathcal{W}_\omega(X)$  with the permutation  $\pi = e^{-1} \circ f$  of  $\omega$ . On injections or permutations of  $\omega$ , define

$$d_{\rightarrow}(\pi, \sigma) = \begin{cases} 0, & \pi = \sigma, \\ 2^{-\min\{k : \pi(k) \neq \sigma(k)\}}, & \pi \neq \sigma. \end{cases}$$

This familiar forward ultrametric is not complete on permutations, by Example 65.3. Instead put

$$D(\pi, \sigma) = \max\{d_{\rightarrow}(\pi, \sigma), d_{\rightarrow}(\pi^{-1}, \sigma^{-1})\}.$$

**Theorem 67.2** (Complete metrization at countable size). *The metric  $D$  is a complete compatible ultrametric on  $\mathcal{W}_\omega(X)$ . This space is homeomorphic to  $\omega^\omega$ , has no isolated points, and is nowhere locally compact.*

*Proof.* The maximum of the two ultrametrics is an ultrametric. To see compatibility, finitely many inverse requirements at a fixed  $\pi$  are enforced by finitely many forward requirements: to ensure  $\sigma^{-1}(j) = \pi^{-1}(j)$  for  $j < n$ , require  $\sigma$  to agree with  $\pi$  at all the finitely many positions  $\pi^{-1}(j)$ . One sufficiently long forward prefix does this. Hence adding inverse requirements does not change the topology.

For a  $D$ -Cauchy sequence  $(\pi_n)$ , each forward coordinate and each inverse coordinate eventually stabilizes. Let their limits be  $h$  and  $g$ . If  $h(k) = j$ , sufficiently late terms have  $\pi_n(k) = j$  and  $\pi_n^{-1}(j) = g(j)$  simultaneously. Thus  $g(j) = k$ . Conversely, if  $g(j) = k$ , the same argument gives  $h(k) = j$ . Therefore  $g = h^{-1}$  and  $h$  is a permutation. The original sequence converges to it in  $D$ .

Theorem 66.2 gives the homeomorphism with  $\omega^\omega$ , since  $\omega^{<\omega} = \omega$ . Every finite prefix admits at least two continuations, so there are no isolated points. Each cylinder is partitioned by its exhaustion-adapted children into countably infinitely many nonempty open cylinders. That cover has no finite subcover, so the original cylinder is not compact. If a point had a compact neighborhood, it would contain a cylinder, which is closed in the whole space and hence would be a compact closed subset of that neighborhood. This contradiction proves nowhere local compactness.  $\square$

### 67.0.2 The Dedekind completion is a real line

**Lemma 67.3** (A countable order-dense subset). *The order  $\mathcal{W}_\omega(X)$  is separable and dense without endpoints. Its Dedekind completion is order-isomorphic to  $\mathbb{R}$ .*

*Proof.* There are countably many finite injective prefixes. Choose one exhaustive extension for each. These chosen points meet every nonempty cylinder and hence every nonempty open interval, giving a countable order-dense subset. Density and absence of endpoints were proved in Lemma 62.5.

The completion is consequently a complete dense linear order without endpoints with a countable order-dense subset. For completeness of the identification, a countable order-dense subset has no endpoints and is itself densely ordered; a standard alternating insertion construction gives an order isomorphism with  $\mathbb{Q}$ . Each point of the complete order is uniquely determined by the rational cut below it, and every real cut is realized by a supremum. This extends the countable isomorphism to an isomorphism with  $\mathbb{R}$ .  $\square$

Fix such an identification of the completion with  $\mathbb{R}$ . For a nonempty finite prefix  $p$ , let  $J_p$  be the open interval between the lower and upper completion edges of its cylinder. Then

$$J_p \cap \mathcal{W}_\omega(X) = [p]_P.$$

Both edges exist because a nonempty cylinder is bounded by words with smaller or larger first labels. It has no endpoints and is clopen in the original order, so neither edge lies in that cylinder. For the empty prefix set  $J_\emptyset = \mathbb{R}$ .

**Theorem 67.4** (Exact descriptive form of the omitted points). *Inside its Dedekind completion  $\mathbb{R}$ , the space  $P = \mathcal{W}_\omega(X)$  is a dense  $G_\delta$  set. Its complement is a dense meager  $F_\sigma$  set of cardinality  $2^{\aleph_0}$ .*

*Proof.* For  $n < \omega$  and  $x \in X$ , set

$$V_n = \bigcup_{\substack{p \in \mathcal{I}_{<\omega}(X) \\ |p|=n}} J_p, \quad W_x = \bigcup_{\substack{p \in \mathcal{I}_{<\omega}(X) \\ x \in \text{ran } p}} J_p.$$

All these sets are open and contain  $P$ , hence are dense. We claim

$$P = \bigcap_{n < \omega} V_n \cap \bigcap_{x \in X} W_x. \quad (16)$$

The forward inclusion is immediate. For the reverse inclusion, a point  $z$  belonging to all  $V_n$  chooses a unique length- $n$  prefix  $p_n$  with  $z \in J_{p_n}$ . Distinct same-level intervals are disjoint: a nonempty intersection would be open and meet the dense original order, contradicting disjointness of the corresponding cylinders. The same argument shows that the chosen prefixes are coherent. Their union is an injective  $\omega$ -word  $h$ .

Membership in every  $W_x$  ensures that each label occurs in one of these prefixes. Indeed, if  $z \in J_p$  and  $x \in \text{ran } p$ , comparison with a chosen prefix of length at least  $|p|$  forces compatibility and hence  $p \subseteq h$ . Thus  $h$  is exhaustive. Finally,  $z$  is its completion point: if they differed, an original point strictly between them would have to belong to every sufficiently long cylinder of  $h$ , contrary to its first disagreement with  $h$ . This proves (16).

The complement is therefore  $F_\sigma$  and meager; each closed set complementary to one of the displayed dense open sets is nowhere dense. It is dense as well. Every completion interval contains an original cylinder interval, and every such cylinder contains the trace cut of an injection that extends the prefix but omits an unused label.

For its cardinality, fix a label  $z_0$  and partition  $X \setminus \{z_0\}$  into countably many pairs. Independently ordering each pair gives  $2^{\aleph_0}$  distinct injective words with range exactly  $X \setminus \{z_0\}$ . Proposition 65.4 gives distinct omitted completion points. The opposite bound follows from the cardinality of  $\mathbb{R}$ .  $\square$

**Corollary 67.5** (Homeomorphic to, but not ordered like, the irrationals). *The minimal enumeration order of the countable surreal cutoff is homeomorphic to the Baire space and hence to the usual irrational-number space. It is not order-isomorphic to the irrationals in their usual order.*

*Proof.* The homeomorphism with Baire space was constructed above. The familiar identification of Baire space with irrationals can also be obtained from infinite continued fractions, or from successive countable interval partitions; only the topological assertion is used here. An order isomorphism of dense orders extends uniquely to their Dedekind completions, by transporting lower cuts. The completion of the irrationals omits only the countably many rational points, whereas Theorem 67.4 gives continuum many omitted points for our order. An isomorphism cannot have these two different complements.  $\square$

The completion description gives a particularly concrete answer to the original question at the first infinite cutoff. It is not a strange topology: it is Baire topology. Its unusual feature is the *placement of that topology in a linear order*, with many more omitted order cuts than the standard irrational presentation. The phenomenon is already visible before any genuinely class-sized issues arise.

### 67.1 Source 21's route, with homogeneity and non-intrinsic cylinders

[merge] Source 21's Section 7, printed whole. Its [theorem 67.6](#) and [theorem 67.10](#) are the theorem above by different proofs: the slice is a  $G_\delta$  in the discrete product  $\mathbb{Q}^\omega$ , and an even-odd back-and-forth coding gives the homeomorphism; the completion theorem adds omitted cuts from numerical next-coordinate splits to those from nonexhaustive branches. Its [lemma 67.7](#), [theorem 67.8](#) and [corollary 67.9](#) are new: the countable minimal slice is strongly finitely homogeneous, has  $2^{\aleph_0}$  automorphisms, and its proper prefix cylinders are not definable in the pure order. They answer source 12's question on the "degrees of homogeneity" ([research question 113.13](#)) at  $\kappa = \omega$ , which Part VI left open ([section 33](#), item (b)); the corollary is the set-level counterpart of source 13's class-level prefix non-rigidity ([theorem 47.12](#)).

Let

$$P = \mathcal{W}_\omega(\mathbb{Q}).$$

The rationals here carry their usual numerical order; the points of  $P$  are all exhaustive enumerations of them. Every countable dense alphabet without endpoints gives the same presentation order, by relabelling. In particular, this treats  $\mathcal{W}_\omega(\mathbf{No}_{<\omega})$ , since the finite-birthday surreals form a countable dense order without endpoints. It does not assert that the finite-birthday surreals equal the rational surreals as sets.

#### 67.1.1 Order topology and an explicit Baire coding

**Theorem 67.6.** *The order topology of  $P$  equals its finite-prefix topology, equivalently the subspace topology inherited from the product of countably many copies of discrete  $\mathbb{Q}$ . It is a zero-dimensional Polish space, homeomorphic to Baire space  $\omega^\omega$ , and it is nowhere locally compact.*

*Proof.* The equality of topologies and the clopen-cylinder assertion follow from [note 62.13](#). In discrete  $\mathbb{Q}^\omega$ , the injective words form a closed subspace. The surjectivity requirement is

$$\bigcap_{q \in \mathbb{Q}} \bigcup_{n < \omega} \{e : e(n) = q\},$$

a countable intersection of open sets. Thus  $P$  is a  $G_\delta$  subspace of a Polish space and is Polish.

Here is also a direct homeomorphism with Baire space, so no topological classification theorem is necessary. Fix a bijection of the underlying set  $\mathbb{Q}$  with  $\omega$  and view a point as a permutation of  $\omega$ . Given  $c \in \omega^\omega$ , build finite partial bijections  $p_s$ . At even stage  $s$ , take the least unused domain element and send it to the  $c(s)$ th unused range element. At odd stage  $s$ , take the least unused range element and assign it to the  $c(s)$ th unused domain element. Unused elements are listed in their natural order.

Every stage adds one pair. The even stages exhaust the domain and the odd stages exhaust the range, so the union is a permutation. Conversely, for a given permutation each prescribed even or odd step has a unique rank among the unused choices, recovering a unique  $c$ . The forward map is continuous because each finite construction stage uses only a finite prefix of  $c$ . Its inverse is continuous because a finite construction trace inspects finitely many values of the permutation or its inverse, and

$$\pi^{-1}(r) = d \iff \pi(d) = r$$

is a clopen coordinate condition. This proves the homeomorphism.

Finally, a cylinder with a prefix of length  $n$  has a continuous surjection, by its next coordinate, onto the infinite discrete set of unused rational labels. It is therefore not compact. If a point had a neighborhood with compact closure, that neighborhood would contain a clopen cylinder. The cylinder would be a closed subset of the compact closure, a contradiction.  $\square$

The adjective “discrete” matters. If one uses the ordinary Euclidean topology on the rational coordinate alphabet, the topology of coordinate agreement is no longer the product topology being described here. At uncountable lengths the bounded-prefix topology requires its own formulation as well.

### 67.1.2 Absorption and interval self-similarity

**Lemma 67.7** (Countable sums are absorbed). *For every nonempty countable linear order  $J$ ,*

$$\sum_{j \in J} P \cong P.$$

*Every nonempty finite-prefix cylinder of  $P$  is also isomorphic to  $P$ .*

*Proof.* After a finite prefix, the unused alphabet is  $\mathbb{Q}$  minus finitely many points. It is again a countable dense order without endpoints and hence isomorphic to  $\mathbb{Q}$ . Reindex the remaining  $\omega$  positions and relabel by such an isomorphism. This proves the cylinder assertion. In particular, first-coordinate decomposition gives

$$P \cong \sum_{q \in \mathbb{Q}} P.$$

Therefore

$$\sum_{j \in J} P \cong \sum_{j \in J} \sum_{q \in \mathbb{Q}} P \cong \sum_{t \in \sum_J \mathbb{Q}} P.$$

The index order  $\sum_J \mathbb{Q}$  is countable, dense, and without endpoints: inside a fiber use density of  $\mathbb{Q}$ , and between distinct fibers use the absence of an endpoint in either relevant copy of  $\mathbb{Q}$ . It is isomorphic to  $\mathbb{Q}$ , completing the proof.  $\square$

**Theorem 67.8** (Strong finite homogeneity). *Every nonempty bounded open interval and every open ray of  $P$  is order-isomorphic to  $P$ . Every finite increasing partial map from  $P$  to itself extends to an order automorphism. Moreover,*

$$|\text{Aut}(P, <)| = 2^{\aleph_0}.$$

*Proof.* Fix  $e \in P$ . Partition the points below  $e$  according to their first disagreement position  $n$ . At a fixed  $n$ , the smaller unused labels form a countable dense order without endpoints, and each such next label has a completion cylinder isomorphic to  $P$ . Thus each part is a  $\mathbb{Q}$ -sum of copies of  $P$ , hence isomorphic to  $P$ . These parts occur in increasing order of  $n$ , giving

$$(-\infty, e)_P \cong \sum_{n < \omega} P \cong P.$$

For the upper ray the first-disagreement parts occur in order  $\omega^*$ , and [lemma 67.7](#) again applies.

For  $e < f$ , let  $n$  be their first disagreement. The interval  $(e, f)$  splits into the upper ray after  $e$  within its length- $(n+1)$  cylinder, the cylinders whose next label lies strictly between  $e(n)$  and  $f(n)$ , and the lower ray before  $f$  within its corresponding cylinder. These are respectively a copy of  $P$ , a  $\mathbb{Q}$ -sum of copies of  $P$ , and a copy of  $P$ . Their sum is isomorphic to  $P$ .

Given finite increasing tuples  $e_1 < \dots < e_k$  and  $f_1 < \dots < f_k$ , match the points and choose isomorphisms of their corresponding intervening intervals and two outer rays. Patching the maps gives an automorphism.

Transitivity on the continuum many points of  $P$  gives the lower bound for the automorphism group. Choose one exhaustive completion of each finite injective prefix. The resulting countable set is order-dense. An order automorphism is determined by its values on this set, so there are at most  $|P|^{\aleph_0} = 2^{\aleph_0}$  automorphisms.  $\square$

**Corollary 67.9** (Prefix cylinders are not intrinsic). *The family of proper positive-length prefix cylinders is not invariant under all automorphisms of  $(P, <)$ . No individual such cylinder is definable in the pure order with finitely many parameters.*

*Proof.* Choose two ordered points in one cylinder and two ordered target points with different first coordinates. By [theorem 67.8](#) there is an automorphism carrying the first pair to the second. The image of the cylinder cannot be a positive-length cylinder, since its two target points disagree at their first coordinate. It cannot be the whole space, since the original cylinder was proper.

For the stronger statement, fix finitely many parameters. The automorphisms fixing them pointwise act transitively on each open component of their complement, by the same finite homogeneity theorem. A proper cylinder has no least or greatest point, and its two boundary cuts are omitted. Near either boundary one can choose an inside point and an outside point in the same component of the complement of the finite parameter set. An automorphism fixing all parameters moves the first point to the second and changes cylinder membership. A definable set would have to be invariant under this automorphism.  $\square$

This supplies a negative answer to a concrete prefix-recovery question. The labels and the displayed tree add real structure. An abstract order automorphism has no obligation to respect that tree.

### 67.1.3 Completion: two mechanisms for missing cuts

**Theorem 67.10.** *The Dedekind completion of  $P$  is order-isomorphic to  $\mathbb{R}$ . Every nonempty prefix cylinder has continuum many omitted cuts arising from nonexhaustive branches and continuum many arising from numerical cuts in a next-coordinate alphabet. In particular,*

$$P \not\cong (\mathbb{R} \setminus \mathbb{Q}, <),$$

*although the two spaces are homeomorphic.*

*Proof.*  $P$  is dense, without endpoints, and has a countable order-dense set as in the preceding proof. Its Dedekind completion is consequently a complete separable dense order without endpoints, hence has type  $\mathbb{R}$ .

Fix  $q_0 \in \mathbb{Q}$  and a bijection  $v : \omega \rightarrow \mathbb{Q} \setminus \{q_0\}$ . Its first-disagreement comparison with every member of  $P$  is defined. Put

$$L_v = \{e \in P : e < v\}, \quad R_v = \{e \in P : v < e\}.$$

Both sides are nonempty. Each has no endpoint: after any given finite first disagreement, agree with  $v$  for longer and then choose a fresh smaller or larger rational label. No point of  $P$  realizes the cut, since any different branch can be separated from  $v$  at its first disagreement by a fresh intermediate label. Distinct  $v$  give distinct cuts by the same separation argument. There are continuum many such bijections. The argument works after any fixed finite prefix by omitting a still-unused label.

For a different mechanism, take any irrational real  $r$  and split  $P$  according to  $e(0) < r$  or  $e(0) > r$ . This is a missing cut because no first coordinate equals  $r$ ; both sides approach it through rational first coordinates. Distinct irrationals give distinct cuts. Within a prefix cylinder use the next unused rational coordinate instead. These cuts do not determine a full rational branch through that level, whereas the preceding omitted-range cuts do.

An order isomorphism extends uniquely to the Dedekind completions and preserves the subset of represented points. The irrational order omits only the countably many rational points of its

completion;  $P$  omits continuum many. Hence they are not order-isomorphic. The homeomorphism assertion follows from [theorem 67.6](#) and the standard Baire-space description of the irrationals, or from their usual continued-fraction coding.  $\square$

Thus separability, complete metrizability, interval self-similarity, finite homogeneity, and the size of the completion do not suffice to identify this order with the irrational line. The placement of its omitted cuts is an additional invariant.

## 67.2 Source 20's route: the slice is not $F_\sigma$

[merge] Source 20's Section 9, printed whole. Its proof of the Baire-space homeomorphism and of the  $G_\delta$  description is source 24's; new are the strict Borel classification (the slice is not  $F_\sigma$  in its completion, because Baire space is not  $\sigma$ -compact) and the omitted cuts from irrational first coordinates, which are source 21's second mechanism ([theorem 67.10](#)).

At the first infinite birthday cutoff, the space of enumerations admits an accessible description that also illustrates a limitation of topological classification. Put

$$X = \mathbf{No}_{<\omega}, \quad P = \mathcal{W}_\omega(X) = \{f : \omega \longrightarrow X : f \text{ is a bijection}\},$$

with numerical first-difference comparison. The numerical order on  $X$  is countable, dense, and without endpoints. Thus it is isomorphic to  $\mathbb{Q}$ ; fix one such identification when needed. Everything in this section is an ordinary set theorem in ZFC. In fact, the proofs apply to any countable dense alphabet without endpoints.

For a finite injective word  $s$  over  $X$ , write

$$[s] = \{f \in P : s \text{ is an initial segment of } f\}.$$

Every such cylinder is nonempty: enumerate its countably infinite remaining alphabet after the prescribed prefix.

**Theorem 67.11** (Topology, completion, and omitted cuts). *The order  $P$  has the following properties.*

1. *Its order topology equals the topology of pointwise convergence when the alphabet  $X$  is discrete. The cylinders  $[s]$  are a countable clopen basis.*
2. *Its Dedekind completion is order-isomorphic to  $\mathbb{R}$ . Under any such identification,  $P$  is a dense  $G_\delta$  subset of  $\mathbb{R}$  that is not  $F_\sigma$ .*
3. *As a topological space,  $P$  is homeomorphic to Baire space  $\omega^\omega$ . No point has a compact neighborhood.*
4. *Every nonempty open interval of the completion contains  $2^{\aleph_0}$  omitted points. Consequently,  $P$  is not order-isomorphic to the irrational numbers with their usual order.*

The last two conclusions are compatible. A homeomorphism of spaces need not preserve their displayed linear orders. Here the order remembers the omitted Dedekind cuts, while the topology alone does not remember their number.

### 67.2.1 The topology comes from finite prefixes

**Lemma 67.12.** *Every cylinder  $[s]$  is convex, has no first or last point, and is clopen in the order topology. Conversely, every neighborhood of  $f \in P$  contains a cylinder determined by an initial segment of  $f$ .*

*Proof.* Convexity follows immediately from first-difference comparison: a word that disagrees with  $s$  before the end of  $s$  lies on the same side of every member of  $[s]$ . Let  $n$  be the length of  $s$  and let  $f \in [s]$ . The residual alphabet  $X \setminus \text{ran } s$  remains dense and without endpoints. Choose unused labels  $a < f(n) < b$ . Complete  $s$  followed by  $a$ , and  $s$  followed by  $b$ , to permutations  $g, h$ . Then  $g < f < h$ , and convexity gives  $(g, h) \subseteq [s]$ . This proves openness and also rules out endpoints. The complement of  $[s]$  is the union of all other cylinders of length  $n$ , so  $[s]$  is closed as well.

For the converse, suppose  $g < f < h$ . Let  $i$  and  $j$  be the first positions at which  $f$  differs from  $g$  and  $h$ , respectively. If  $n > \max\{i, j\}$ , then every word sharing  $f$ 's first  $n$  entries remains between  $g$  and  $h$ . The same argument, using one comparison, handles an open ray. Hence the finite cylinders form a basis for the order topology, exactly as they do for pointwise convergence on the discrete alphabet.  $\square$

There are countably many finite prefixes. Choosing one completion of each produces a countable dense subset of  $P$ . Moreover,  $P$  itself is densely ordered: at the first difference between two permutations, choose an unused numerical label strictly between their unequal labels and then complete the resulting prefix. Varying the first label also shows that  $P$  has no endpoints.

For completeness, these facts identify its completion without a cardinality argument. A countable dense subset  $D \subseteq P$  is itself a dense order without endpoints, and the usual alternating extension of finite partial isomorphisms identifies  $D$  with  $\mathbb{Q}$ . Cuts of  $D$  then identify the Dedekind completion of  $P$  with  $\mathbb{R}$ . We henceforth use one such identification and regard  $P$  as a dense suborder of  $\mathbb{R}$ .

### 67.2.2 An explicit homeomorphism with Baire space

Fix a listing  $X = \{x_0, x_1, \dots\}$ . At a finite injective prefix  $s$ , let  $x_{m(s)}$  be the first label in this listing that has not yet appeared in  $s$ . Partition  $[s]$  according to the finite extension ending at the first subsequent occurrence of this required label. The parts are the cylinders  $[t]$  with

$$t = s \frown u \frown \langle x_{m(s)} \rangle,$$

where  $u$  is any finite injective word over  $X \setminus (\text{ran } s \cup \{x_{m(s)}\})$ , including the empty word. These prefixes are pairwise incomparable under extension: each ends precisely at that first occurrence. Their cylinders therefore form a disjoint partition of  $[s]$ . The partition is countably infinite, and we enumerate its members using a fixed coding of finite words by natural numbers.

Given  $z \in \omega^\omega$ , start with  $s_0$  empty and take  $s_{n+1}$  to be the prefix indexing the  $z(n)$ -th part of this partition at  $s_n$ . The union

$$\Phi(z) = \bigcup_{n < \omega} s_n$$

is an injective sequence of length  $\omega$ , because the lengths strictly increase. It is surjective as well: after  $n$  steps all of  $x_0, \dots, x_{n-1}$  have appeared, since every step inserts the least missing label. Thus  $\Phi(z) \in P$ .

Conversely, any  $f \in P$  selects a unique member of each successive partition and hence determines a unique  $z$ . The image of a basic finite-prefix neighborhood in  $\omega^\omega$  is exactly the cylinder  $[s_n]$  reached by that prefix. These are open, and their lengths tend to infinity along each branch. They consequently form a neighborhood basis at  $\Phi(z)$ . This proves directly that  $\Phi$  is a homeomorphism. No compactness theorem or classification theorem for Polish spaces is needed for this construction.

There is also a direct local compactness obstruction. For each  $s$ , the cylinders  $[s \frown \langle a \rangle]$ , as  $a$  ranges over the unused alphabet, are a countably infinite disjoint open cover of  $[s]$  with no finite subcover. Thus  $[s]$  is not compact. If a point had a compact neighborhood, a sufficiently small clopen cylinder inside that neighborhood would be a closed subset of a compact space and hence compact, a contradiction.

### 67.2.3 Recognizing the genuine permutations inside the completion

The  $G_\delta$  assertion has an explicit description in terms of finite prefixes and eventual occurrence of every label. For each nonempty  $s$ , let

$$I_s = (\inf[s], \sup[s]) \subseteq \mathbb{R}, \quad I_\emptyset = \mathbb{R}.$$

The endpoints for nonempty  $s$  are finite: comparison of the first entry with smaller and larger labels bounds the cylinder. By convexity and the absence of endpoints in  $[s]$ ,

$$I_s \cap P = [s]. \quad (17)$$

Intervals belonging to different prefixes of the same length are disjoint. Otherwise their open intersection would meet the dense set  $P$ , contradicting disjointness of the cylinders. More generally, if  $I_s$  and  $I_t$  intersect, their prefixes are comparable under extension.

Define open subsets of the completion by

$$U_n = \bigcup_{\substack{s \text{ injective} \\ |s|=n}} I_s \quad (n \geq 1), \quad V_a = \bigcup_{\substack{s \text{ finite injective} \\ a \in \text{ran } s}} I_s \quad (a \in X).$$

Every permutation belongs to all these open sets. We claim the exact identity

$$P = \bigcap_{n \geq 1} U_n \cap \bigcap_{a \in X} V_a. \quad (18)$$

Indeed, a real point in every  $U_n$  determines a unique prefix  $s_n$  of every length, and the intersection rule makes these prefixes compatible. Their union is an injective sequence  $f$ . Membership in every  $V_a$  forces every label to occur in  $f$ , so  $f \in P$ . The real point in question and  $f$  both lie in every  $I_{s_n}$ . If they were different, a member of the dense set  $P$  strictly between them would lie in every  $I_{s_n}$  and hence share all entries of  $f$ , an impossibility. This proves the identity.

The conditions in (18) have distinct purposes. The  $U_n$  require a genuine label at every position; the  $V_a$  impose exhaustion of the alphabet. An infinite injective word omitting a label is excluded by the second requirement. A cut that separates possible next labels without selecting one is excluded by the first. Since each displayed open set contains the dense set  $P$ , the complement of  $P$  is a countable union of closed nowhere dense sets.

The Borel classification is strict:  $P$  is not  $F_\sigma$  in its completion. First observe that  $\omega^\omega$  is not  $\sigma$ -compact. Given compact sets  $K_n \subseteq \omega^\omega$ , their projections onto coordinate  $n$  are finite; choosing the  $n$ -th entry outside that finite projection constructs a point outside  $\bigcup_n K_n$ . The homeomorphism above gives the same conclusion for  $P$ . But an  $F_\sigma$  subset of  $\mathbb{R}$  is  $\sigma$ -compact, by intersecting its closed pieces with the compact intervals  $[-m, m]$ . This contradiction proves the assertion.

### 67.2.4 Continuum many missing points in every interval

Identify the alphabet with  $\mathbb{Q}$ . For every irrational  $r \in \mathbb{R}$ , split the permutations according to

$$L_r = \{f \in P : f(0) < r\}, \quad R_r = \{f \in P : f(0) > r\}.$$

These two sets partition  $P$ , the first has no greatest member, and the second has no least member. Indeed, a rational first entry can always be chosen closer to  $r$  on its own side and completed to a permutation. Thus this cut is an omitted point of the completion. Distinct irrational numbers

give distinct cuts, because a rational first entry between them separates the cuts. The completion therefore has  $2^{\aleph_0}$  omitted points.

The same argument works inside every cylinder: its residual alphabet is again a countable dense order without endpoints. Every nonempty open interval of the completion contains a cylinder, by density of  $P$  and [lemma 67.12](#). Hence every such interval contains  $2^{\aleph_0}$  omitted points. In particular, the complement is both dense and meager.

Finally, an order isomorphism between two dense orders extends uniquely to an isomorphism of their Dedekind completions, by mapping cuts. If  $P$  were order-isomorphic to  $\mathbb{R} \setminus \mathbb{Q}$ , this extension would identify the omitted points of their completions. One complement has cardinality  $2^{\aleph_0}$  and the other is countable. This is impossible, and completes the proof of [theorem 67.11](#).

This example supplies a specific answer at the level of topology and descriptive complexity. It does not by itself classify the arrangement of all omitted cuts up to order isomorphism. Extending the analysis to uncountable birthday cutoffs requires explicit choices of generalized topology and of the permitted lengths of prefixes; the countable Polish-space conclusions do not transfer merely by replacing  $\omega$  with a larger cardinal.

### 67.3 Source 19's route

[merge] Source 19's Section 8, printed whole. Its  $G_\delta$  proof reads the omitted points off the normal forms of [theorem 65.11](#), and it counts the original as well as the omitted points of every interval.

The first infinite birthday cutoff already distinguishes order type from topology in a concrete way. Let  $D = \mathbf{No}_{<\omega}$  and  $P = \mathcal{W}_\omega(D)$ . The proof below applies to every countable dense alphabet without endpoints.

**Theorem 67.13** (A real completion with many omitted points). *The order  $P$  has the following properties:*

1. *its Dedekind completion is order-isomorphic to  $\mathbb{R}$ ;*
2. *its order topology is homeomorphic to Baire space  $\omega^\omega$ ;*
3. *in its real-line completion it is a dense  $G_\delta$  subset;*
4. *every nonempty open interval of the completion contains  $2^{\aleph_0}$  original points and  $2^{\aleph_0}$  omitted completion points;*
5. *it is not order-isomorphic to the irrational numbers.*

*Proof.* Finite prefix cylinders form a clopen basis for the order topology. For  $e \in C_p$ , choose an unused smaller next digit and an unused larger next digit at some coordinate at or after the end of  $p$ , and complete to obtain  $a < e < b$  inside  $C_p$ . Convexity gives  $(a, b) \subseteq C_p$ , proving openness. Its complement is a union of incompatible prefix cylinders and is also open. Conversely, an interval around  $e$  contains a sufficiently long finite prefix cylinder of  $e$ , since both endpoint comparisons are decided at finite coordinates.

Only countably many finite prefixes exist. Choosing one completion of each gives a countable order-dense subset. The order is dense and has no endpoints. Its Dedekind completion is consequently a complete dense order without endpoints and with a countable dense subset, hence isomorphic to  $\mathbb{R}$ : identify a countable dense skeleton with  $\mathbb{Q}$  and then identify the two completions through their cuts. This proves the first assertion.

For an explicit Baire-space homeomorphism, fix an enumeration  $d_0, d_1, \dots$  of  $D$ . At a finite injective prefix  $p$ , let  $m(p)$  be the least-indexed unused label. Split  $C_p$  according to the finite block  $q$  that starts immediately after  $p$  and ends at the first occurrence of  $m(p)$ . Thus  $q$  is nonempty and injective, uses only unused labels, ends with  $m(p)$ , and has no earlier occurrence of that label.

There are countably infinitely many such blocks; enumerate them by natural numbers using the fixed alphabet enumeration.

Their cylinders  $C_{p \smallfrown q}$  are nonempty, clopen, pairwise disjoint, and cover  $C_p$ . Two such blocks cannot be proper prefixes of one another because both end at their first occurrence of the same required label. Given  $s \in \omega^\omega$ , at stage  $n$  append the block numbered  $s(n)$ . The prefix length increases at every stage, and each stage inserts the least missing label. The union is therefore an injection of domain  $\omega$  using every label, hence a permutation. Conversely, every permutation splits uniquely into these successive blocks. These procedures are inverse. A finite Baire cylinder maps to exactly one of the corresponding permutation cylinders, and these cylinders form bases on both sides. This proves the homeomorphism without a separate classification theorem for Polish spaces.

For the  $G_\delta$  assertion, view  $\overline{P}$  as the real line and, for each nonempty finite prefix  $p$ , put

$$J_p = (\inf C_p, \sup C_p).$$

These cylinder boundaries exist in the completion. For  $n \geq 1$  and  $d \in D$ , define the open sets

$$U_n = \bigcup_{\text{length}(p)=n} J_p, \quad V_d = \bigcup_{d \in \text{ran}(p)} J_p,$$

where the second union is over finite injective prefixes. Then

$$P = \bigcap_{n \geq 1} U_n \cap \bigcap_{d \in D} V_d.$$

Indeed, a numerical-split code at a prefix of length  $k$  fails  $U_{k+1}$ . There are no nonzero short limit prefixes below  $\omega$ . A full branch omitting  $d$  fails  $V_d$ . Every surjective branch belongs to every displayed open set. Theorem 65.11 exhausts all cases. This is a countable intersection of open sets. Each contains the dense set  $P$ , so the representation is a dense  $G_\delta$ .

Every nonempty interval contains a finite prefix cylinder. Reserve one unused label  $d$ . There are  $2^{\aleph_0}$  full injective branches extending that prefix and omitting  $d$ , for example by permuting the countably infinite remaining alphabet with  $d$  removed. Distinct branches give distinct proper gaps: at their first unequal coordinate, choose a fresh label strictly between their two entries and complete to a permutation between them. Thus the original interval contains continuum many omitted completion points. The cylinder also contains continuum many surjective permutations. This proves the fourth assertion.

Finally, the irrational order has real-line completion with exactly countably many omitted points, namely the rationals. An order isomorphism extends uniquely to the completions and preserves their complements. Our continuum-sized omitted set therefore excludes an order isomorphism with the irrationals.  $\square$

The conclusion illustrates a limitation of topological classification: the explicit Baire-space topology coexists with a substantially different pattern of Dedekind omissions. The completion normal forms retain that order information. For uncountable  $\mu$ , the same full-size-interval hypothesis makes bounded-length prefix cylinders a clopen basis, but the countable Baire-space construction and the real-line completion conclusion must not be transferred without new hypotheses.

## 68 Countable strata of length $\omega + n$ (sources 29 and 30)

[merge] One section from source 29's Section 8 (the base) and source 30's Section 6, written independently: neither saw the other. They prove the same theorems on the strata  $\mathcal{W}_{\omega+n}(D)$  of a

countable dense alphabet  $D$  without endpoints (for example  $\mathbf{No}_{<\omega}$ ). Source 29 writes  $P_\alpha = \mathcal{W}_\alpha(D)$  for every countable  $\alpha$ , source 30 writes  $P_n$  for the stratum of length  $\omega + n$  and  $X$  for the alphabet; here source 29's indexing is used throughout, so source 30's  $P_n$  is printed  $P_{\omega+n}$ , its  $X$  is printed  $D$ , its set  $D_n$  of nonisolated points is printed  $S_n$  (source 29's  $S$ ), and its relation-table space  $\mathcal{T}_n$  is printed  $\text{Tab}_n$ ; source 29's real completion  $C$  is printed  $\hat{I}$ . The base is source 29 for the category theorem, the comparison of the native and coordinate topologies at every countable length, the measurable trichotomy and the two product  $\sigma$ -algebras; source 30 for the nonisolated set and its Cantor–Bendixson analysis, the relation-table presentation, the ranking maps and the single orientation predicate; its weight corollary for arbitrary alphabets is printed with source 22's table (corollary 63.12). The duplicates: source 29's theorem 68.2 ( $n \geq 1$ ) is source 30's proposition 68.4, in a different ambient space; its proposition 68.6 is the third item of lemma 68.3; its theorem 68.8 is theorem 68.9; its theorem 68.13 is note 68.14 (classical, Fremlin's 419L(b)); its theorem 68.15 is theorem 68.16 in another formulation; the second clause of proposition 68.11 is corollary 68.17. At  $\mu = \omega$  the finite-tail normal form, the isolated points, the weight and the one-step derivative are source 22's proposition 63.8, theorem 63.9, corollary 63.10, and example 63.11; the density threshold at three labels is theorem 27.2. New against this report are the category, metrizability and complete-metrizability distinctions, the Baire property for  $n \geq 3$ , the topology comparison and all Borel results. The case  $n = 0$  is the countable-cutoff theorem of section 67.

The first countable stage gives a particularly concrete way to distinguish interpretations that have the same cardinality and the same embedding spectra. Let  $D$  be a countable dense linear order without endpoints; the intended example is  $D = \mathbf{No}_{<\omega}$  with its numerical order. For every countably infinite ordinal  $\alpha$ , put

$$P_\alpha = \{f : \alpha \longrightarrow D : f \text{ is bijective}\}.$$

We compare these functions at their first unequal ordinal coordinate. There are two topologies on the same set that must be named separately:

$$\tau_{\text{lex}} = \text{the topology of the displayed linear order}, \quad \tau_{\text{coord}} = \text{the subspace topology from } D^\alpha,$$

where the alphabet  $D$  is discrete in the second definition. The latter topology specifies finitely many coordinate values, at arbitrary positions of  $\alpha$ . A fixed prefix extending through an infinite ordinal need not be an open coordinate condition.

The previous countable-cutoff result says that these topologies agree on  $P_\omega$  and give Baire space (sources 21 and 20; theorems 67.6 and 67.11). The repository also already determines density and cellularity for every fixed stratum: in the present case the first three strata have countable density and all later ones have density  $\mathfrak{c}$  (theorem 27.2). We use these as background and prove refinements that are not consequences of the cardinal invariants: the precise topology comparison, a category distinction at one extra label, and different Borel sigma-algebras at two extra labels.

## 68.1 A common real completion for finite omissions

Let

$$I = \{p : \omega \longrightarrow D : p \text{ is injective}\}, \quad E_n = \{p \in I : |D \setminus \text{ran } p| = n\} \quad (n < \omega).$$

Here  $E_0 = P_\omega$ . Both  $I$  and each  $E_n$  carry finite-coordinate first-difference comparison. For a finite injective word  $s$ , its cylinder consists of all extensions of  $s$  in the order under discussion.

**Lemma 68.1** (A common completion). *The order  $I$  is dense, has no endpoints, and has a countable clopen cylinder basis. Its Dedekind completion  $\hat{I}$  is a copy of  $\mathbb{R}$ . Every  $E_n$  is order-dense in  $I$  and in  $\hat{I}$ . The order topology of  $E_n$  is its subspace topology in  $\hat{I}$ , and is also its finite-prefix topology.*

*Proof.* After any finite prefix the unused alphabet is again countable, dense, and without endpoints. Given unequal entries at the first difference, choose an unused entry strictly between them and extend to an infinite injection. The same construction on either side of the next entry proves that each cylinder has no endpoints and is open. Cylinders of one fixed finite length partition the order, so they are also closed. Every order interval containing  $p$  contains a sufficiently long finite prefix cylinder of  $p$ . Thus the countably many cylinders form a basis. Choosing one point of each nonempty cylinder gives a countable dense subset, whose order is the rational order. Passing to cuts identifies the completion with  $\mathbb{R}$ .

Every finite injective prefix can be completed with exactly  $n$  omitted labels: reserve  $n$  labels outside the prefix and enumerate all the other unused labels. Consequently each  $E_n$  meets every cylinder. It is order-dense in  $I$  and  $\hat{I}$ . Density ensures that the order topology is the inherited topology; the cylinder proof also works directly in  $E_n$ .  $\square$

The real completion in this lemma is shared by all  $E_n$ . In particular, it gives an unambiguous setting for comparing the complexity of their realized points. No class of proper-class orders occurs in this argument.

For each nonempty finite injective  $s$ , let

$$J_s = (\inf[s], \sup[s]) \subseteq \hat{I}, \quad J_\emptyset = \hat{I},$$

where the cylinder is now taken in  $I$ . Its finite endpoints exist, and  $J_s \cap I = [s]$ . Put

$$U_k = \bigcup_{|s|=k} J_s \quad (k \geq 1), \quad V_a = \bigcup_{a \in \text{ran } s} J_s \quad (a \in D).$$

All these sets are open in  $\hat{I}$ . Distinct cylinders of a fixed length give disjoint open intervals: an intersection would meet the dense order  $I$ . More generally, intersecting intervals have compatible prefixes. It follows, exactly as in the exhaustive case, that

$$I = \bigcap_{k \geq 1} U_k. \quad (19)$$

Indeed, a point in the intersection determines a compatible infinite injective branch. The point equals that branch in the completion, because otherwise an intervening member of  $I$  would share all of its coordinates. For a branch  $p \in I$ , membership in  $V_a$  says exactly that the label  $a$  occurs in  $p$ .

Define, for  $n \geq 0$ ,

$$G_{\leq n} = I \cap \bigcap_{A \in [D]^{n+1}} \bigcup_{a \in A} V_a. \quad (20)$$

This is a dense  $G_\delta$  subset of  $\hat{I}$ : it contains  $E_0$ , which is dense, and the displayed intersections are countable. Its branches omit at most  $n$  labels. Therefore

$$E_0 = G_{\leq 0}, \quad E_n = G_{\leq n} \setminus G_{\leq n-1} \quad (n \geq 1). \quad (21)$$

**Theorem 68.2** (The category change at one omission). *The following statements hold in the common real completion  $\hat{I}$ .*

1.  $E_0$  is a dense  $G_\delta$ , homeomorphic to Baire space, and is not  $F_\sigma$ .
2. For every  $n \geq 1$ ,  $E_n$  is a difference of two dense  $G_\delta$  sets, and hence is  $\Delta_3^0$ . It is neither  $G_\delta$  nor  $F_\sigma$ .
3. For every  $n \geq 1$ ,  $E_n$  is meager in itself, has no compatible complete metric, and contains a closed copy of Baire space.

Every nonempty interval of  $\widehat{I}$  contains  $\mathfrak{c}$  points of every  $E_n$ . Thus equal cardinalities of realized and omitted points do not detect this category distinction.

*Proof.* The first assertion is the previous  $\omega$ -enumeration theorem, applied to  $D$ . The explicit least-missing-label block construction gives the homeomorphism with  $\omega^\omega$ . For completeness, this space is not sigma-compact: if  $K_i$  are compact subsets, the projection of  $K_i$  to coordinate  $i$  is finite, and a diagonal choice outside these finite projections avoids  $\bigcup_i K_i$ . Since an  $F_\sigma$  subset of  $\mathbb{R}$  is sigma-compact,  $E_0$  is not  $F_\sigma$ .

Fix  $n \geq 1$ . For  $F \in [D]^n$ , let

$$A_F = \{p \in E_n : D \setminus \text{ran } p = F\}.$$

Within  $E_n$  this is the closed condition that no member of  $F$  ever occurs. It has empty interior. A finite prefix of a point of  $A_F$  can be extended by a member of  $F$  and then completed with  $n$  different omissions. Such a completion lies outside  $A_F$  in the same prescribed prefix neighborhood. The countable family  $(A_F)_{F \in [D]^n}$  covers  $E_n$ , proving that  $E_n$  is meager in itself. Each  $A_F$ , with its inherited prefix topology, is exactly the permutation space of the countable dense alphabet  $D \setminus F$ , hence is homeomorphic to Baire space. The Baire category theorem rules out a compatible complete metric on the nonempty space  $E_n$ .

Equation (21) proves the asserted Borel upper bound. If  $E_n$  were  $G_\delta$  in  $\widehat{I}$ , it would be a dense  $G_\delta$  disjoint from the dense  $G_\delta$  set  $E_0$ , contradicting the Baire theorem for  $\mathbb{R}$ . If  $E_n$  were  $F_\sigma$  in  $\widehat{I}$ , it would be sigma-compact, and its relatively closed subspace  $A_F$  would be sigma-compact as well. This contradicts the preceding diagonal argument for Baire space.

Finally, inside any fixed finite prefix choose one permissible omitted set  $F$  and vary the permutation of the remaining countably infinite alphabet. There are  $\mathfrak{c}$  such permutations. Every nonempty interval contains a prefix cylinder, and no  $E_n$  has more than  $\mathfrak{c}$  points.  $\square$

The description  $\Delta_3^0$  here is an upper bound together with strict exclusion from both second-level classes. It does not assert  $\Sigma_3^0$ - or  $\Pi_3^0$ -completeness. The more precise information we use is the explicit difference-of- $G_\delta$  representation.

[merge] Source 30 states the case  $n \geq 1$  in the injection space  $I = \text{Inj}(\omega, D) \subseteq D^\omega$  rather than in the completion; its Section 6 begins:

The countable birthday stage already distinguishes several notions that cardinality and ordinal-embedding spectra do not distinguish. Throughout this section let  $D$  be a countable dense linear order without endpoints, such as  $\mathbb{Q}$  or  $\mathbf{No}_{<\omega}$  with its numerical order. For a nonnegative integer  $n$  put

$$P_{\omega+n} = \text{Bij}(\omega + n, D), \quad E_n = \{p : \omega \hookrightarrow D : |D \setminus \text{ran}(p)| = n\}.$$

Both sets carry lexicographic orders;  $P_{\omega+n}$  carries its order topology. The topology on  $E_n$  will shortly be identified with the subspace topology inherited from  $D^\omega$ , where  $D$  is *discrete*. This use of the discrete topology is an encoding convention, and does not change the numerical order used in lexicographic comparisons.

The additional results in this section concern the progression

$$\omega, \quad \omega + 1, \quad \omega + 2, \quad \omega + 3.$$

At the first added terminal coordinate, complete metrizability fails. At the second, metrizability and standard Borel structure fail. At the third, a dense set of isolated points appears and the ranking map from relation tables ceases to be Borel measurable. These are different thresholds.

### 68.1.1 The cofinite-prefix model

For  $S \in [D]^n$  write

$$E_{n,S} = \{p \in E_n : \text{ran}(p) = D \setminus S\}.$$

For a finite injective sequence  $s$  in  $D$ , write  $[s] = \{p \in E_n : s \subseteq p\}$ . Every such cylinder is nonempty: choose  $n$  unused labels to omit, and enumerate all remaining labels.

**Lemma 68.3** (Prefix topology and finite fibers). *For every finite  $n$  the following assertions hold.*

1. *The finite-prefix cylinders form a countable clopen base for the order topology of  $E_n$ . Consequently this topology is precisely its product subspace topology.*
2.  *$E_n$  is densely ordered, has no endpoints, and has cardinality  $\mathfrak{c}$ .*
3. *Restriction to the first  $\omega$  coordinates identifies  $P_{\omega+n}$  as an ordered set with*

$$E_n \xrightarrow{\times} \{1, \dots, n!\},$$

*where the displayed finite set has its usual order and the product is lexicographic. The projection  $\pi_n : P_{\omega+n} \rightarrow E_n$  is continuous.*

*Proof.* If  $p$  extends  $s$ , choose two unused labels, one below and one above  $p(|s|)$ , and complete the two resulting finite prefixes to elements of  $E_n$ . The interval between these two elements contains  $p$  and lies in  $[s]$ . Thus  $[s]$  is open. Its complement is a union of the other cylinders of the same length, so it is also closed. If  $a < p < b$ , the two first disagreements with  $p$  occur at finite coordinates. A sufficiently long finite prefix of  $p$  therefore has its entire cylinder in  $(a, b)$ . The same argument applies to rays. This proves the first assertion.

If  $p < q$  first differ at  $k$ , choose an unused label strictly between  $p(k)$  and  $q(k)$  and extend the resulting prefix. The extension lies strictly between  $p$  and  $q$ . Choosing a smaller or larger first label proves the absence of endpoints. The upper cardinal bound is  $|D^\omega| = \mathfrak{c}$ . For a fixed omitted set  $S$ , the permutations of  $D \setminus S$  already give  $\mathfrak{c}$  elements: independently switch countably many disjoint pairs.

Finally, a prefix  $p \in E_n$  leaves exactly  $n$  labels, and its continuations are their  $n!$  permutations in lexicographic order. Different prefixes are compared before any of these terminal coordinates. This gives the displayed order isomorphism. For example, for  $a < b$  in  $E_n$ ,

$$\pi_n^{-1}((a, b)) = ((a, n!), (b, 1)),$$

and the corresponding ray identities prove continuity. □

**Proposition 68.4** (The category and Borel class of cofinite prefixes). *The space  $E_0$  is Polish and Baire. For each  $n \geq 1$ ,  $E_n$  is metrizable and second countable, but meagre in itself and therefore not Polish. As a subset of the Polish space  $I = \text{Inj}(\omega, D) \subseteq D^\omega$ ,  $E_n$  belongs to  $\Delta_3^0$  and is neither  $F_\sigma$  nor  $G_\delta$  when  $n \geq 1$ .*

*Proof.* Injectivity is a closed condition in  $D^\omega$ . Surjectivity is the  $G_\delta$  condition

$$\bigcap_{x \in D} \bigcup_{k < \omega} \{p : p(k) = x\}.$$

Thus  $E_0$  is a  $G_\delta$  subspace of a Polish space, hence Polish and Baire.

For  $n \geq 1$  the countable family  $\{E_{n,S} : S \in [D]^n\}$  covers  $E_n$ . Each member is closed in  $E_n$ , since it is specified there by the condition that every label in  $S$  is omitted. Each has empty interior: a

finite prefix can always be extended while omitting a different  $n$ -element set. This proves meagreness. A nonempty Polish space is Baire, so  $E_n$  is not Polish.

The condition “at most  $n$  labels are omitted” is  $G_\delta$ : for each  $(n+1)$ -element subset of  $D$ , at least one of its labels must occur. The condition “at least  $n$  labels are omitted” is  $F_\sigma$ : some  $n$ -element set is avoided. Their intersection is  $E_n$ , so  $E_n \in \Delta_3^0$ . It cannot be  $G_\delta$ , since that would make it Polish.

To rule out  $F_\sigma$ , fix  $S \in [D]^n$  and let

$$I_S = \{p \in I : \text{ran}(p) \subseteq D \setminus S\}.$$

This is a closed Polish subspace of  $I$ , and  $E_n \cap I_S = E_{n,S}$  is a dense  $G_\delta$  in  $I_S$ . Its complement is also dense: any finite injective prefix can be extended while omitting one additional label. Consequently every closed subset of  $I_S$  contained in  $E_{n,S}$  is nowhere dense. If  $E_n$  were  $F_\sigma$  in  $I$ , then  $E_{n,S}$  would be a meagre dense  $G_\delta$  in the Baire space  $I_S$ , a contradiction.  $\square$

*Note 68.5* (Source 30, Corollary 6.3, “An explicit Baire-space presentation”). *The space  $P_\omega = E_0$  is homeomorphic to  $\omega^\omega$  with its usual product topology.* This is [theorem 67.2](#), by the same least-missing-label tree ([theorem 66.2](#) at  $\mu = \omega$ ): at a cylinder  $[s]$  of full permutations, the first label  $a_j$  of a fixed list absent from  $s$  splits  $[s]$  into the countably many cylinders  $[s \cap v \cap (a_j)]$ , “exactly the possible blocks ending at the first future occurrence of  $a_j$ ”.

The preceding argument pinpoints why appending one final label matters. An enumeration of type  $\omega$  must eventually display *every* label; an enumeration of type  $\omega+1$  must leave exactly one label undisplayed at all finite stages. The latter condition is a countable union of closed, nowhere-dense alternatives, one for each possible final label. In particular  $P_{\omega+1}$  is not homeomorphic to the Baire space  $P_\omega$ .

## 68.2 Finite tails as finite split orders

**Proposition 68.6** (The exact finite-tail reduction). *For each  $n < \omega$  there is an order isomorphism*

$$P_{\omega+n} \cong E_n \times_{\text{lex}} \{0, \dots, n! - 1\}. \quad (22)$$

*It sends an enumeration to its first  $\omega$  entries and to the lexicographic rank of its finite terminal permutation. For  $n = 0$  and  $n = 1$  the second factor is a singleton.*

*Proof.* The first  $\omega$  entries omit exactly the  $n$  labels used in the tail. For a fixed prefix  $p \in E_n$ , the  $n!$  possible tails form a finite chain in numerical lexicographic order. Different prefixes first differ at a finite coordinate, so their entire tail fibers are ordered by the prefix comparison. This proves bijectivity and order preservation.  $\square$

**Corollary 68.7** (All the finite successors have different order types). *The orders  $P_{\omega+n}$ , for  $n < \omega$ , are pairwise nonisomorphic. In particular,  $P_\omega$  and  $P_{\omega+1}$  are equimorphic but are not isomorphic.*

*Proof.* The latter two orders are respectively  $E_0$  and  $E_1$ , and their order topologies are respectively Baire and meager in themselves. An order isomorphism is a homeomorphism, so no such isomorphism exists. Their equimorphism follows from the existing countable binary-cube classification ([theorem 31.2](#)); it is not a new embedding-spectrum assertion.

For  $n \geq 2$ , the equivalence relation saying that the closed interval between two points is finite has exactly the fibers in (22) as its classes. A fiber has  $n!$  elements. Different fibers have infinitely many whole fibers between them because  $E_n$  is densely ordered. Thus the size  $n!$  of the maximal finite convex blocks is an intrinsic invariant, distinguishing every  $n \geq 2$  from every other such  $n$  and from  $n = 0, 1$ .  $\square$

**Theorem 68.8** (Finite-tail topological classification). *In its native order topology,  $P_{\omega+n}$  has the following properties.*

1. *For  $n = 0$  it is Baire space.*
2. *For  $n = 1$  it is separable and metrizable, but is meager in itself and is not completely metrizable.*
3. *For  $n = 2$  it is first countable and separable, is meager in itself, and is not metrizable.*
4. *For  $n \geq 3$  it is first countable and nonmetrizable, and has a dense open set of  $\mathfrak{c}$  isolated points. It is therefore a Baire space, although its density is  $\mathfrak{c}$ .*

*For  $n \geq 2$  its topological weight is  $\mathfrak{c}$ .*

*Proof.* The cases  $n = 0, 1$  have already been proved. Consider a finite split order  $L = E \times_{\text{lex}} m$ , where  $E = E_n$  and  $m = n! \geq 2$ . The projection  $\pi : L \rightarrow E$  is continuous. A countable dense subset of  $E$  gives countable sequences approaching every base point from both sides. Together with the immediate neighbors inside a finite fiber, these give a countable local base at every point of  $L$ .

Let  $S = E \times \{0, m-1\}$  be the first and last points of the fibers. Its complement consists of isolated interior points and is open; hence  $S$  is closed. The induced topology on  $S$  is precisely the order topology of  $E \times_{\text{lex}} 2$ . This can also be seen directly from neighborhoods of the first and last point of each fiber: the first is approached through earlier base fibers and the last through later ones. Removing only the interior of the finite fibers changes neither of these neighborhoods.

The double split of  $E$  is separable. If  $B$  is a countable dense subset of  $E$ , then  $B \times 2$  is dense, since every nonempty open set contains a point over a nonempty base interval. It is not second countable. For each  $x \in E$ , choose a basis element containing  $(x, 0)$  and contained in the open ray  $(-\infty, (x, 1))$ . The chosen basis elements must be distinct: if  $x < y$ , the one chosen for  $x$  cannot contain  $(y, 0)$ . Thus every basis has cardinality at least  $|E| = \mathfrak{c}$ . A separable metrizable space is second countable, so the double split is not metrizable. Since  $S$  is a subspace, neither is  $L$ . First countability and  $|L| = \mathfrak{c}$  give the matching upper bound for weight.

When  $m = 2$ , the inverse images of the relatively closed nowhere dense sets  $A_F \subseteq E_n$  remain nowhere dense. Every nonempty open set in the double split contains all fibers over a nonempty base interval, which cannot be contained in  $A_F$ . These countably many inverse images cover  $L$ , proving that it is meager in itself.

When  $m \geq 3$ , the interior points of every fiber are isolated. They form a dense open set: any neighborhood of a first or last point meets another whole fiber, because the base order is dense and has no endpoints. Every dense open subset must contain every isolated point. Consequently a countable intersection of dense open subsets contains this same dense set, which proves the Baire assertion. There are  $\mathfrak{c}$  isolated points, so density is  $\mathfrak{c}$ .  $\square$

The threshold for category differs from the threshold for metrizability. One omitted label destroys complete metrizability. Two terminal labels produce uncountably many jumps and destroy metrizability. Three terminal labels introduce a dense set of isolated points and restore the Baire property. The density transition at three labels is already in the repository; the category and measurable-structure refinements here explain additional distinctions it does not record.

[merge] Source 30's Theorem 6.4 proves the four regimes again and adds the nonisolated set  $S_n$  (its  $D_n$ ), which is order-homeomorphic to the doubled order  $\text{Split}(E_n)$  and closed nowhere dense for  $n \geq 3$ :

### 68.2.1 The four topological regimes

We first isolate the elementary topology of a doubled order. If  $E$  is densely ordered without endpoints, put

$$\text{Split}(E) = E \overrightarrow{\times} \{-, +\}.$$

The two points  $p^- < p^+$  over each  $p \in E$  are adjacent, but neither is isolated. The term “split” here specifies this exact two-point construction.

**Theorem 68.9** (Finite-tail topology). *The following properties hold for  $P_{\omega+n}$ .*

1.  $P_\omega$  is zero-dimensional, Polish and Baire.
2.  $P_{\omega+1}$  is zero-dimensional, second countable and metrizable, but meagre in itself and not Polish.
3.  $P_{\omega+2}$  is zero-dimensional, first countable and separable, but meagre in itself and nonmetrizable. Its weight is  $\mathfrak{c}$ .
4. For  $n \geq 3$ ,  $P_{\omega+n}$  is zero-dimensional and first countable. It has a dense open discrete set of  $\mathfrak{c}$  isolated points, and is therefore Baire. Its density, cellularity and weight are all  $\mathfrak{c}$ , and it is nonmetrizable.

For  $n \geq 2$ , the nonisolated-point subspace is exactly

$$S_n = \{(p, 1), (p, n!) : p \in E_n\}.$$

With its inherited topology,  $S_n$  is order-homeomorphic to  $\text{Split}(E_n)$ . It is separable, meagre in itself and nonmetrizable, and has no isolated points. For  $n \geq 3$  it is closed and nowhere dense in  $P_{\omega+n}$ ; moreover  $P'_{\omega+n} = S_n = S'_n$ .

*Proof.* The assertions about  $P_\omega$  and  $P_{\omega+1}$  follow from the singleton-fiber cases of Lemma 68.3 and Proposition 68.4.

Consider  $E_n$  with each point replaced by two points. Every nonempty open subset contains the full inverse image of some finite-prefix cylinder. Indeed, a nonempty basic interval cannot have both bounds in one two-point fiber; between their distinct prefixes choose an intermediate prefix and then a sufficiently small finite-prefix cylinder. Choosing one point in the lift of each of the countably many finite-prefix cylinders gives a countable dense subset. Moreover

$$\text{Split}(E_n) = \bigcup_{S \in [D]^n} \pi^{-1}(E_{n,S}) \quad (n \geq 1)$$

is a countable union of closed nowhere-dense sets. Closedness follows from continuity of the projection; the preceding finite-prefix observation proves empty interior. This proves separability and meagreness for all these split spaces.

There are  $\mathfrak{c}$  adjacent pairs in  $\text{Split}(E_n)$ . From any base choose, for each  $p$ , a basic set  $U_p$  with

$$p^- \in U_p \subseteq (-\infty, p^+).$$

These basic sets are distinct. If  $p < q$ , then  $q^- \geq p^+$ , so a set contained in  $(-\infty, p^+)$  cannot also contain  $q^-$ . Hence the weight is at least  $\mathfrak{c}$ ; the family of all order intervals and rays gives the reverse bound. A separable metric space has countable weight, so the split space is nonmetrizable.

For completeness, the local topology can be described explicitly. Let  $C_k(p)$  be the length- $k$  prefix cylinder about  $p$  in  $E_n$ , and put  $m = n!$ . At the first point of a fiber with  $m \geq 2$ , the sets

$$\pi_n^{-1}(C_k(p)) \cap (-\infty, (p, 2)) \quad (k < \omega)$$

form a clopen local base. At the last point use

$$\pi_n^{-1}(C_k(p)) \cap ((p, m-1), \infty).$$

Every interior point of a finite fiber is an open singleton. This proves first countability and zero-dimensionality.

There are no adjacent points in distinct fibers, because  $E_n$  is densely ordered. Thus the isolated points in  $P_{\omega+n}$  are precisely  $(p, j)$  with  $1 < j < n!$ . For  $n \geq 3$  these points form a set of cardinality  $\mathfrak{c}$ . They are dense: a neighborhood of a fiber endpoint contains points from other fibers on its nonadjacent side, and hence contains an entire intervening fiber and an interior point of that fiber. Every dense open set contains every isolated point. Any countable intersection of dense open sets therefore contains this fixed dense set, proving the Baire property.

Deleting the interior points leaves exactly the two endpoints of each fiber. The displayed local bases show directly that their inherited topology is the order topology of  $\text{Split}(E_n)$ . This subspace has no isolated points. It is closed, and for  $n \geq 3$  it is nowhere dense because the isolated points are dense. Consequently the Cantor–Bendixson derivative stabilizes after the first step. Its nonmetrizability also proves that  $P_{\omega+n}$  itself is nonmetrizable for  $n \geq 3$ . Finally, the open singletons give cellularity and density at least  $\mathfrak{c}$ , while the size of the entire space gives all upper bounds claimed.  $\square$

Thus the Baire property is lost at  $\omega + 1$  and recovered at  $\omega + 3$  for an entirely different reason. The recovered Baire space is not completely Baire: it contains the nonempty closed subspace  $S_n$ , which is meagre in itself. There is no conflict with the minimal-type result, and no implication that the spaces in the final regime are Polish. Nor does the theorem assert that all  $P_{\omega+n}$  with  $n \geq 3$  are mutually homeomorphic.

### 68.3 Comparing the two topologies at every countable length

**Theorem 68.10** (Exact comparison of native and coordinate topologies). *For a countably infinite ordinal  $\alpha$ , the coordinate topology on  $P_\alpha$  is always homeomorphic to Baire space. The two displayed topologies satisfy*

| $\alpha$                            | comparison                                                      |
|-------------------------------------|-----------------------------------------------------------------|
| $\omega$                            | $\tau_{\text{lex}} = \tau_{\text{coord}}$                       |
| $\omega + 1$                        | $\tau_{\text{lex}} \subsetneq \tau_{\text{coord}}$              |
| $\omega + 2 \leq \alpha < \omega_1$ | $\tau_{\text{lex}}$ and $\tau_{\text{coord}}$ are incomparable. |

*The native order topology is first countable for every such  $\alpha$ .*

*Proof.* Choose any bijection  $b : \omega \rightarrow \alpha$ . Reindexing by  $b$  identifies the coordinate permutation space with the coordinate space  $P_\omega$ , which is Baire space. This reindexing makes no claim to preserve the native lexicographic order.

For  $\alpha = \omega + 1$ , two distinct exhaustive enumerations must differ before  $\omega$ : if their first  $\omega$  entries agreed, the single remaining label would agree too. Consequently finite initial cylinders form the order-topology basis, making every native-open set coordinate-open. The final-coordinate condition  $f(\omega) = a$  is coordinate-open but has empty interior in the native order: any finite prefix can be completed with a different omitted label. The inclusion is strict.

We give witnesses valid for every  $\alpha > \omega$ , writing  $\alpha = \omega + \tau$ . First, the coordinate topology is never contained in the native topology. Choose a bounded numerical interval in  $D$  and a suborder  $Y$  of that interval of order type  $\tau$ . Such a suborder exists because every countable linear order embeds in a countable dense order. For finite  $\tau$  this just means choosing finitely many increasing

labels. Enumerate  $D \setminus Y$  in the first  $\omega$  positions and enumerate  $Y$  increasingly thereafter; call the resulting point  $f$ . It is the least point in its first- $\omega$  prefix fiber. If  $a = f(\omega)$ , the coordinate-open set

$$O_a = \{g : g(\omega) = a\}$$

is not a native neighborhood of  $f$ . Given  $h < f$ , the first difference between  $h$  and  $f$  occurs at a finite position. Preserve a longer finite prefix of  $f$ , choose the next entry smaller than the corresponding entry of  $f$ , and prescribe a value other than  $a$  at coordinate  $\omega$ . The finite partial injection extends to a bijection, producing  $h < g < f$  with  $g \notin O_a$ . Thus every native neighborhood of  $f$  leaves  $O_a$ .

Second, if  $\tau$  has at least two elements, the native topology is not contained in the coordinate topology. Keep a first- $\omega$  prefix enumerating  $D \setminus Y$ , where  $Y$  lies in a bounded interval and has cardinality  $|\tau|$ ; choose two completions  $f < h$  of this prefix. The native ray  $(-\infty, h)$  contains  $f$ . In every finite-coordinate neighborhood of  $f$ , select two unfixed finite positions  $i < j$  with  $f(i) < f(j)$  and transpose their values. These exist arbitrarily late because  $D \setminus Y$  is unbounded above and deleting finitely many entries does not change that. The modified enumeration  $g$  respects the prescribed finite coordinates, but its first difference from  $h$  is at  $i$ , with a larger value. Thus  $g > h$ . The native ray is not coordinate-open.

Finally, no increasing sequence of type  $\omega_1$  can occur in  $P_\alpha$ , nor can a decreasing one. To see this directly, suppose  $(f_\xi)_{\xi < \omega_1}$  is increasing. On a final segment its first coordinate stabilizes, since it is monotone in a countable alphabet. Recursively stabilize each coordinate after stabilizing all earlier ones. There are only countably many coordinates, so the supremum of the stabilization indices is still below  $\omega_1$ . The sequence is eventually constant, a contradiction. If the portion below any point had no countable cofinal subset, recursion would build an increasing  $\omega_1$ -sequence there. The dual argument applies above the point. Countable cofinal and coinital sets give the required countable local bases.  $\square$

**Proposition 68.11** (Low-complexity comparison is not low-complexity topology). *For every countably infinite  $\alpha$ , the relation*

$$\{(f, g) \in P_\alpha^2 : f <_{\text{lex}} g\}$$

*is both  $F_\sigma$  and  $G_\delta$  in the product coordinate topology. Nevertheless, for every  $\alpha \geq \omega + 3$  there are native-open subsets of  $P_\alpha$  that are not coordinate-Borel.*

*Proof.* For each  $\beta < \alpha$ , the condition

$$f \restriction \beta = g \restriction \beta, \quad f(\beta) < g(\beta)$$

is closed in the product coordinate topology: the equality is an intersection of closed coordinate equalities, and the last condition is clopen because the alphabet is discrete. The lexicographic relation is the countable union of these closed sets, hence is  $F_\sigma$ . Its complement is the reverse strict relation together with the closed diagonal, again  $F_\sigma$ . Thus the strict relation is also  $G_\delta$ .

For the second assertion, write  $\alpha = \omega + \tau$  and choose  $Y \subset D$  with  $|Y| = |\tau|$  and infinite complement. There are  $\mathfrak{c}$  prefixes of length  $\omega$  enumerating  $D \setminus Y$ . Each of their convex tail fibers has at least three points, since  $\tau \geq 3$ , and therefore contains a nonempty ambient open interval. These intervals are pairwise disjoint. This is the countable case of the existing cellularity argument (theorem 27.2). Their arbitrary unions yield  $2^{\mathfrak{c}}$  distinct native-open sets, while the coordinate Polish space has only  $\mathfrak{c}$  Borel sets [57]. For finite tails, arbitrary subsets of the  $\mathfrak{c}$  isolated interior permutations give the same conclusion.  $\square$

Thus a Borel comparison relation on a standard Borel code space does not make every open set of the corresponding order topology Borel. The order topology permits arbitrary unions; the Borel sigma-algebra permits only countable iterations of its generating operations.

[merge] Source 30's presentation of the strata by relation tables, which its measurable comparison below uses:

### 68.3.1 Relation tables as a standard Borel presentation

Let  $\text{Tab}_n$  be the set of strict well-order relations of type  $\omega + n$  on  $D$ , regarded as a subspace of the Cantor space  $2^{D \times D}$ . Its topology records finitely many answers to questions of the form “does  $xRy$ ?” There are mutually inverse set bijections

$$\Phi_n : P_{\omega+n} \longrightarrow \text{Tab}_n, \quad r_n : \text{Tab}_n \longrightarrow P_{\omega+n},$$

where  $\Phi_n(e)$  is the relation induced by  $e$  and  $r_n$  is its unique increasing enumeration. The order topology on  $P_{\omega+n}$  and the table topology on  $\text{Tab}_n$  should not be identified.

**Proposition 68.12** (The fixed finite-tail table domains). *For every finite  $n$ ,  $\text{Tab}_n$  is a  $\Pi_3^0$ -complete Borel subset of  $2^{D \times D}$  and hence is a standard Borel space. Each coordinate of  $r_n$ , regarded as a map into the product  $D^{\omega+n}$  with discrete  $D$ , is Borel measurable. In fact, each singleton coordinate fiber is  $F_\sigma$  relative to  $\text{Tab}_n$ .*

*Proof.* Let  $\text{FinPred}_x$  say that  $x$  has finitely many predecessors. This is  $F_\sigma$ : some finite set contains all predecessors. Let  $\text{Succ}_k(x)$  say that  $x$  has exactly  $k$  successors. This too is  $F_\sigma$ , by choosing the finite successor set and specifying all remaining comparison bits. The set  $\text{LO}(D)$  of strict linear orders is closed.

For  $n = 0$  the required definition is

$$\text{LO}(D) \cap \bigcap_{x \in D} \text{FinPred}_x.$$

For  $n \geq 1$  a  $\Pi_3^0$  definition is the conjunction of

1. being a strict linear order;
2. among any  $n + 1$  distinct elements, at least one has finitely many predecessors;
3. some element has exactly  $n - 1$  successors.

To verify this definition, condition (2) leaves at most  $n$  points with infinitely many predecessors. The remaining points form an infinite initial segment of type  $\omega$ . Hence the entire order has type  $\omega + k$  for some  $k \leq n$ . Condition (3) forces  $k = n$ . The definability bounds follow from the displayed  $F_\sigma$  descriptions.

The  $\Pi_3^0$ -completeness of the isomorphism class of  $\omega$  is classical; see Miller [60, §2, Example 5]. Appending a fixed  $n$ -point terminal order, after relabeling  $D$  into a cofinite subset, is a continuous reduction from  $\text{Tab}_0$  to  $\text{Tab}_n$ . Indeed, appending finitely many points preserves any failure of well-foundedness, and for ordinals  $\gamma + n = \omega + n$  implies  $\gamma = \omega$ . This proves completeness for every finite  $n$ . Miller's full calculation in [60, §3, Lemma 3.5] gives the same classification as part of the classification for all countable ordinals.

Finally,  $r_n(R)(k) = x$  for  $k < \omega$  means exactly that  $x$  has  $k$  predecessors. For  $j < n$ ,

$$r_n(R)(\omega + j) = x \iff x \text{ has exactly } n - 1 - j \text{ successors.}$$

These are  $F_\sigma$  conditions. They prove the coordinate claim and product Borel measurability. □

The last assertion does *not* imply Borel measurability into the lexicographic order topology. This distinction becomes decisive below.

There is a third natural topology to keep separate. For every fixed countable ordinal  $\alpha$ , the space  $\text{Bij}(\alpha, D)$  is Polish in the *full discrete product topology* inherited from  $D^\alpha$ : injectivity is closed and surjectivity is  $G_\delta$ . The map from this product presentation to relation tables is continuous, since the relative order of two labels is determined once their two coordinates have been specified. For  $\alpha = \omega + 1$ , observing the terminal coordinate is product-open but not lexicographically open; its lexicographic fiber is one of the closed nowhere-dense sets above. Thus even the two topologies on the same set of enumerations must be named explicitly. The pathologies proved here concern the *order topology*, and do not contradict the existence of a Polish product presentation.

## 68.4 The exact native Borel sigma-algebra of a double split

The next elementary split-order lemma provides a full measurable description at  $\omega + 2$ . The general split-interval phenomenon is classical: for the split interval the following formula is Fremlin's [59, 419L(b)]. Applying it to the finite terminal permutation fibers supplies the present refinement. We include the complete proof so that no classification theorem is needed.

**Theorem 68.13** (Borel sets in the double split). *Let  $E$  be a separable dense linear order without endpoints, identified with a dense suborder of  $\mathbb{R}$ , and let*

$$L = E \times_{\text{lex}} \{0, 1\}, \quad \pi : L \rightarrow E.$$

*With the native order topologies,*

$$\mathcal{B}(L) = \{\pi^{-1}(B) \triangle N : B \in \mathcal{B}(E), N \subseteq L \text{ countable}\}. \quad (23)$$

*In particular, a native-Borel set can contain exactly one point of a split pair at only countably many base points. If  $E$  is uncountable,  $\mathcal{B}(L)$  is not countably generated and is not a standard Borel structure.*

*Proof.* The projection is continuous. In particular, inverse images of Borel base sets are Borel, and all countable subsets of  $L$  are Borel because singletons are closed. This proves one inclusion in (23).

The family on its right-hand side is a sigma-algebra. Complements preserve the form; the union of countably many such sets differs from the inverse image of the union of their base sets at only countably many points. It remains to show that it contains every open subset  $U \subseteq L$ .

The order  $L$  is separable, by the dense-set argument in the preceding theorem. Decompose  $U$  into its maximal convex components. Every component is open and contains a point of a fixed countable dense set, so there are only countably many of them. The projection of a convex component is a convex subset of  $E$ , hence a Borel interval of  $E$ , allowing any endpoint convention. A convex component contains either both or neither points of every fiber except, possibly, at its two boundary fibers. Consequently  $U$  differs from  $\pi^{-1}(\pi[U])$  at only countably many points, and  $\pi[U]$  is a countable union of Borel base intervals. This proves the other inclusion.

Suppose, finally, that  $(B_i)_{i < \omega}$  generated  $\mathcal{B}(L)$ . Each  $B_i$  distinguishes the two points over at most countably many base points. Outside the union of these countable exceptional sets, the two points have the same membership in every generator, hence in every set in the generated sigma-algebra. But their singletons are Borel and distinguish them. For uncountable  $E$  this is impossible. A standard Borel structure is countably generated [59, 424B(a)], so it is excluded as well.  $\square$

The hypothesis that  $E$  sits densely in its real completion matters for this formulation. We are not claiming that every separable linear order embeds densely in  $\mathbb{R}$ ; orders with jumps need a different statement. Each  $E_n$  satisfies exactly the hypothesis used here.

*Note 68.14* (Source 30, Lemma 6.7, “Borel sets split only countably many fibers”). *Let  $E$  be a second-countable dense linear order without endpoints, and suppose  $\text{Split}(E)$  is separable. With  $\pi$  the projection, its Borel sets are precisely the sets  $\pi^{-1}(B) \triangle C$  with  $B$  Borel in  $E$  and  $C$  countable; in particular every Borel set splits only countably many fibers; if  $E$  is uncountable, this Borel  $\sigma$ -algebra is not countably generated and is not a standard Borel structure.* This is [theorem 68.13](#), by the same component argument (an open set has countably many maximal convex components, each splitting at most its two boundary fibers). Source 30 adds: “For example, the set of all lower endpoints is not Borel. Its failure is stronger than a failure to be open: it splits every fiber. For  $E = E_n$ , the split space has exactly  $\mathfrak{c}$  Borel sets  $\dots$ , despite the failure of countable generation.” Source 29 credits the formula to Fremlin [59], 419L(b), for the split interval.

**Theorem 68.15** (The measurable trichotomy for finite tails). *Let  $\mathcal{B}_{\text{lex}}$  and  $\mathcal{B}_{\text{coord}}$  be the Borel sigma-algebras of the two topologies on  $P_{\omega+n}$ . Then*

| $n$        | comparison of Borel sigma-algebras                                            |
|------------|-------------------------------------------------------------------------------|
| 0, 1       | $\mathcal{B}_{\text{lex}} = \mathcal{B}_{\text{coord}}$                       |
| 2          | $\mathcal{B}_{\text{lex}} \subsetneq \mathcal{B}_{\text{coord}}$              |
| $n \geq 3$ | $\mathcal{B}_{\text{lex}}$ and $\mathcal{B}_{\text{coord}}$ are incomparable. |

For  $n = 2$ , formula (23) with  $E = E_2$  describes the native Borel sigma-algebra exactly, and it is not countably generated. For  $n \geq 3$ , the native Borel sigma-algebra has cardinality  $2^{\mathfrak{c}}$ .

*Proof.* For  $n = 0$  the topologies agree. For  $n = 1$ , native-open sets are coordinate-open. Conversely, the extra coordinate events are already native-Borel:

$$\{f : f(\omega) = a\} = P_{\omega+1} \setminus \bigcup_{k < \omega} \{f : f(k) = a\}.$$

The events on the right are native-clopen. A countable coordinate basis therefore consists of native-Borel sets, proving equality of the two sigma-algebras.

For  $n = 2$ , use the double-split representation. The prefix map to  $E_2$  is continuous for the coordinate topology, and countable sets are coordinate-Borel. Formula (23) therefore gives  $\mathcal{B}_{\text{lex}} \subseteq \mathcal{B}_{\text{coord}}$ . Fix  $a < b$  in  $D$  and consider the coordinate-clopen event

$$O_a = \{f : f(\omega) = a\}.$$

For each prefix enumerating  $D \setminus \{a, b\}$ , the two possible tails are  $(a, b)$  and  $(b, a)$ , and  $O_a$  contains exactly one of them. There are  $\mathfrak{c}$  such prefixes. The split-pair criterion in the preceding theorem shows that  $O_a$  is not native-Borel. The inclusion is strict.

For  $n \geq 3$ , let  $m = n!$  and let  $S = E_n \times \{0, m-1\}$  be the closed endpoint subspace from Theorem 68.8. It is the double split of  $E_n$ . Choose a fixed  $n$ -element residual set  $F$  with minimum  $a$  and with a different maximum. The coordinate-clopen event  $O_a$  contains the first but not the last point over every prefix enumerating  $D \setminus F$ : the first tail is increasing and the last decreasing. Its trace on  $S$  distinguishes  $\mathfrak{c}$  endpoint pairs, so the double-split theorem shows that the trace is not Borel in  $S$ . If  $O_a$  were native-Borel, its trace on this closed subspace would be Borel, a contradiction.

In the other direction, the isolated interior points form a set of cardinality  $\mathfrak{c}$ , every subset of which is native-open. There are  $2^{\mathfrak{c}}$  such subsets and only  $\mathfrak{c}$  coordinate-Borel sets [57]. Some native-open subsets are therefore not coordinate-Borel. This also proves the asserted cardinality of the native Borel sigma-algebra.  $\square$

There is a slightly fuller normal form when  $n \geq 3$ . Put

$$J = E_n \times \{1, \dots, n! - 2\}, \quad S = E_n \times \{0, n! - 1\}.$$

A set is native-Borel exactly when its intersection with  $J$  is arbitrary and its intersection with  $S$  has the form

$$\pi_S^{-1}(B) \triangle N, \quad B \in \mathcal{B}(E_n), \quad N \subseteq S \text{ countable.}$$

Indeed  $J$  is open and discrete,  $S$  is closed, and the induced topology on  $S$  is the double split. This gives an explicit description of every native-Borel set, not just a cardinality argument.

For comparison, under the same finite-split identification the coordinate Borel sigma-algebra is exactly

$$\left\{ \bigcup_{j < n!} B_j \times \{j\} : B_j \in \mathcal{B}(E_n) \right\}. \quad (24)$$

To verify this without a Borel-isomorphism theorem, the prefix projection is coordinate-continuous and the finite tail rank is coordinate-continuous. Conversely, partition  $E_n$  into the countably many closed sets  $A_F$  of prescribed omissions. On  $A_F \times \{j\}$ , every tail value is fixed. Thus the inverse image of every coordinate cylinder is a countable union of Borel pieces in the displayed finite product.

[merge] Source 30 states the measurable comparison through the ranking map  $r_n$  and the table map  $\Phi_n$ ; by its [proposition 68.18](#), coordinate Borel sets and relation-table Borel sets agree, so its theorem and [theorem 68.15](#) are one result in two formulations. Source 30's theorem adds that for  $n \leq 1$  ranking is a pointwise limit of continuous maps, and that the preimage of every lexicographic ray is  $F_\sigma$  for every  $n$ .

#### 68.4.1 A sharp, two-direction coding threshold

**Theorem 68.16** (Ranking and relation-table maps). *With the topologies specified above:*

1. For  $n = 0, 1$ ,  $\Phi_n$  is continuous and  $r_n$  is Borel measurable. Thus the two presentations have the same standard Borel structure. Nevertheless,  $r_n$  is discontinuous at every point; it is a pointwise limit of continuous maps into  $P_{\omega+n}$ .
2. For  $n = 2$ ,  $r_2$  is Borel measurable, but  $\Phi_2$  is not Borel measurable. The order-topological Borel structure of  $P_{\omega+2}$  is strictly smaller than the relation-table Borel structure and is not standard Borel.
3. For every finite  $n \geq 3$ , neither  $r_n$  nor  $\Phi_n$  is Borel measurable. The order topology on  $P_{\omega+n}$  has  $2^{\mathfrak{c}}$  open sets, whereas  $\text{Tab}_n$  has only  $\mathfrak{c}$  Borel sets.

More precisely, for  $n \leq 2$  the inverse image under  $r_n$  of every open set is  $F_\sigma$  relative to  $\text{Tab}_n$ . For every finite  $n$ , the inverse image of each individual lexicographic ray is  $F_\sigma$ , including when ranking is not Borel measurable.

*Proof.* For  $n \leq 1$ , at least one of any two distinct labels  $a, b$  occurs at a finite coordinate. The condition that  $a$  precedes  $b$  is therefore

$$\exists k < \omega \quad [e(k) = a \text{ and } b \notin \{e(0), \dots, e(k)\}].$$

Both this condition and its complementary orientation are unions of finite-prefix cylinders. Every relation bit is consequently continuous, proving continuity of  $\Phi_n$ . The countable finite-prefix base for  $P_{\omega+n}$  and [Proposition 68.12](#) prove Borel measurability of  $r_n$ .

To see discontinuity of ranking, fix a relation  $R$  and a table neighborhood determined by finitely many labels  $F$ . Move a finite-rank label outside  $F$ , distinct from the original first label, to the first position and preserve the relative order of all other labels. The order type remains  $\omega + n$  and all specified comparison bits remain unchanged, but the first enumerated label changes. The first-coordinate cylinder is open in  $P_{\omega+n}$ , so  $r_n$  is discontinuous at  $R$ .

There is also an explicit sequence of continuous approximations when  $n \leq 1$ . Fix an auxiliary enumeration  $x_0, x_1, \dots$  of  $D$ . At stage  $m$ , sort  $\{x_0, \dots, x_{m-1}\}$  by  $R$  and complete the resulting finite prefix to an element of  $P_{\omega+n}$  by a fixed deterministic rule. This map depends on finitely many comparison bits and is continuous. Every true finite initial segment eventually occurs correctly in these finite sorts, because each of its elements has only finitely many predecessors. The approximations therefore converge in the finite-prefix topology of  $P_\omega$  or  $P_{\omega+1}$  to  $r_n(R)$ .

For  $n = 2$ , write a Borel set of  $P_{\omega+2} = \text{Split}(E_2)$  as  $\pi_2^{-1}(B) \triangle C$  using [Note 68.14](#). The map  $R \mapsto r_2(R)|_\omega$  is Borel into  $E_2$ , by its countable finite-prefix base and the coordinate descriptions above. The inverse image of the countable set  $C$  is countable and therefore Borel in  $\text{Tab}_2$ . Thus  $r_2$  is Borel measurable.

In the reverse direction, fix  $a < b$  in  $D$ . In every fiber whose omitted pair is  $\{a, b\}$ , the lower point has terminal order  $(a, b)$  and the upper point has terminal order  $(b, a)$ . Therefore the inverse image under  $\Phi_2$  of the clopen table condition  $aRb$  splits  $\mathfrak{c}$  fibers. It is not Borel by [Note 68.14](#). This proves all the assertions at  $n = 2$ , including strictness of the two Borel structures.

For  $n \geq 3$ , arbitrary subsets of the dense isolated-point set are open. There are  $2^{\mathfrak{c}}$  such subsets. Distinct open subsets have distinct inverse images under the bijection  $r_n$ , while a standard Borel space of size  $\mathfrak{c}$  has only  $\mathfrak{c}$  Borel subsets. Thus  $r_n$  cannot be Borel measurable.

Finally, restrict to the closed subspace  $S_n \cong \text{Split}(E_n)$ . Fix an omitted  $n$ -element set  $S$  containing  $a < b$ . For each of the  $\mathfrak{c}$  prefixes omitting exactly  $S$ , the first terminal permutation is the increasing one and the last is the decreasing one. The table condition  $aRb$  distinguishes these two endpoints. Its inverse image in  $S_n$  splits  $\mathfrak{c}$  fibers and is not Borel. The trace on a closed subspace of a Borel set would be Borel. Consequently  $\Phi_n$  is not Borel measurable in  $P_{\omega+n}$  either.

For the final assertions, fix  $e \in P_{\omega+n}$ . The condition  $r_n(R) < e$  is a countable union over finite first-disagreement coordinates  $k$ , together with a finite exceptional set of relations whose enumerations agree with  $e$  through all of  $\omega$  and differ only in the terminal permutation. Each finite-disagreement condition is  $F_\sigma$ : it specifies finitely many exact finite ranks, and then one finite rank carrying any of countably many labels below  $e(k)$ . The exceptional relation codes are closed singletons. The same proof treats the opposite ray.

Every open subset of a separable linear order is a countable union of basic intervals and rays with actual order points as endpoints. To check the assertion without assuming a countable base, first decompose it into countably many maximal convex open components. In each component choose countable coinital and cofinal subsets, adding a least or greatest point if present. Intervals with endpoints from these countable subsets cover the component except possibly its least and greatest points; one additional ambient basic neighborhood covers each such point. These neighborhoods exist because the component is open. Applying this observation to the separable spaces  $P_\omega, P_{\omega+1}, P_{\omega+2}$ , and using closure of  $F_\sigma$  sets under finite intersections and countable unions, proves the open-set assertion. This is a statement about the inverse images of open sets; no Baire-class terminology for maps into the nonmetrizable space  $P_{\omega+2}$  is required.  $\square$

The theorem gives a concrete warning for formalization. On a fixed countable carrier, relation tables and enumerations are unambiguously interconvertible as *sets*. Their natural topologies and measurable structures need not be interconvertible, even though every individual enumeration coordinate has a low Borel description in table codes. At  $\omega + 2$  there are too many adjacent pairs

for a countably generated Borel structure; at  $\omega + 3$  there are too many open sets for ranking to be measurable at all.

**Corollary 68.17** (Nonmeasurable ranking at every later countable type). *Let  $\alpha \geq \omega + 3$  be countable. Equip the well-orders of type  $\alpha$  on  $D$  with their relation-table standard Borel structure, and their increasing enumerations with the lexicographic order topology. The ranking bijection from the former to the latter is not Borel measurable.*

*Proof.* The fixed-type table class is Borel by the classical Borelness of the isomorphism class of a countable structure; for ordinals see Miller [60, §3]. The established fixed-type cellularity theorem supplies  $\mathfrak{c}$  pairwise disjoint nonempty open intervals in the enumeration order. Their arbitrary unions are  $2^{\mathfrak{c}}$  distinct open sets. The same counting argument as in Theorem 68.16 applies.  $\square$

**Proposition 68.18** (One orientation predicate restores the standard Borel structure). *For  $P_{\omega+2}$ , let*

$$H = \{e \in P_{\omega+2} : e(\omega) <_D e(\omega + 1)\},$$

*the set of lower endpoints of the adjacent fibers. Then*

$$\sigma(\text{Bor}_{\text{lex}}(P_{\omega+2}) \cup \{H\}) = \text{Bor}_{\text{prod}}(P_{\omega+2}) = \{r_2(B) : B \in \text{Bor}(\text{Tab}_2)\}.$$

*Thus one additional binary predicate suffices, and none suffices.*

*Proof.* The equality between the full-product and transported table Borel structures follows from the coordinate formulas for ranking and continuity of relation coding in the product topology. Put

$$C_{a,b} = \{e \in P_{\omega+2} : D \setminus \text{ran}(e|_{\omega}) = \{a, b\}\}.$$

This is lexicographically closed: it says that neither  $a$  nor  $b$  ever occurs at a finite coordinate. For each  $a \in D$ ,

$$\{e : e(\omega) = a\} = \bigcup_{b > a} (C_{a,b} \cap H) \cup \bigcup_{b < a} (C_{a,b} \setminus H).$$

There is an analogous formula for  $e(\omega + 1) = a$ . All finite-coordinate observations are already lexicographically continuous. These countable unions therefore show that the enlarged sigma-algebra contains every product coordinate cylinder and hence the full-product Borel structure. Conversely, the lexicographic Borel structure is contained in the product Borel structure, and  $H$  is product-clopen. This proves equality. Finally  $H$  itself is not lexicographically Borel, since it splits every adjacent fiber, so an enrichment is necessary.  $\square$

*Remark 68.19* (Sigma-algebra inclusion is not topology inclusion). The full-product topology on  $P_{\omega+2}$  is Polish, but is not a refinement of its lexicographic topology. The two topologies are incomparable. The predicate  $H$  is product-clopen but not lexicographically Borel. In the other direction, the lexicographic ray  $(-\infty, p^+)$  is not product-open at  $p^-$ . A product neighborhood fixes only finitely many finite coordinates, along with possibly the terminal ones. At a later finite coordinate one can increase the label, retain the same omitted pair and terminal order, and complete the enumeration. The resulting point still belongs to that product neighborhood but lies above  $p^+$ . The proposition compares the generated sigma-algebras, not an inclusion of the two topologies.

### 68.5 Two different products of the native Borel structure

At two terminal labels a further distinction appears. For a topology on  $L$ , the Borel sigma-algebra  $\mathcal{B}(L \times L)$  of its topological product need not equal the sigma-algebra  $\mathcal{B}(L) \otimes \mathcal{B}(L)$  generated by Borel rectangles. The equality familiar from Polish spaces fails for the native split orders. Related split-interval product phenomena are classical [59, 419X(g)]; the following proof uses only the explicit Borel normal form above.

**Theorem 68.20** (Native comparison is not measurable for the rectangle product). *Let  $E$  be an uncountable dense suborder of  $\mathbb{R}$  without endpoints and let  $L = E \times_{\text{lex}} m$  for a finite  $m \geq 2$ . Then*

$$\{(x, y) \in L^2 : x < y\} \in \mathcal{B}(L \times L) \quad \text{but} \quad \{(x, y) \in L^2 : x < y\} \notin \mathcal{B}(L) \otimes \mathcal{B}(L).$$

*Consequently the two product sigma-algebras are distinct. This applies to  $P_{\omega+n}$  for every finite  $n \geq 2$ .*

*Proof.* Strict order is open in the product topology of any linearly ordered topological space. If  $x < z < y$ , the product of the rays below and above  $z$  is a suitable neighborhood of  $(x, y)$ . If  $x < y$  is an adjacent pair, use  $(-\infty, y) \times (x, \infty)$  instead. Thus the displayed relation belongs to  $\mathcal{B}(L \times L)$ .

First let  $m = 2$ . Every member of a sigma-algebra generated by a family uses only countably many members of that family: the sets having such a countable supporting subfamily themselves form a sigma-algebra containing all generators. Hence any member of  $\mathcal{B}(L) \otimes \mathcal{B}(L)$  is generated by countably many rectangles  $B_k \times C_k$ .

By Theorem 68.13, each  $B_k$  and  $C_k$  distinguishes the two points of only countably many fibers. Choose  $p \in E$  outside the union of all these exceptional base sets. Every generating rectangle has the same membership value at

$$((p, 0), (p, 1)) \quad \text{and} \quad ((p, 1), (p, 0)).$$

Equality of membership is preserved by complements and countable unions, so every set generated by these rectangles has the same value at those two ordered pairs. Strict order takes opposite values there. It cannot belong to the rectangle-generated product sigma-algebra.

For  $m > 2$ , the closed endpoint subspace  $S = E \times \{0, m-1\}$  is a double split. Its inclusion in  $L$  is continuous, hence Borel measurable. Pulling a rectangle-product measurable strict order on  $L$  back along the product of these inclusions would give a rectangle-product measurable strict order on  $S$ , contrary to the case just proved.  $\square$

The coordinate coding has none of this product ambiguity: it is Polish, and its strict lexicographic relation is  $\Delta_2^0$  by Proposition 68.11. Thus three separate objects occur naturally: the coordinate Borel structure, the native Borel structure, and the Borel structure of a native topological product. Their distinctions already matter for an elementary question such as whether comparison of two coded well-orders is a measurable operation.

### 68.6 What the countable analysis says about formalization

All the underlying carriers in this section are ordinary sets, and all arguments take place in ZFC. Nonetheless, the choice of coding and topology changes even the measurable sets. It is therefore insufficient to say that a formalization uses “the Borel structure on well-orders” without naming the topology.

A proof-assistant development can make the distinction concrete as follows. The set of bijections  $\alpha \rightarrow D$  is one underlying type. Use two tagged copies of it: one with the induced product topology

and one with the topology of the first-difference linear order. Prove the finite-tail order isomorphism before transporting any topological structure. The prefix-omission sets  $E_n$  should retain the prefix topology, not silently acquire the finer topology obtained by exposing the finite residual labels as extra coordinates. At  $n = 2$ , the coordinate event  $f(\omega) = a$  is a particularly useful negative regression test: it must be coordinate-clopen and fail to be native Borel. Identifying the two Borel structures would contradict an explicit mathematical theorem.

The comparison relation itself remains low in the coordinate Borel hierarchy for every countable ordinal length. This makes that code space useful for descriptive-set-theoretic questions even when the native order topology has a much larger family of open or Borel sets. The native topology is appropriate for order completion and cuts; the coordinate topology is appropriate for finite observations of enumerations. Both are rigorous interpretations, and the results above state exactly where they coincide and where they diverge.

### 68.7 Further questions made precise by these results

1. Are the dense base orders  $E_n$  and  $E_m$  isomorphic for distinct positive integers  $m, n$ ? The finite-tail orders themselves are pairwise nonisomorphic, but their finite-condensation quotients might forget the exact positive number of omitted labels. The common category and Borel bounds established here do not settle this question.
2. What is the exact difference-hierarchy or Wadge degree of  $E_n$  in the common real completion for  $n \geq 1$ ? The explicit difference of  $G_\delta$  sets is a sharper starting point than an unqualified third-level Borel bound.
3. Classify the ordered pairs  $(C, E_n)$  and their order automorphism groups. Any automorphism preserving  $E_0$  must preserve a comeager realized set; for positive  $n$  it preserves a dense meager realized set. Determine which features of the omitted-label decomposition can be recovered from the ordered pair alone.
4. For  $\alpha \geq \omega \cdot 2$ , characterize the native Borel sigma-algebra in terms of the first- $\omega$  prefix and the varying infinite residual orders. A low-complexity coordinate comparison relation is already available, but the finite split-pair normal form no longer describes the fibers.
5. Determine which infinite-length native order topologies are Baire, and where compatible complete metrics can exist. First countability holds at every countable length, whereas the coordinate topology is always Polish; these facts do not settle native metrizability beyond the finite-tail cases.
6. Find a functorial formalization of the two tagged topologies and their Borel sigma-algebras. The exact inclusion at one omitted label and failure of Borel measurability at two labels give concrete milestones before moving to generalized topologies at uncountable birthday stages.

## 69 Singular cardinalities: continuity, complete metrizability and non-Borel boundaries (sources 24 and 26)

[merge] Source 24's Section 8 and source 26's Sections 4–10. At a singular enumeration cardinal  $\mu$  a set of fewer than  $\mu$  positions can be unbounded, and controlling a bounded initial segment is no longer controlling a small set of coordinates. Source 24 finds the exact continuity criteria for the permutation operations and isolates the boundedness-preserving subgroup  $H_\mu$ ; source 26 answers source 24's question whether the minimal slice is completely metrizable when  $\text{cf } \mu = \omega < \mu$ : it never is, it is not even Borel in its completion, and no nonempty open subspace is completely metrizable

(theorem 69.18). Source 26 writes  $\kappa$  for  $|X|$  and  $\theta$  for the birthday cutoff; they are printed  $\mu$  and  $\kappa$  (part X). Source 28's further results on these groups are in section 70.

### 69.1 The permutation-group obstruction (source 24)

A fixed enumeration of the alphabet identifies  $\mathcal{W}_\mu(X)$  as a set with  $\text{Sym}(\mu)$ . At countable or regular cardinalities, it is tempting to import the usual topological permutation-group picture. At singular cardinalities that import is invalid unless an additional boundedness condition is checked.

**Definition 69.1** (Preservation of bounded sets). A function  $u : \mu \rightarrow \mu$  is *boundedness preserving* if

$$\forall \alpha < \mu \exists \beta < \mu \quad u[\alpha] \subseteq \beta.$$

Equivalently, it takes every bounded subset of  $\mu$  to a bounded subset. Here “bounded” refers to the ordinal order on  $\mu$ , not to cardinality alone.

On  $\text{Sym}(\mu)$  let  $L_\tau(\pi) = \tau \circ \pi$  and  $R_\sigma(\pi) = \pi \circ \sigma$ . All topology in the next theorem is the forward bounded-prefix topology.

**Theorem 69.2** (Exact continuity criteria). *For every infinite  $\mu$ :*

- (i) *Every left translation  $L_\tau$  is a homeomorphism.*
- (ii) *Right translation  $R_\sigma$  is continuous at every point if  $\sigma$  is boundedness preserving, and is continuous at no point otherwise.*
- (iii) *Inversion  $\pi \mapsto \pi^{-1}$  is continuous at a particular  $\pi$  exactly when  $\pi^{-1}$  is boundedness preserving.*

*Proof.* Left translation is a relabelling of output values. Equality of any forward restrictions is preserved in both directions, proving (i).

For (ii), to determine  $(\pi \circ \sigma) \upharpoonright \alpha$ , it suffices to determine  $\pi$  on  $\sigma[\alpha]$ . If that image is contained in a bounded initial segment  $\beta$ , agreement with  $\pi$  below  $\beta$  enforces the desired output agreement. Conversely, suppose  $\sigma[\alpha]$  is unbounded. Given any input neighborhood  $[\pi \upharpoonright \beta]$ , choose  $u \in \sigma[\alpha] \setminus \beta$  and a different  $v \in \mu \setminus \beta$ . Precompose  $\pi$  with the transposition of  $u, v$ . The new permutation agrees with  $\pi$  below  $\beta$ , but its composition with  $\sigma$  changes at the coordinate below  $\alpha$  whose image under  $\sigma$  is  $u$ . Thus no input neighborhood controls that output prefix, at any  $\pi$ .

For (iii), determining  $\pi^{-1}$  below  $\alpha$  is equivalent to fixing the positions  $\pi^{-1}[\alpha]$  of those labels. If this set is bounded, a sufficiently long forward restriction of  $\pi$  fixes all these preimages. If it is unbounded, given  $\beta < \mu$  choose  $u \in \pi^{-1}[\alpha] \setminus \beta$  and a different  $v \notin \beta$ . Again precompose with their transposition. The forward prefix below  $\beta$  is unchanged, but the inverse position of the label  $\pi(u) < \alpha$  changes from  $u$  to  $v$ . This is precisely failure of continuity at  $\pi$ .  $\square$

**Corollary 69.3** (Regular and singular cases diverge). *If  $\mu$  is regular, the forward topology makes  $\text{Sym}(\mu)$  a topological group. If  $\mu$  is singular, it does not: there are right translations discontinuous everywhere, and inversion has points of discontinuity.*

*Proof.* For regular  $\mu$ , every set of size less than  $\mu$  is bounded, so every permutation and its inverse preserve bounded sets. Joint continuity of multiplication follows directly: to control  $\pi' \circ \sigma'$  below  $\alpha$ , first require  $\sigma' \upharpoonright \alpha = \sigma \upharpoonright \alpha$  and then require  $\pi'$  to agree with  $\pi$  on a prefix containing the bounded set  $\sigma[\alpha]$ .

For singular  $\mu$ , let  $q = \text{cf } \mu < \mu$ . Choose  $A = \{a_\xi : \xi < q\}$  bounded in  $\mu$  and a disjoint cofinal set  $B = \{b_\xi : \xi < q\}$ . The involution  $\sigma$  exchanging each  $a_\xi$  with  $b_\xi$  and fixing everything else takes the bounded set  $A$  to the unbounded set  $B$ . It and its inverse fail the criterion in Theorem 69.2.  $\square$

This is not a pathology of surreal multiplication. It already occurs for permutations of a naked singular cardinal, before any numerical alphabet is supplied. Nor does it contradict Corollary 62.8: left translation is relabelling, whereas right translation changes the *positions* on which a bounded prefix depends.

### 69.1.1 The subgroup where the usual picture survives

Define

$$H_\mu = \{\pi \in \text{Sym}(\mu) : \pi \text{ and } \pi^{-1} \text{ preserve bounded sets}\}.$$

It is a subgroup: boundedness preservation is closed under composition, and the definition is symmetric under inversion. At a regular cardinal  $H_\mu = \text{Sym}(\mu)$ ; at a singular cardinal the involution above shows that it is proper.

For  $\alpha < \mu$  define two-sided entourages

$$E_\alpha^{\leftrightarrow} = \{(\pi, \sigma) : \pi \restriction \alpha = \sigma \restriction \alpha \text{ and } \pi^{-1} \restriction \alpha = \sigma^{-1} \restriction \alpha\}.$$

They define a Hausdorff uniformity on the full permutation set, independently of continuity of the group operations.

**Theorem 69.4** (Two-sided completeness and the bounded subgroup). *The full space  $\text{Sym}(\mu)$  is complete for the two-sided uniformity. On  $H_\mu$ , that uniformity induces the forward topology and is complete; with this topology  $H_\mu$  is a topological group. On all of  $\text{Sym}(\mu)$  the two uniform topologies agree when  $\mu$  is regular and differ when  $\mu$  is singular.*

*Proof.* A two-sided Cauchy filter determines coherent stabilized forward prefixes and coherent stabilized inverse prefixes. Their unions are injections  $h, g : \mu \rightarrow \mu$ . If  $h(\xi) = \eta$ , choose a filter member on which the forward value at  $\xi$  and the inverse value at  $\eta$  have both stabilized. Every permutation in that nonempty member witnesses  $g(\eta) = \xi$ . The converse is identical. Hence  $g = h^{-1}$  and  $h$  is a permutation. Stabilization on each initial segment gives convergence in the two-sided uniformity.

At a point  $\pi \in H_\mu$ , an inverse-prefix requirement below  $\alpha$  is implied by a forward requirement on a prefix bounding  $\pi^{-1}[\alpha]$ . Thus the two topologies agree on  $H_\mu$ . If the original Cauchy filter consists of elements of  $H_\mu$ , its limiting forward prefix  $h \restriction \alpha$  is a restriction of one such element and therefore has bounded image. The same holds for  $g \restriction \alpha$ . Thus  $h \in H_\mu$ , proving completeness of the subgroup. The proof of joint continuity and the inversion criterion above now apply inside the subgroup.

For regular  $\mu$ , all permutations belong to  $H_\mu$ , proving equality of the topologies on the full space. For singular  $\mu$ , inverse stabilization defines a two-sided neighborhood at the involution in Corollary 69.3 that contains no forward neighborhood there. The topology is strictly finer.  $\square$

**Corollary 69.5** (A complete metric on the bounded subgroup). *If  $\text{cf } \mu = \omega$ , the forward topology on  $H_\mu$  has a complete compatible ultrametric. Choose a countable cofinal sequence of ordinal lengths and take the maximum of the resulting forward and inverse first-disagreement ultrametrics.*

*Proof.* The cofinal sequence gives a countable base for the complete two-sided uniformity. On  $H_\mu$  that uniformity induces the forward topology by Theorem 69.4. Its ultrametric is therefore complete and compatible, exactly as in the countable permutation proof.  $\square$

*Remark 69.6* (A finer complete uniformity is not a universal group repair). The two-sided uniformity exists and is complete on the full singular permutation set, but this by itself does not make all group

operations continuous in its topology. For the unboundedness-preserving  $\sigma$  above, right translation is still discontinuous at the identity: at the identity, a sufficiently long fixed forward prefix also fixes that inverse prefix, while  $\sigma[\alpha]$  remains unbounded. The subgroup  $H_\mu$  is the clean topological-group statement proved here.

### 69.1.2 What is established when cofinality is countable

If  $\text{cf } \mu = \omega$ , Proposition 62.7 provides a compatible forward ultrametric, and Theorem 65.1 identifies its uniform completion with injections. When  $\mu = \omega$ , Theorem 67.2 supplies a different complete compatible metric. At an uncountable singular  $\mu$  of countable cofinality, Theorem 69.4 provides a complete *finer* uniform topology on the full permutation space, but not a complete metric for its original topology.

The earlier dense-open fusion theorem (source 17, theorem 30.5) proves that these forward spaces are Baire. Its proof extends a short prefix at stage  $n$  to meet the next dense open set and to cover a growing block of labels. This does not automatically give the point-preserving choices needed for a stronger topological completeness argument. Therefore neither forward incompleteness nor the failure of inversion continuity settles complete metrizability. The exact singular question is retained as its Question 13.1 (note 69.7).

*Note 69.7* ([merge]; source 24's singular question, answered (3 October 2026)). Source 24 retains the “exact singular question” as its Question 13.1: *for singular  $\mu > \omega$  with  $\text{cf } \mu = \omega$ , is the forward-prefix space  $\mathcal{W}_\mu(X)$  completely metrizable? Equivalently, can the dense permutation subspace of its metrizable injection completion be characterized as a  $G_\delta$  subset? Determine whether the answer depends on cardinal arithmetic.* Source 26 answers it negatively in ZFC, with no cardinal-arithmetic hypothesis: the permutation space is not even Borel in  $\mathcal{I}_\mu(X)$ , and no nonempty open subspace is completely metrizable (theorems 69.17 and 69.18 and corollary 69.19). Source 24's own results do not settle it, as it says; source 28's dense complete locus does not either (note 70.13).

## 69.2 The complete-metric subspace criterion (source 24, Appendix C)

[merge] Source 24's Appendix C, used in the singular question above and in source 26's classification: “For completeness, the characterization used in Question 13.1 can be proved without a separability hypothesis.”

**Proposition 69.8** (Complete metric subspaces and  $G_\delta$  sets). *Let  $B$  be a completely metrizable space and  $A \subseteq B$ . Then  $A$  has a complete compatible metric if and only if it is  $G_\delta$  in  $B$ .*

*Proof.* Fix a complete metric  $d$  on  $B$ . First suppose  $\rho$  is a complete compatible metric on  $A$ . For each positive integer  $n$ , cover  $A$  by ambient open sets  $U$  that meet  $A$ , have  $d$ -diameter less than  $2^{-n}$ , and have  $\rho$ -diameter less than  $2^{-n}$  on  $U \cap A$ . Such sets exist by compatibility of the two subspace topologies. Let  $O_n$  be their union.

If  $z \in \bigcap_n O_n$ , choose  $U_n \ni z$  from the  $n$ th cover and  $a_n \in U_n \cap A$ . Then  $a_n \rightarrow z$  in  $d$ . For fixed  $N$ , the ambient neighborhood  $U_N$  of  $z$  contains all sufficiently late  $a_n$ . Their pairwise  $\rho$ -distances are less than  $2^{-N}$ . Thus  $(a_n)$  is  $\rho$ -Cauchy and converges in  $A$  to some  $a$ . Compatibility gives convergence to  $a$  in  $d$  as well; hence  $z = a \in A$ . Therefore  $A = \bigcap_n O_n$ .

Conversely, suppose  $A = \bigcap_{n \geq 1} O_n$  with each  $O_n$  open in  $B$ . Put  $F_n = B \setminus O_n$  and, on  $A$ , set  $t_n(x) = 1/d(x, F_n)$ , with  $t_n = 0$  if  $F_n$  is empty. The denominator is positive because  $x \in O_n$ . Define

$$\rho(x, y) = d(x, y) + \sum_{n \geq 1} 2^{-n} \min\{1, |t_n(x) - t_n(y)|\}.$$

The triangle inequality follows term by term, and positivity follows from  $d$ . Continuity of every  $t_n$ , followed by control of the summable tail, shows that  $\rho$  induces the subspace topology.

A  $\rho$ -Cauchy sequence is  $d$ -Cauchy and has a limit  $z \in B$ . For each fixed  $n$ , its  $t_n$ -values are Cauchy in the ordinary real metric: truncated-distance Cauchyness is ordinary Cauchyness once the required error is less than 1. They therefore have a finite limit. If  $z \in F_n$ , the distances to  $F_n$  would tend to zero and their reciprocals would diverge, a contradiction. Hence  $z \in A$ . Continuity of the  $t_n$  and the same summable-tail estimate give convergence in  $\rho$ , proving completeness.  $\square$

*Note 69.9* (Source 26, Appendix A, Theorem A.1, and source 28, Appendix B, Proposition B.1). Both sources prove [proposition 69.8](#) again, by the same two constructions (a  $G_\delta$  from covers of shrinking diameter in both metrics; the complete metric  $d + \sum_n 2^{-n} \min\{1, |t_n(x) - t_n(y)|\}$  with  $t_n = 1/d(\cdot, F_n)$ ), “without assuming separability”. Source 26: “The earlier manuscript also records this criterion; the proof is repeated to make the logical dependence visible ... Only the necessity direction is required to turn Theorem 6.2 into the main negative conclusion. Its proof does not use completeness of the ambient metric; it uses the complete compatible metric hypothesized on the subspace. The converse supplies the positive conclusions for  $\mu = \omega$  and for  $H_\mu$ .” Source 28 uses it for its dense locus ([theorem 70.11](#)) and its own Question 1. Source 29 cites it in the form “an  $F_\sigma$  subset of  $\mathbb{R}$  is  $\sigma$ -compact”; the criterion is classical (Alexandrov).

### 69.3 Local character, the countable exception and the Baire property (source 26)

*Note 69.10* (Source 26, Theorem 4.3, “Local character”). *At every point of  $\mathcal{W}_\mu(X)$  and  $\mathcal{I}_\mu(X)$ , the least cardinality of a neighborhood base is  $\text{cf } \mu$ . In particular, either space is metrizable if and only if  $\text{cf } \mu = \omega$ .* This is [proposition 62.7](#), by the same argument; source 26 adds that the cofinal-length ultrametric is complete on  $\mathcal{I}_\mu(X)$  by [theorem 65.1](#), which its classification uses.

[merge] Source 26’s proof of the countable case is a route through the  $G_\delta$  criterion; its second paragraph is source 24’s metric  $D$  ([theorem 67.2](#)):

**Proposition 69.11** (The countable exception). *For  $\mu = \omega$ , the space  $\mathcal{W}_\omega(X)$  is completely metrizable.*

*Proof.* Its injection completion is completely metrizable, and [note 65.5](#) expresses the permutation subspace as a countable intersection of open sets. The complete-metric subspace criterion, proved in [note 69.9](#), applies.

An explicit alternative is to fix a bijection  $X \cong \omega$  and combine the forward first-disagreement metric with the corresponding metric on inverses. Stabilization of both a permutation and its inverse produces mutually inverse limiting injections. At  $\omega$ , a finite inverse-prefix requirement is already implied, at a given permutation, by a sufficiently long finite forward prefix. Thus the combined complete metric has the original topology.  $\square$

The last compatibility argument fails for general singular permutations: a bounded set of labels can have an unbounded inverse image. A finer complete metric on forward and inverse prefixes is not evidence that the forward topology itself is completely metrizable.

[merge] Source 26’s Baire theorem is the fusion theorem [theorem 30.5](#) (source 17, for  $X = \mathbf{No}_{<\kappa}$ ) for an arbitrary alphabet of every infinite cardinality, by the same fusion with coverage blocks:

### 69.3.1 Baire category survives the failure of completeness

**Theorem 69.12** (Baire property). *For every infinite cardinal  $\mu$ ,  $\mathcal{W}_\mu(X)$  is a Baire space in its bounded-prefix topology.*

*Proof.* Let  $(O_n)_{n < \omega}$  be dense open subsets and start inside an arbitrary cylinder  $N_p$ . If  $\text{cf } \mu > \omega$ , successively extend the prefix so that its cylinder lies inside  $O_n$ . The union of the countably many prefix domains remains bounded in  $\mu$ , and its injective union extends to a permutation. This extension belongs to every chosen cylinder and hence to every  $O_n$ .

If  $\text{cf } \mu = \omega$ , choose increasing sets  $Y_n \subseteq X$  with  $|Y_n| < \mu$  and union  $X$ , and cofinal domain lengths  $\gamma_n < \mu$ . At stage  $n$ , first refine the current cylinder into  $O_n$ , using density and openness. Then append all labels of  $Y_n$  not already used, in some order, and lengthen the prefix to length at least  $\gamma_n$ . Both operations still use fewer than  $\mu$  coordinates: a finite sum of ordinals whose cardinalities are below the initial cardinal  $\mu$  remains below  $\mu$ . [Note 62.9](#) supplies any additional unused labels required. The new cylinder stays inside  $O_n$ .

The union of the resulting prefixes has domain  $\mu$ , is injective, and covers every  $Y_n$ . It is a permutation in the original cylinder and in every  $O_n$ . The proof includes  $\mu = \omega$ , using finite  $Y_n$  and finite lengths.  $\square$

This fusion argument controls both domain growth and eventual coverage. It is not a proof of complete metrizability: it produces one point meeting a prescribed countable family of dense open sets, rather than a complete compatible metric or a  $G_\delta$  description inside the completion.

## 69.4 Compact coding of omitted labels (source 26)

[merge] Source 26's Section 5, printed whole: the central construction of the singular theory.

This section supplies the central construction. It only uses the cardinality of the alphabet and the countable cofinality of the domain. Surreal arithmetic is not involved.

**Theorem 69.13** (Compact coding of omitted labels). *Suppose  $\mu > \omega$ ,  $\text{cf } \mu = \omega$ , and  $|X| = \mu$ . For every  $A \subseteq 2^\omega$  with  $|A| < \mu$ , there exist distinct labels  $(y_a)_{a \in A}$  and a continuous topological embedding*

$$F : 2^\omega \longrightarrow \mathcal{I}_\mu(X)$$

*with compact, closed image such that*

$$X \setminus \text{ran } F(z) = \begin{cases} \{y_z\}, & z \in A, \\ \emptyset, & z \notin A. \end{cases} \quad (25)$$

*In particular,*

$$F^{-1}(\mathcal{W}_\mu(X)) = 2^\omega \setminus A. \quad (26)$$

*If  $X$  is linearly ordered,  $F$  can also be chosen as an order embedding for the binary and  $X$ -valued lexicographic orders.*

*Proof. Step 1: large finite-stage reservoirs.* Because  $\mu$  is an uncountable cardinal of countable cofinality, it is a limit cardinal. Choose strictly increasing infinite cardinals

$$\max\{|A|, \aleph_0\} < \lambda_0 < \lambda_1 < \cdots < \mu, \quad \sup_{n < \omega} \lambda_n = \mu.$$

Put  $\lambda_{-1} = 0$  as an endpoint convention and define consecutive domain blocks

$$D_n = [\lambda_{n-1}, \lambda_n), \quad |D_n| = \lambda_n.$$

Every bounded initial segment of  $\mu$  meets only finitely many of these blocks.

Choose a disjoint partition

$$X = Y \sqcup \bigsqcup_{n < \omega} R_n, \quad Y = \{y_a : a \in A\}, \quad |R_n| = \lambda_n.$$

This is possible because removing fewer than  $\mu$  labels leaves cardinality  $\mu$ , and  $\sum_n \lambda_n = \mu$ .

**Step 2: release a label at its first mismatch.** For  $t \in 2^{n+1}$ , define

$$A_t = \{a \in A : a \upharpoonright n = t \upharpoonright n \text{ and } a(n) \neq t(n)\}. \quad (27)$$

Thus  $A_t$  consists exactly of the branches of  $A$  whose first disagreement with  $t$  occurs at coordinate  $n$ . For any infinite branch  $z$ , the sets  $A_{z \upharpoonright (n+1)}$  are pairwise disjoint and

$$\bigcup_{n < \omega} A_{z \upharpoonright (n+1)} = A \setminus \{z\}. \quad (28)$$

When  $z \notin A$ , the right side is just  $A$ . Equation (28) is the entire logical mechanism of the code: distinct infinite binary sequences have a unique finite first disagreement.

**Step 3: fill each block and mark its bit.** For every  $n$  choose distinct marker labels  $r_n^0, r_n^1 \in R_n$ . If  $X$  is ordered, choose them with  $r_n^0 < r_n^1$ . Let  $d_n$  and  $d_n + 1$  be the first two positions of  $D_n$ . For each  $t \in 2^{n+1}$  choose a bijection

$$\vartheta_t : D_n \longrightarrow R_n \sqcup \{y_a : a \in A_t\} \quad (29)$$

subject to

$$\vartheta_t(d_n) = r_n^{t(n)}, \quad \vartheta_t(d_n + 1) = r_n^{1-t(n)}.$$

The remaining domain and target both have cardinality  $\lambda_n$ :  $\lambda_n$  is infinite and absorbs the smaller released set as well as the removal of two markers. Hence these bijections exist. Only set-sized choice is used.

**Step 4: assemble the injection.** For  $z \in 2^\omega$ , define

$$F(z) \upharpoonright D_n = \vartheta_{z \upharpoonright (n+1)}. \quad (30)$$

Within a block the map is injective. Distinct blocks use disjoint reservoirs  $R_n$ , and by (28) each distinguished label  $y_a$  is released into at most one block. Therefore  $F(z)$  is injective on all of  $\mu$ . Every reservoir is exhausted, and the union of the released labels is precisely  $Y \setminus \{y_z\}$  when  $z \in A$ , or all of  $Y$  otherwise. This proves (25) and (26).

**Step 5: topology and order.** A prescribed output prefix of length  $\alpha < \mu$  is contained in finitely many blocks. It is therefore determined by finitely many input bits. This proves continuity of  $F$ . Its markers recover every bit: the value at  $d_n$  is  $r_n^{z(n)}$ . Thus  $F$  is injective. A continuous injection from compact Cantor space into the Hausdorff space  $\mathcal{I}_\mu(X)$  is a homeomorphism onto a compact closed image.

Finally, if  $z < w$  first differ at bit  $n$ , they have the same output on every block before  $D_n$ . At the very first position  $d_n$  of that block, their values are  $r_n^0 < r_n^1$ . This is the first output disagreement, proving  $F(z) <_{\text{lex}} F(w)$ .  $\square$

### 69.4.1 Why countable cofinality is the effective resource

The construction hides arbitrarily many labels in an early reservoir  $Y$ , but schedules their release according to a finite first-disagreement test. To make the resulting map continuous, every bounded output prefix must see only finitely many stages. The block decomposition by a countable cofinal sequence guarantees precisely this. Each stage has a reservoir large enough to absorb all currently released labels without changing its domain cardinality.

The markers have a separate role. Release scheduling alone establishes the desired range equation but need not separate all input branches. Two permanent marker positions in each infinite block make the code injective and, with ordered markers, order-preserving. Finite tests check the release partition and first-disagreement markers; they cannot check the infinite cardinal absorption used in (29).

*Remark 69.14* (A particularly small defect). Every point in the compact image of  $F$  is either exhaustive or omits exactly one label. Thus the complexity established below does not require injections with large or complicated omitted ranges. The zero-versus-one omission distinction already suffices.

*Remark 69.15* (The strict cardinal bound). The hypothesis  $|A| < \mu$  is used to choose a first reservoir size larger than  $|A|$ . The theorem does not assert the same construction for  $|A| = \mu$ . Likewise, a cofinality- $\omega$  decomposition is not replaced without argument by finitely many stages or by stages indexed by a larger regular cardinal. These are genuine boundaries of the present proof.

## 69.5 Non-Borelness and exact complete metrizability (source 26)

[merge] Source 26's Section 6, printed whole. Its classification answers source 24's Question 13.1 (note 69.7) and source 28's Question 1 (note 70.13); it also answers, for the minimal slices, source 17's question on complete metrizability beyond the proved fusion length (research question 113.72), and source 22's question on descriptive topology when cofinalities are countable (section 72). "The earlier *Prefix Completions* manuscript" is source 24.

**Lemma 69.16** (A small non-Borel set of branches). *In ZFC there is a non-Borel set  $A \subseteq 2^\omega$  of cardinality  $\aleph_1$ .*

*Proof.* We use the classical theorem that every uncountable Borel subset of Cantor space contains a nonempty perfect subset, and every such perfect subset has cardinality  $\mathfrak{c}$  [57].

If  $\mathfrak{c} > \aleph_1$ , take any subset  $A$  of cardinality  $\aleph_1$ . It is uncountable and cannot contain a perfect subset, so it is not Borel.

If  $\mathfrak{c} = \aleph_1$ , enumerate all nonempty perfect subsets of Cantor space as  $(K_\xi)_{\xi < \omega_1}$ . There are exactly  $\mathfrak{c}$  such sets: at most that many because closed subsets are coded by countable trees, and at least that many, for example by fixing one infinite subsequence of coordinates while varying its binary values. Recursively choose two distinct new points  $a_\xi, b_\xi \in K_\xi$ , avoiding all earlier chosen points. Each stage forbids only countably many points, whereas  $K_\xi$  has size  $\aleph_1$ . Put  $A = \{a_\xi : \xi < \omega_1\}$ . No  $b_\xi$  belongs to  $A$ , by the continued avoidance requirement. Thus every perfect set meets the complement of  $A$ , and  $A$  contains no perfect subset. Again it is uncountable and not Borel.  $\square$

**Theorem 69.17** (The singular non-Borel boundary). *Let  $\mu > \omega$  have  $\text{cf } \mu = \omega$ , and let  $|X| = \mu$ . Then  $\mathcal{W}_\mu(X)$  is not an ordinary Borel subset of  $\mathcal{I}_\mu(X)$  in their bounded-prefix topology. This is already witnessed on a compact subspace consisting of injections with at most one omitted label.*

*Proof.* An uncountable cardinal of countable cofinality is strictly larger than  $\aleph_1$ . Choose  $A$  from Lemma 69.16 and apply Theorem 69.13. If  $\mathcal{W}_\mu(X)$  were Borel in  $\mathcal{I}_\mu(X)$ , continuity of  $F$  would imply that

$$2^\omega \setminus A = F^{-1}(\mathcal{W}_\mu(X))$$

is Borel in Cantor space. Taking its complement would make  $A$  Borel, a contradiction. The last assertion is (25).  $\square$

No separability assumption on  $\mathcal{I}_\mu(X)$  is being smuggled into this argument. Continuous inverse images preserve the sigma-algebra generated by open sets in arbitrary topological spaces. The perfect-set theorem is used only inside the ordinary separable Cantor domain.

**Theorem 69.18** (Complete-metrizability classification). *For every infinite cardinal  $\mu$  and every set  $X$  with  $|X| = \mu$ ,*

$$\mathcal{W}_\mu(X) \text{ is completely metrizable in the prefix topology} \iff \mu = \omega.$$

*For  $\mu > \omega$  of countable cofinality, no nonempty open subspace of  $\mathcal{W}_\mu(X)$  is completely metrizable.*

*Proof.* The countable case is Proposition 69.11. If  $\text{cf } \mu > \omega$ , note 69.10 shows that the space is not even first countable, hence is not metrizable.

It remains to consider uncountable  $\mu$  of countable cofinality. The injection space has a complete compatible metric by note 69.10. A completely metrizable subspace of a metrizable space must be  $G_\delta$  there; note 69.9 gives a proof that does not require separability. Complete metrizability of  $\mathcal{W}_\mu(X)$  would therefore contradict Theorem 69.17.

Finally, any nonempty open subspace contains a cylinder. The cylinder is clopen in the full permutation space and is homeomorphic to that space by Proposition 62.10. If the open subspace admitted a compatible complete metric, its closed cylinder would also be completely metrizable, which is impossible.  $\square$

**Corollary 69.19** (Answer to the earlier question). *Question 13.1 of the earlier Prefix Completions manuscript (source 24; note 69.7) has a negative answer in ZFC. The answer does not depend on the value of the continuum or on additional cardinal-arithmetic hypotheses.*

### 69.5.1 Why several plausible positive arguments fail

First, the fact that all exhaustion requirements  $U_x$  are open dense gives a  $\mu$ -indexed intersection, not necessarily a countable one. Theorem 69.17 shows that there is no replacement by a countable Borel construction at all. Second, the forward metric being incomplete is weaker than the conclusion: another compatible metric can repair that problem at  $\omega$ , but not at the uncountable singular lengths considered here. Third, imposing inverse-prefix stabilization gives a complete uniformity, but in general changes the topology. Fourth, the Baire fusion proof of Theorem 69.12 does not imply that every closed subspace is Baire or that the original space is completely metrizable.

The precise hierarchy is therefore useful:

$$\text{complete compatible metric} \implies \text{Baire}, \quad \text{but the converse fails here even locally.}$$

For these spaces, “the completion is well understood” and “the original topology is completely metrizable” are sharply different assertions.

## 69.6 Closed universality and ordered Cantor traces (source 26)

**Theorem 69.20** (Every Cantor subset as a closed trace). *Suppose  $\text{cf } \mu = \omega$  and  $\mu > \mathfrak{c}$ . For every  $B \subseteq 2^\omega$ , there is a closed subspace of  $\mathcal{W}_\mu(X)$  homeomorphic to  $B$ . If  $X$  is linearly ordered, the homeomorphism can simultaneously be an order isomorphism from  $B$  with its inherited binary lexicographic order to the image with its inherited enumeration order.*

*Proof.* Set  $A = 2^\omega \setminus B$ . Its cardinality is at most  $\mathfrak{c} < \mu$ . Apply Theorem 69.13 and put  $K = F[2^\omega]$ . Then  $K$  is closed in the injection space and

$$K \cap \mathcal{W}_\mu(X) = F[B].$$

This is closed relative to  $\mathcal{W}_\mu(X)$ , and the restriction of the embedding  $F$  is a homeomorphism from  $B$  to  $F[B]$ . The ordered-marker version of  $F$  gives the order statement.  $\square$

The theorem does not say that  $F[B]$  is closed in  $K$  or in the ambient injection space. Such a claim would be false for a nonclosed  $B$ . It is closed in the *permutation subspace*, precisely because that subspace meets the compact family in the prescribed trace.

**Corollary 69.21** (Closed topological universality). *If  $\text{cf } \mu = \omega$  and  $\mu > \mathfrak{c}$ , every zero-dimensional separable metrizable space is homeomorphic to a closed subspace of  $\mathcal{W}_\mu(X)$ .*

*Proof.* A zero-dimensional separable metrizable space has a countable clopen base  $(V_n)_{n < \omega}$ . Indeed, take a countable ordinary base, refine each of its members by clopen neighborhoods, and use Lindelöfness to extract countably many such refinements. The characteristic map

$$x \mapsto (\mathbf{1}_{V_n}(x))_{n < \omega}$$

is a topological embedding into  $2^\omega$ : the base separates points and recovers the topology. Apply Theorem 69.20 to its image.  $\square$

**Corollary 69.22** (Closed rational subspaces). *Under the hypotheses of Corollary 69.21, the permutation space has a closed subspace homeomorphic to  $\mathbb{Q}$ . In particular it is not hereditarily Baire.*

*Proof.* The rational line is a zero-dimensional separable metrizable space: intervals with irrational endpoints give a countable clopen base after choosing a countable dense set of irrational endpoints. Apply the corollary. The space  $\mathbb{Q}$  is a countable union of nowhere dense singletons in itself and has no isolated points, so it is not Baire.  $\square$

This supplies another obstruction to complete metrizability when  $\mu > \mathfrak{c}$ , since closed subspaces of completely metrizable spaces are completely metrizable and hence Baire. The non-Borel proof is stronger in range: it also covers singular cardinals  $\mu \leq \mathfrak{c}$ . It is therefore important not to replace Theorem 69.17 with a closed-rational argument whose hypothesis is stronger.

### 69.6.1 How much of the order is retained

The ordered-marker construction gives a true order embedding, not merely an injection continuous for an unrelated topology. When the alphabet is thick, [note 62.9](#) identifies the ambient topology with the lexicographic order topology, so the closedness statements concern that actual ordered space. A subset is always being given its inherited topology for the topological assertion and its restricted order for the order assertion. The order topology intrinsic to an arbitrary suborder need

not be silently identified with every ambient subspace topology; no such general identification is required for our proof.

These results distinguish order-theoretic largeness from completeness. A linear order can have strong embedding properties, can contain arbitrary closed topological traces, and can still fail complete metrizability on every nonempty open piece. Mutual order embeddability with a familiar lexicographic cube would not prevent this: equimorphism preserves neither the missing-cut pattern nor all topological completeness properties.

### 69.7 Bounded images and bounded inverses (source 26)

[merge] Source 26's Section 8, printed whole. Its  $\mathcal{I}_\mu^b$  (its  $\mathcal{B}^+$ ) is source 28's  $\mathcal{I}_\mu^b$ , and  $H_\mu$  is source 24's boundedness-preserving subgroup. Part (ii) re-derives source 24's complete metric on  $H_\mu$  (the corollary to [theorem 69.4](#)) by a  $G_\delta$  route; source 28 proves the closure and completion statements for every infinite  $\mu$  ([theorems 70.10](#) and [70.26](#)) and the dense inverse locus ([theorem 70.11](#)).

Fix a bijection  $X \cong \mu$  so that boundedness of labels is meaningful. A subset of  $\mu$  is bounded when it is contained in some  $\beta < \mu$ . Define

$$\mathcal{I}_\mu^b = \{f \in \mathcal{I}_\mu(\mu) : f[\alpha] \text{ is bounded for every } \alpha < \mu\}$$

and

$$H_\mu = \{\pi \in \text{Sym}(\mu) : \pi[\alpha] \text{ and } \pi^{-1}[\alpha] \text{ are bounded for every } \alpha < \mu\}.$$

The boundedness-preserving subgroup  $H_\mu$  and its compatible two-sided completeness occur in the earlier manuscript (source 24, [theorem 69.4](#)). The following ambient description and coding refinement separate the two boundedness requirements directly.

**Theorem 69.23** (The bounded-image completion and its complete subgroup). *Suppose  $\mu > \omega$  and cf  $\mu = \omega$ .*

- (i)  $\mathcal{I}_\mu^b$  is closed in  $\mathcal{I}_\mu(\mu)$ , hence completely metrizable.
- (ii)  $H_\mu$  is dense and  $G_\delta$  in  $\mathcal{I}_\mu^b$ , hence completely metrizable in the forward-prefix topology.
- (iii)  $\mathcal{I}_\mu^b \cap \mathcal{W}_\mu(\mu)$  is not Borel in  $\mathcal{I}_\mu^b$  and is not completely metrizable.

*Proof.* A failure of bounded-image preservation is witnessed by a single prefix  $f \upharpoonright \alpha$  whose range is unbounded. Every injection in that cylinder has the same failure. The complement of  $\mathcal{I}_\mu^b$  is therefore open, proving (i).

Fix cofinal lengths  $\gamma_n < \mu$ . For each  $n$ , let

$$V_n = \{f \in \mathcal{I}_\mu^b : \exists \beta < \mu \ \gamma_n \subseteq \text{ran}(f \upharpoonright \beta)\}.$$

This is open: a witnessing prefix continues to witness membership throughout its cylinder. We claim

$$H_\mu = \bigcap_{n < \omega} V_n. \tag{31}$$

A member of the right side covers every label and is thus a permutation. For any bounded label set, choose  $\gamma_n$  containing it; its inverse image lies in a witnessing  $\beta$ , so the inverse preserves boundedness. The forward condition is built into  $\mathcal{I}_\mu^b$ . Conversely, a member of  $H_\mu$  has bounded inverse image of each  $\gamma_n$ , giving the required witness. This proves (31).

To see density, start with a prefix  $p = f \upharpoonright \alpha$  of a bounded-image injection. Both its domain and range are bounded. Choose an infinite initial cardinal  $\rho < \mu$  strictly above their bounds. The

complements of  $\text{dom } p$  and  $\text{ran } p$  inside  $\rho$  both have size  $\rho$ . Complete  $p$  to a permutation of  $\rho$  and extend by the identity outside  $\rho$ . This permutation belongs to  $H_\mu$  and extends  $p$ . Part (ii) follows from [note 69.9](#).

For (iii), repeat the proof of [Theorem 69.13](#) with the distinguished labels  $Y$  placed in an initial segment  $\eta = |A| < \lambda_0$ . Take

$$R_0 = [\eta, \lambda_0), \quad R_n = [\lambda_{n-1}, \lambda_n) \quad (n \geq 1).$$

Each block target is contained in  $\lambda_n$ , so

$$F(z)[\lambda_n] \subseteq \lambda_n \quad (n < \omega).$$

Consequently the entire compact coded family lies in  $\mathcal{I}_\mu^b$ . Choosing the non-Borel  $A$  of [Lemma 69.16](#) proves (iii) by the same continuous-preimage argument, now in this closed ambient space. Noncomplete metrizability follows from the  $G_\delta$  criterion.  $\square$

**Proposition 69.24** (What the inverse condition sees on the code). *For the localized construction in the proof of [Theorem 69.23](#),*

$$F^{-1}(H_\mu) = 2^\omega \setminus \overline{A}, \quad F^{-1}(\mathcal{I}_\mu^b \cap \mathcal{W}_\mu(\mu)) = 2^\omega \setminus A,$$

where  $\overline{A}$  is the ordinary Cantor-space closure.

*Proof.* The second equation is already known. If  $z \notin \overline{A}$ , some finite prefix  $z \upharpoonright N$  has no extension in  $A$ . Every distinguished label is then released in a block before  $N$ . The inverse images of  $Y$  are bounded. The inverse images of the finitely many reservoir blocks intersecting any prescribed bounded label segment are bounded as well. Thus  $F(z)$  is exhaustive and has bounded inverse images.

If  $z \in A$ , the code is not exhaustive. If  $z \in \overline{A} \setminus A$ , then for every  $N$  some  $a \in A$  agrees with  $z$  on its first  $N$  bits. This  $a$  is distinct from  $z$  and is released at a first disagreement at stage at least  $N$ . The preimages of the bounded set  $Y$  therefore meet arbitrarily late domain blocks and are unbounded in  $\mu$ . Hence  $F(z) \notin H_\mu$ .  $\square$

This is a useful conceptual refinement. On the coded family, surjectivity tests membership outside  $A$ , whereas bounded inverse behavior tests membership outside its closure. The forward condition alone does not remove the descriptive complexity; the inverse condition removes exactly the accumulation-branch phenomenon responsible for delayed coverage of a bounded reservoir.

The proof also explains the limit of the group analogy. At a regular cardinal every set of size less than the cardinal is bounded, so every permutation preserves boundedness in both directions. At a singular cardinal a permutation can send a bounded cofinality-sized set onto an unbounded set. Consequently the full permutation space with forward-prefix topology is not automatically a topological group. Nor does merely naming a two-sided uniformity prove continuity of every translation on the full singular permutation set. The subgroup  $H_\mu$  is the precise safe statement used here.

## 69.8 The minimal surreal slices (source 26)

[merge] Source 26's Section 9, printed whole. Its birthday cutoff  $\theta$  is printed  $\kappa$ , so that  $\mu = 2^{<\kappa}$  as elsewhere in this report. Its [lemma 69.25](#) is [lemma 29.2](#) with a different sign trunk; its  $\beth_\omega$  example extends this report's  $\beth_\omega$  examples ([example 30.21](#), [theorem 8.3](#)) to the topology.

We use the ordinal-length sign model of surreal numbers [12]. A surreal  $x$  is a function from an ordinal  $\text{bd}(x)$  to  $\{-, +\}$ . Numerical comparison uses the first disagreement after extending each sign function by the termination value 0, with  $- < 0 < +$ . The ordinal  $\text{bd}(x)$  is its birthday. The model separates numerical order from simplicity, which is proper prefix extension.

For an infinite initial cardinal  $\kappa$ , set

$$\mathbf{No}_{<\kappa} = \{x \in \mathbf{No} : \text{bd}(x) < \kappa\}, \quad \mu = 2^{<\kappa} = \sup_{\alpha < \kappa} 2^{|\alpha|}.$$

This is a set of labels. It is not the whole surreal class and is not, without additional closure hypotheses, being treated as a subfield.

**Lemma 69.25** (Cardinality and thickness). *For every infinite cardinal  $\kappa$ ,*

$$|\mathbf{No}_{<\kappa}| = 2^{<\kappa},$$

*and every nonempty numerical interval and each ray in  $\mathbf{No}_{<\kappa}$  has this same cardinality.*

*Proof.* There are  $2^{|\alpha|}$  sign sequences of each birthday  $\alpha < \kappa$ . Their union has cardinality at least the supremum  $\mu$ . Also  $\kappa \leq \mu$ : successor cardinal bounds below a limit cardinal, or Cantor's inequality at the predecessor cardinal in the successor case, give this, and the case  $\kappa = \omega$  is immediate. Thus the union has size at most  $\kappa \cdot \mu = \mu$ .

For thickness, we construct a sign trunk all of whose extensions lie between given  $x < y$ . Let  $\delta$  be their first disagreement, with termination included. If  $\delta < \text{bd}(x)$ , take  $t = x \frown \langle + \rangle$ . Every extension of  $t$  is above  $x$ , by the plus at position  $\text{bd}(x)$ , and below  $y$ , by the earlier disagreement at  $\delta$ .

The remaining case is  $\delta = \text{bd}(x)$ : the lower word terminates and the upper word has a plus there. Start with the common prefix followed by that plus, follow the subsequent minus signs of  $y$  until its first later plus or its end, and put a minus at that position. Call the resulting trunk  $t$ . It lies above  $x$  by its plus at  $\delta$  and below  $y$  by the final minus, compared with either a plus or termination. Both comparisons are witnessed strictly before the end of  $t$ , so they persist through every extension. The length of  $t$  is at most one more than one of the original birthdays, hence is below  $\kappa$ .

In either case, if the trunk length is  $\beta < \kappa$ , every sign tail of length  $\alpha < \kappa$  gives an element of the interval, since  $\beta + \alpha < \kappa$ . These extensions are distinct and give at least  $2^{|\alpha|}$  elements for each  $\alpha$ . Taking the supremum yields  $\mu$ , and the opposite bound is the cardinality of the whole cutoff.

For a ray, choose an ordinal sign sequence above the given birthday, or its all-minus counterpart below it, still with birthday below  $\kappa$ . An interval between that point and the original point lies in the ray. The interval result supplies the same cardinality.  $\square$

*Remark 69.26* (No hidden regularity). The bound  $\beta + \alpha < \kappa$  uses that  $\kappa$  is an infinite initial cardinal and that only two ordinals are being added. It does not require  $\kappa$  to be regular. This is why the thickness argument remains valid at the singular cutoff central to source 26.

**Theorem 69.27** (Topological classification of the minimal surreal slices). *Let  $\kappa$  be an infinite cardinal, let  $\mu = 2^{<\kappa}$ , and compare the bijections  $\mu \rightarrow \mathbf{No}_{<\kappa}$  lexicographically by numerical surreal labels. Their order topology is the bounded-prefix topology. In that topology,*

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \text{ is metrizable} \iff \text{cf}(2^{<\kappa}) = \omega,$$

*and*

$$\mathcal{W}_\mu(\mathbf{No}_{<\kappa}) \text{ is completely metrizable} \iff \kappa = \omega.$$

*If  $\mu > \omega$  and  $\text{cf } \mu = \omega$ , it is non-Borel in its injection completion and has no nonempty completely metrizable open subspace.*

*Proof.* Lemma 69.25 supplies exactly the thickness interface needed by note 62.9. Apply note 69.10 and Theorems 69.17 and 69.18 with cardinal parameter  $\mu$ . For  $\kappa = \omega$ , the union of all finite sign levels is countably infinite. For  $\kappa > \omega$ , the level of birthday  $\omega$  already contains  $2^{\aleph_0}$  signs, so  $\mu > \omega$ . Thus  $\mu = \omega$  holds exactly when  $\kappa = \omega$ .  $\square$

### 69.8.1 Three instructive cutoffs

At  $\kappa = \omega$ , the labels are finite sign sequences, equivalently the finite-birthday surreal numbers. The minimal enumeration space is completely metrizable; the forward metric still has nonexhaustive injections as completion points, but the topology admits a different complete metric. The earlier manuscript gives a more detailed Baire-space model and a distinction from the order type of the irrational line (source 24, corollary 67.5).

At  $\kappa = \omega_1$ , one has  $\mu = 2^{\aleph_0} = \mathfrak{c}$ . König's cofinality inequality gives  $\text{cf}(2^{\aleph_0}) > \omega$ , so the minimal enumeration space is not even first countable. Indeed, countable cofinality of  $\mathfrak{c}$  would yield a sequence of smaller cardinals whose successor product is greater than  $\mathfrak{c}$  by König's theorem, but at most  $\mathfrak{c}^\omega = \mathfrak{c}$ , a contradiction. This shows why “the labels contain real-like objects” does not make the space metrizable.

At

$$\kappa = \beth_\omega = \sup_{n < \omega} \beth_n, \quad \beth_0 = \aleph_0, \quad \beth_{n+1} = 2^{\beth_n},$$

we have a singular strong limit cardinal of countable cofinality. For each  $\nu < \kappa$ , choose  $n$  with  $\nu \leq \beth_n$ ; then  $2^\nu \leq \beth_{n+1} < \kappa$ . Hence  $2^{<\kappa} = \kappa$ , and  $\kappa > \mathfrak{c}$  because  $\beth_2 > \beth_1 = \mathfrak{c}$ .

**Corollary 69.28** (The unconditional  $\beth_\omega$  example). *The lexicographic minimal enumeration order*

$$L = \mathcal{W}_{\beth_\omega}(\mathbf{No}_{<\beth_\omega})$$

*has all of the following properties in ZFC: it is a dense linear order without endpoints; its order topology is zero-dimensional and metrizable; it is Baire; no nonempty open subspace is completely metrizable; it is non-Borel in its completely metrizable injection completion; and it is closed-universal for zero-dimensional separable metrizable spaces. Every subset of binary Cantor space can be realized as a closed trace by an order-preserving coding.*

*Proof.* Combine Lemma 69.25 with note 62.9, Theorems 69.12, 69.17, 69.18, and 69.20, and Corollary 69.21.  $\square$

This corollary is about an explicitly defined *set* of surreal-labelled well-orders. It is not obtained by pretending that  $\beth_\omega$  is inaccessible or that its birthday fragment is the set universe of a full class-theory model.

### 69.8.2 Relation to the earlier singular order-spectrum transition

The repository report also studies the minimal slices at these birthday cutoffs and gives a different singular transition (theorem 8.3). In its notation, if  $\mu = 2^{<\kappa}$ , the minimal enumeration order is equimorphic with the binary lexicographic cube of length  $\kappa \cdot \kappa$  when  $\kappa$  is singular strong limit, and with the cube of length  $\mu$  otherwise. Here  $\kappa \cdot \kappa$  is *ordinal* multiplication. This earlier assertion is not used as an input to the proofs above.

The two transitions measure different structures. The repository transition concerns mutual order embeddings into cubes. The present classification concerns the order topology and the descriptive complexity of exhaustiveness inside a prefix completion. They agree that singular strong-limit stages

deserve attention, but neither assertion can be substituted for the other. Equimorphism does not identify the topology with that of a compact cube, and the equality  $\mu = \kappa$  at  $\beth_\omega$  does not collapse ordinal length  $\kappa \cdot \kappa$  to  $\kappa$ .

## 69.9 Nonminimal lengths and varying carriers (source 26)

The minimality of the ordinal domain is structural, not a convenience in notation. For  $\lambda$  of cardinality  $\mu$ , one can define  $\mathcal{W}_\lambda(X) = \text{Bij}(\lambda, X)$  and its proper-prefix topology, but the cardinalities and order types of residual tails vary with the prefix.

**Proposition 69.29** (Successor-length isolation). *If  $\lambda = \delta + 1$  and  $|\lambda| = |X|$ , the proper-prefix topology on  $\mathcal{W}_\lambda(X)$  is discrete.*

*Proof.* For a given bijection  $f$ , fix its prefix of length  $\delta$ . Exactly one label remains, so exactly one full bijection extends this prefix. Thus the corresponding cylinder is the singleton  $\{f\}$ .  $\square$

Even for a dense numerical alphabet, this prefix topology need not coincide with enumeration order topology at nonminimal lengths: the singleton argument has no two unused choices with which to bracket the last coordinate. This gives a concrete reason that Theorem 69.18 cannot simply be restated with “all ordinals of cardinality  $\mu$ ” in place of the initial cardinal.

More generally, if a prefix leaves  $m$  positions and exactly  $m$  labels for finite  $m$ , its cylinder is a finite residual permutation order. Its adjacency and endpoints are finite combinatorial data. If it leaves an infinite residual cardinal, cardinal size alone still does not identify the residual *ordinal length*. A systematic theory should retain both the order type of the domain tail and the numerical order on the residual labels. The previous repository reports already analyze several such residual and adjacency phenomena (theorem 16.2 and section 31); the present minimal-slice proofs intentionally use only the uniform residual situation guaranteed by initial-cardinal length.

For varying set carriers, write

$$\mathcal{I} = \{p : p \text{ is a set function, } \text{dom } p \in \text{Ord}, \text{ran } p \subseteq \mathbf{No}, p \text{ injective}\}.$$

This is an ordinary class of sets. Every individual range has bounded birthdays: take the supremum of its birthday successors. Thus a fixed word belongs to a suitable set-sized fragment, while the class of all words is not bounded in one such fragment. The increasing-word subclass is obtained by requiring  $p(\xi) <_{\mathbf{No}} p(\eta)$  whenever  $\xi < \eta$ .

One can compare words with an explicitly specified termination rule. A prefix-first order has a least empty word and extensions lying immediately on one designated side of every terminating prefix; the numerical surreal sign order instead uses central termination. These endpoint and prefix distinctions prevent an automatic identification with  $\mathbf{No}$  even when an order embedding into  $\mathbf{No}$  is available. The earlier reports supply explicit sign codings and analyze the relevant limit-length cuts (part VII). Our new compact coding applies to fixed exhaustive and injective  $\mu$ -words, and does not purport to classify every variable-length cut.

## 70 Permutation groups at singular cardinalities: maximality, self-normalization and the canonical group envelope (source 28)

[merge] Source 28’s Sections 4–10, printed whole; its Section 3 is recorded in section 62 and its Sections 11–12 in section 71. Source 28 continues source 24 and answers source 24’s question on the boundedness-preserving subgroup (“its closure properties in the two ambient topologies,

its normalizers, and the possible topological-group structures on larger natural subgroups. How much of the ordinal bounded-set ideal is recoverable from this group together with its topology?”) in the natural action, and its question on uniformities with an exhaustion interpretation in part (section 72). It works on  $S_\mu = \text{Sym}(\mu)$ , identified with  $\mathcal{W}_\mu(X)$  by a fixed label enumeration  $e : \mu \rightarrow X$  ( $f \mapsto e^{-1} \circ f$ ), with topologies  $\tau_{\mathcal{J}}$  of agreement on the members of an admissible coordinate ideal  $\mathcal{J}$ ; its bounded ideal  $\mathcal{B}_\mu$  is printed  $\mathcal{J}_b$ , its loci  $B_\mu^\pm$  are printed  $H_\mu^\pm$ , and its  $\delta = \text{cf } \mu$  is printed  $q$  (part X).

Several of its statements are known from sources 24 and 26 and are credited where they occur. Theorem 70.2 and corollary 70.3 generalize source 24’s theorem 69.2 and the group clause of theorem 69.4 from the bounded ideal to every admissible ideal, by the same transposition witnesses. Proposition 70.19 is source 24’s remark 69.6. Source 28’s Proposition 8.1 is proposition 62.7 (note 70.20). Theorem 70.25 generalizes source 24’s theorem 65.1 to ideals; theorem 70.26, and the equality in theorem 70.10, are the closedness and density parts of source 26’s theorem 69.23, for every infinite  $\mu$  (source 26 assumes  $\text{cf } \mu = \omega < \mu$ ); lemma 70.9 is the bounded case of the balanced reserve (theorem 49.7; source 24’s note 71.1); theorem 70.11 uses the same open sets as source 26’s proof of theorem 69.23(ii), for a different set; the Baire clause of corollary 70.12 is a case of theorem 69.12, and the complete metric on  $H_\mu$  is its third proof (after corollary 69.5 and theorem 69.23(ii)); proposition 70.24 is, for  $\tau_b$ , the case  $\alpha = \mu$  of theorem 27.2 and of source 22’s weight column (theorem 63.4). New in source 28 are the maximality and self-normalization theorems, the recovery of the bounded ideal from the action, the nowhere density of  $H_\mu^+$  and  $H_\mu$ , the dense inverse locus, the explicit one-sided permutations, the canonical group envelope  $\tau_{<\mu}$ , its character  $\text{cof}([\mu]^{<\mu}, \subseteq)$ , the two-sided completeness of the envelope and the filtration-invariance proposition.

### 70.1 Coordinate control by an ideal (source 28)

Fix  $S_\mu = \text{Sym}(\mu)$  and use composition  $(p \circ q)(\xi) = p(q(\xi))$ . A fixed label enumeration  $e : \mu \rightarrow X$  identifies  $\mathcal{W}_\mu(X)$  with  $S_\mu$  by  $f \mapsto e^{-1} \circ f$ . The prefix topology on  $S_\mu$  has basic neighborhoods

$$N_\alpha(p) = \{q : q \upharpoonright \alpha = p \upharpoonright \alpha\}, \quad \alpha < \mu.$$

The numerical order on  $X$  does not enter this topology; thickness was what identified it with the order topology.

**Definition 70.1** (Admissible coordinate ideal). An ideal  $\mathcal{J}$  on  $\mu$  is *admissible* here if it contains every finite set, is closed under subsets and finite unions, and satisfies  $\mathcal{J} \subseteq [\mu]^{<\mu}$ . Define  $\tau_{\mathcal{J}}$  by the basic neighborhoods

$$N_A(p) = \{q : q \upharpoonright A = p \upharpoonright A\} \quad (A \in \mathcal{J}).$$

Write  $\text{Fix}(A) = N_A(\text{id})$ . A map  $u : \mu \rightarrow \mu$  preserves  $\mathcal{J}$  if  $u[A] \in \mathcal{J}$  for every  $A \in \mathcal{J}$ .

The bounded ideal

$$\mathcal{J}_b = \{A \subseteq \mu : \exists \alpha < \mu (A \subseteq \alpha)\}$$

gives  $\tau_{\mathcal{J}_b} = \tau_b$ . The small-set ideal  $[\mu]^{<\mu}$  gives  $\tau_{<\mu}$ . They agree at regular  $\mu$  and differ at singular  $\mu$ . Admissibility ensures that outside every control set there remain  $\mu$  coordinates, so transpositions can witness the necessity of continuity conditions.

**Theorem 70.2** (Exact ideal continuity criteria). *In  $(S_\mu, \tau_{\mathcal{J}})$ :*

- (i) *Every left translation  $L_s(p) = s \circ p$  is a homeomorphism.*
- (ii) *Right translation  $R_s(p) = p \circ s$  is continuous everywhere if  $s$  preserves  $\mathcal{J}$ , and nowhere otherwise.*

(iii) *Inversion is continuous at  $p$  if and only if  $p^{-1}$  preserves  $\mathcal{J}$ .*

*Proof.* Equality of restrictions on a fixed domain is unchanged by applying the same injective map to their values. This proves (i), including continuity of the inverse left translation.

To control  $p \circ s$  on  $A$ , it suffices to control  $p$  on  $s[A]$ . This proves sufficiency in (ii). If  $s[A] \notin \mathcal{J}$ , then for every  $B \in \mathcal{J}$  some  $u \in s[A] \setminus B$  exists; otherwise downward closure would put  $s[A]$  in  $\mathcal{J}$ . Choose  $v \notin B \cup \{u\}$ . The permutation  $q = p \circ (u \ v)$  agrees with  $p$  on  $B$ , but  $q \circ s$  changes at the coordinate  $s^{-1}(u) \in A$ . Thus continuity fails at every  $p$ .

To fix  $p^{-1}$  on  $A$ , it suffices to fix  $p$  on  $p^{-1}[A]$ . If this set belongs to  $\mathcal{J}$ , this proves the required local implication. If it does not, use the same transposition construction with  $u \in p^{-1}[A] \setminus B$ . The inverse position of the label  $p(u) \in A$  changes from  $u$  to  $v$ , while the forward restriction on  $B$  stays fixed. This proves necessity in (iii).  $\square$

**Corollary 70.3** (The ideal-preserving subgroup). *The set*

$$H_{\mathcal{J}} = \{p \in S_{\mu} : p \text{ and } p^{-1} \text{ preserve } \mathcal{J}\}$$

*is a subgroup, and its inherited  $\tau_{\mathcal{J}}$  topology makes it a topological group.*

*Proof.* Ideal preservation is closed under composition, and the definition is symmetric under inversion. For joint continuity at  $(p, s)$ , to control  $p' \circ s'$  on  $A \in \mathcal{J}$ , require  $s' \restriction A = s \restriction A$  and  $p' \restriction s[A] = p \restriction s[A]$ . Both are valid control requirements when  $s \in H_{\mathcal{J}}$ . Inversion is continuous by Theorem 70.2.  $\square$

At a singular cardinal, a bounded set of size  $\text{cf } \mu$  can be sent onto a cofinal set by a permutation. Thus Theorem 70.2 reproduces the predecessor's obstruction (source 24, [corollary 69.3](#)): the original forward topology need not make the full permutation group a topological group. The ideal formulation also identifies exactly which part of the proof is general and which part depends on ordinal boundedness.

## 70.2 Maximality and self-normalization (source 28)

**Theorem 70.4** (Maximal inherited topological subgroup). *Let  $\mathcal{J}$  be admissible. Among subgroups  $G \leq S_{\mu}$  that contain every finite-support permutation and for which the inherited  $\tau_{\mathcal{J}}$  topology is a group topology,  $H_{\mathcal{J}}$  is the largest.*

*Proof.* Corollary 70.3 proves that  $H_{\mathcal{J}}$  is such a subgroup; finitary permutations preserve  $\mathcal{J}$  in both directions because they change a set by only finitely many points.

Suppose  $G$  has the stated properties and  $p \in G$ . If  $p^{-1}$  does not preserve  $\mathcal{J}$ , the transposition witnesses in the proof of Theorem 70.2(iii) all lie in  $G$ : each is  $p \circ (u \ v)$ , and  $(u \ v)$  is finitary. They show that inversion on the subspace  $G$  is not continuous at  $p$ . This contradicts the group-topology assumption. Thus  $p^{-1}$  preserves  $\mathcal{J}$ . Applying the same argument to  $p^{-1} \in G$  shows that  $p$  preserves  $\mathcal{J}$ . Hence  $G \subseteq H_{\mathcal{J}}$ .  $\square$

The finitary hypothesis matters. Discontinuity in an ambient space does not automatically remain a discontinuity after restriction to an arbitrary subgroup. It is precisely the supply of internal transposition witnesses that makes this maximality argument valid.

For the bounded ideal, let  $H_{\mu} = H_{\mathcal{J}_b}$ . The next result answers the normalizer part of the predecessor's subgroup question (source 24; [section 72](#)).

**Lemma 70.5** (A bounded part and a cofinal part). *Let  $\mu$  be singular and  $q = \text{cf } \mu$ . If  $C \subseteq \mu$  is unbounded and  $|C| > q$ , then  $C$  contains a bounded subset  $D$  of size  $q$  and, disjoint from  $D$ , a cofinal subset  $E$  of size  $q$ .*

*Proof.* Choose an increasing cofinal sequence  $(\gamma_i)_{i < q}$  in  $\mu$ . If every  $C \cap \gamma_i$  had size less than  $q$ , their union would have size at most  $q \cdot q = q$ , contrary to  $|C| > q$ . Some bounded intersection therefore contains a subset  $D$  of size  $q$ . The portion of  $C$  above a bound for  $D$  remains unbounded, so it has a cofinal subset  $E$  of size  $q$ .  $\square$

**Theorem 70.6** (Self-normalization at singular cardinalities). *If  $\mu$  is singular, then*

$$N_{S_\mu}(H_\mu) = H_\mu.$$

*Proof.* Every element of  $H_\mu$  normalizes  $H_\mu$ . Conversely, let  $s$  normalize  $H_\mu$ . Suppose that  $s$  fails to preserve bounded sets. Choose a bounded  $A_0$  with  $s[A_0]$  unbounded. Since a singular cardinal is a limit cardinal, there is a bounded set  $A \supseteq A_0$  with

$$\text{cf } \mu < |A| < \mu.$$

For example, enlarge a bounded initial segment containing  $A_0$  to one of cardinality greater than  $\text{cf } \mu$ . Put  $C = s[A]$ . It is unbounded and has size greater than  $\text{cf } \mu$ .

Every permutation supported on  $A$  belongs to  $H_\mu$ . Conjugation by  $s$  therefore implies that *every* permutation supported on  $C$  belongs to  $H_\mu$ . By Lemma 70.5, choose a bounded  $D \subseteq C$  and a disjoint cofinal  $E \subseteq C$ , both of size  $\text{cf } \mu$ . Exchange  $D$  and  $E$  bijectively and fix all remaining coordinates. The resulting involution is supported on  $C$  but sends the bounded set  $D$  to the unbounded set  $E$ . It is not in  $H_\mu$ , a contradiction.

Thus  $s$  preserves bounded sets. Its inverse also normalizes  $H_\mu$ , so the same argument shows that  $s^{-1}$  preserves bounded sets. Consequently  $s \in H_\mu$ .  $\square$

*Remark 70.7* (Why the cardinal enlargement is essential). An unbounded set of size exactly  $\text{cf } \mu$  may have too few points in every bounded interval for the exchange used above. It is not valid to assert that every unbounded support set carries a permutation violating boundedness. Enlarging  $A_0$  to cardinality greater than  $\text{cf } \mu$  is what makes the proof work.

**Proposition 70.8** (Recovering boundedness from the natural action). *For  $A \subseteq \mu$ , the pointwise stabilizer of  $A$  in  $H_\mu$  is open in the inherited prefix topology if and only if  $A$  is bounded.*

*Proof.* If  $A$  is bounded, a bounded initial segment containing it has an open pointwise stabilizer contained in its stabilizer. That larger subgroup is open as a union of cosets. If  $A$  is unbounded, then for every  $\beta < \mu$  choose  $u \in A \setminus \beta$  and  $v \notin \beta \cup \{u\}$ . The finitary transposition  $(u \ v)$  belongs to  $H_\mu$  and fixes  $\beta$ , but does not fix  $A$ . No identity neighborhood can lie inside the stabilizer of  $A$ .  $\square$

This reconstructs the bounded-set ideal from the *topological group together with its specified permutation action*. It does not prove that the bare abstract group alone determines the ideal, nor that every abstract automorphism is induced by a permutation of  $\mu$ .

### 70.3 One-sided boundedness: closure, density and a complete locus (source 28)

Write

$$\begin{aligned} H_\mu^+ &= \{p \in S_\mu : p[A] \text{ is bounded for every bounded } A\}, \\ H_\mu^- &= \{p \in S_\mu : p^{-1}[A] \text{ is bounded for every bounded } A\}. \end{aligned}$$

Then  $H_\mu = H_\mu^+ \cap H_\mu^-$  and inversion exchanges  $H_\mu^+$  with  $H_\mu^-$ . By Theorem 70.2,  $H_\mu^-$  is exactly the continuity locus of inversion in the full forward topology. At singular cardinals these two one-sided loci have strikingly different positions in the same space.

### 70.3.1 A bounded extension lemma

**Lemma 70.9** (Extending a bounded partial injection). *Let  $A, C \subseteq \mu$  be bounded and let  $q : A \rightarrow C$  be a bijection. There is a permutation  $h \in H_\mu$  extending  $q$ , with bounded support.*

*Proof.* Put  $D_0 = A \cup C$ . If  $D_0$  is finite, the two residual sets  $D_0 \setminus A$  and  $D_0 \setminus C$  have equal finite size, so choose a bijection between them and complete  $q$  to a permutation of  $D_0$ .

If  $D_0$  is infinite, put  $\nu = |D_0| < \mu$ . Choose a bounded ordinal block  $R$  of size  $\nu$  above  $D_0$  and set  $D = D_0 \cup R$ . Such a block remains below  $\mu$  because both its starting ordinal and  $\nu$  have cardinality less than the initial cardinal  $\mu$ . Both  $D \setminus A$  and  $D \setminus C$  contain  $R$  and have size  $\nu$ . Complete  $q$  by a bijection between these residual sets.

In either case, extend the resulting bounded permutation by the identity outside its carrier. A bounded-support permutation and its inverse send a bounded set into the union of that set and the bounded support. Hence the extension belongs to  $H_\mu$ .  $\square$

The reserve in the infinite case avoids a genuine pitfall: an infinite partial bijection need not extend to a permutation of the union of its domain and range, since the residual sets inside that union need not have equal cardinality.

**Theorem 70.10** (Exact forward closure). *In  $(S_\mu, \tau_b)$ ,*

$$\overline{H_\mu} = H_\mu^+.$$

*For singular  $\mu$ , the set  $H_\mu^+$  is closed nowhere dense, and therefore  $H_\mu$  is nowhere dense as well.*

*Proof.* If  $p \notin H_\mu^+$ , choose  $\alpha < \mu$  for which  $p[\alpha]$  is unbounded. Every permutation with the same restriction to  $\alpha$  also fails the forward condition. Thus  $H_\mu^+$  is closed, and its closure contains no additional point of  $S_\mu$ .

If  $p \in H_\mu^+$ , then  $p \restriction \alpha$  has bounded domain and bounded range for every  $\alpha < \mu$ . Lemma 70.9 extends this restriction to an element of  $H_\mu$ . Every prefix neighborhood of  $p$  consequently meets  $H_\mu$ , proving the equality.

Now assume  $\mu$  singular and put  $q = \text{cf } \mu$ . Given any short injective prefix, the unused labels form an unbounded set: fewer than  $\mu$  used labels cannot contain a tail of cardinality  $\mu$ . Choose a cofinal sequence of  $q$  distinct unused labels and append it to the prefix. The enlarged prefix still has length less than  $\mu$ , since a finite ordinal sum of ordinals of cardinality less than  $\mu$  remains below  $\mu$ . It has unbounded range on a bounded domain. Its nonempty cylinder, obtained by [note 62.12](#), is disjoint from  $H_\mu^+$ . Thus the closed set  $H_\mu^+$  has empty interior.  $\square$

### 70.3.2 A dense inverse-continuity locus

Fix an increasing cofinal sequence  $(\mu_i)_{i < q}$  in  $\mu$ , where  $q = \text{cf } \mu$ . On the injection space  $\mathcal{I}_\mu(\mu)$  with its forward prefix topology, define

$$O_i = \{h : \exists \alpha < \mu (\mu_i \subseteq \text{ran}(h \restriction \alpha))\}.$$

Here  $\mu_i$  denotes the set of all ordinals below that ordinal; the condition requires an entire bounded block of labels to have appeared by some bounded time.

**Theorem 70.11** (Inverse-boundedness as a dense intersection). *Each  $O_i$  is open dense, and as a subspace of  $\mathcal{I}_\mu(\mu)$ ,*

$$H_\mu^- = \bigcap_{i < q} O_i.$$

*This intersection is dense. If  $q = \omega$ , it is a dense completely metrizable  $G_q$  subspace of  $\mathcal{I}_\mu(\mu)$  and of  $S_\mu$ . Its complement is meager in both spaces.*

*Proof.* Once the labels below  $\mu_i$  have appeared in a prefix, every continuation satisfies the same condition, so  $O_i$  is open. Any short prefix can be extended to include the as-yet unused labels below  $\mu_i$ ; there are fewer than  $\mu$  of them. The extension remains short, proving density.

If an injection belongs to every  $O_i$ , it is onto, since these label blocks cover  $\mu$ . Further, the preimage of each  $\mu_i$  is bounded. Every bounded subset of  $\mu$  is contained in some  $\mu_i$ , so the inverse of the resulting permutation preserves boundedness. Conversely, inverse boundedness supplies the required witness  $\alpha$  for every  $i$ . This proves the displayed equality.

For density of the full intersection, start with any prescribed short prefix. At stage  $i < q$ , extend it to include every label below  $\mu_i$  and to have length at least  $\mu_i$ . At a limit stage  $j < q$ , take the union of the preceding prefixes. This union is still short, since fewer than  $\text{cf } \mu$  lengths below  $\mu$  have been used. At the final stage  $q$ , the union has domain  $\mu$ , is injective, and covers every label. Each block  $\mu_i$  was covered at a short intermediate stage, so the final permutation belongs to  $H_\mu^-$  and extends the original prefix.

If  $q = \omega$ , agreement along the cofinal lengths  $\mu_i$  defines a compatible ultrametric on the injection space. A Cauchy sequence stabilizes a coherent injective prefix at every such length, and their union is its limit. Thus the injection space is completely metrizable. A  $G_q$  subspace of a completely metrizable space is completely metrizable; a proof not requiring separability is recalled in [note 69.9](#). Since every  $O_i$  is open dense, the complement of the intersection is a countable union of closed nowhere dense sets. Intersecting with  $S_\mu$  gives the same conclusion there, because each  $O_i \cap S_\mu$  is open dense by the same prefix-extension argument.  $\square$

**Corollary 70.12** (A complete core and the Baire property). *If  $\text{cf } \mu = \omega$ , then  $S_\mu$  with the forward topology is a Baire space, and  $H_\mu$  has a complete compatible metric. At an uncountable singular such  $\mu$ , this completely metrizable subgroup is nevertheless nowhere dense in  $S_\mu$ .*

*Proof.* The dense completely metrizable subspace  $H_\mu^-$  is Baire. If  $U_n$  are open dense in  $S_\mu$ , their intersections with  $H_\mu^-$  are open dense there: every open set in  $S_\mu$  meeting  $H_\mu^-$  meets  $U_n$  in a nonempty open set, which again meets the dense subspace. Hence  $\bigcap_n U_n$  meets every nonempty open set of  $S_\mu$ . This proves the Baire property.

By Theorem 70.10,  $H_\mu^+$  is closed in  $S_\mu$ , so  $H_\mu = H_\mu^+ \cap H_\mu^-$  is closed in the completely metrizable space  $H_\mu^-$ . The final assertion is Theorem 70.10.  $\square$

Complete metrizability is not inherited upward from a dense subspace. Consequently this corollary does not settle whether  $S_\mu$  itself admits a complete compatible metric when  $\mu > \omega$  is singular of countable cofinality. It does supply a concrete large complete locus and another proof of the Baire property in that case.

*Note 70.13* ([merge]; source 28's Question 1, answered by source 26 (3 October 2026)). Source 28 calls the complete metrizability of the full singular forward space its remaining question: “The remaining complete-metrizability question for the *full* singular forward permutation space is not settled by the dense complete subspace constructed here” (its introduction); the paragraph above; its ledger (“Does not settle complete metrizability of the full forward space”); and its Question 1, “Complete metrizability of the full singular space”: *let  $\mu > \omega$  be singular with  $\text{cf } \mu = \omega$ ; is  $\text{Sym}(\mu)$ , with its bounded-prefix topology, completely metrizable? Equivalently, is it a  $G_\delta$  subspace of the complete forward injection space?* Source 28's own results do not settle it, as it says: complete metrizability is not inherited upward from the dense locus  $H_\mu^-$ . The question is answered negatively in ZFC by source 26's [theorem 69.18](#): under the identification of  $S_\mu$  with  $\mathcal{W}_\mu(X)$ ,  $S_\mu$  is not Borel, hence

not  $G_\delta$ , in  $\mathcal{I}_\mu(\mu)$ , and no nonempty open subspace of it is completely metrizable. Source 28 read source 24 but not source 26: both were written at the same repository pin 7ff7736ec, and source 26 arrived first (commit 0d7b2441d; source 28 in 79049d58c). Source 28's Question 3, on the descriptive complexity of the one-sided loci, is answered in part by [theorem 69.17](#) and [theorem 69.23\(iii\)](#).

### 70.3.3 The forward and inverse conditions are independent

**Proposition 70.14** (An explicit one-sided permutation). *At every singular  $\mu$ ,*

$$H_\mu \subsetneq H_\mu^+, \quad H_\mu \subsetneq H_\mu^-.$$

*In particular,  $H_\mu$  is not closed in the forward topology.*

*Proof.* Put  $q = \text{cf } \mu < \mu$ . Choose a bounded set

$$B = \{b_{i,n} : i < q, n < \omega\}$$

of distinct coordinates. Above  $B$ , choose disjoint countably infinite blocks

$$A_i = \{a_{i,n} : n < \omega\} \quad (i < q)$$

in successively higher bounded ordinal intervals, with their starting positions cofinal in  $\mu$ . The intervals can be chosen so that every bounded set meets only blocks with indices bounded in  $q$ .

Define  $p$  on these coordinates by

$$p(a_{i,0}) = b_{i,0}, \quad p(a_{i,n+1}) = a_{i,n}, \quad p(b_{i,n}) = b_{i,n+1},$$

and fix all other coordinates. On each  $i$ -chain this is a bilateral shift, so it defines a permutation. A bounded input set meets only boundedly many of the high blocks. Its image is contained in the union of that input set, the bounded set  $B$ , and a bounded initial collection of the high blocks. Therefore  $p \in H_\mu^+$ .

But  $p^{-1}[B]$  contains every  $a_{i,0}$  and is cofinal in  $\mu$ . Thus  $p \notin H_\mu^-$ . Its inverse lies in  $H_\mu^- \setminus H_\mu^+$ . The nonclosedness assertion follows from  $\overline{H_\mu} = H_\mu^+$ .  $\square$

**Corollary 70.15** (A discrete subgroup outside the bounded subgroup). *There is a subgroup of  $S_\mu$  not contained in  $H_\mu$  whose inherited forward topology is a group topology.*

*Proof.* For the permutation  $p$  in Proposition 70.14, the orbit of  $b_{0,0}$  under the integer powers of  $p$  has no repetitions. Thus the only element of the cyclic subgroup  $\langle p \rangle$  fixing  $b_{0,0}$  is the identity. A sufficiently long prefix condition isolates that identity, and left translations isolate every other group element. The inherited topology is discrete, hence is a group topology. But  $p \notin H_\mu$ . This subgroup does not contain all finitary permutations, exactly as Theorem 70.4 requires.  $\square$

This example explains why a single condition such as “the permutation respects small prefixes” is insufficient. Forward boundedness concerns where early positions go; inverse boundedness concerns how late one must search to find early labels. They are different constraints at singular cardinalities.

## 70.4 The canonical group envelope (source 28)

The two-sided bounded topology  $\tau_{\leftrightarrow}$  has basic neighborhoods at  $p$  requiring

$$q \restriction \alpha = p \restriction \alpha, \quad q^{-1} \restriction \alpha = p^{-1} \restriction \alpha \quad (\alpha < \mu).$$

The predecessor proved that its defining uniformity is complete (source 24, [theorem 69.4](#)). This does not make the full singular permutation set a topological group: conjugating bounded control sets can produce unbounded control sets. We now identify the exact coarsest refinement that does make all group operations continuous.

**Definition 70.16** (Symmetric closure of a coordinate ideal). For an admissible ideal  $\mathcal{J}$ , let  $\mathcal{J}^{\text{sym}}$  be the ideal generated by the sets  $s[A]$ , with  $A \in \mathcal{J}$  and  $s \in S_\mu$ . Thus its members are subsets of finite unions of such images. It remains contained in  $[\mu]^{<\mu}$  and is invariant under every permutation.

**Theorem 70.17** (Smallest group refinement for an ideal). *The topology  $\tau_{\mathcal{J}^{\text{sym}}}$  is the coarsest group topology on  $S_\mu$  finer than  $\tau_{\mathcal{J}}$ .*

*Proof.* Every permutation and its inverse preserve  $\mathcal{J}^{\text{sym}}$ . Corollary 70.3, or the direct multiplication argument there, makes  $\tau_{\mathcal{J}^{\text{sym}}}$  a group topology. It contains  $\tau_{\mathcal{J}}$ .

Let  $\tau$  be any group topology containing  $\tau_{\mathcal{J}}$ . Each  $\text{Fix}(A)$  for  $A \in \mathcal{J}$  is  $\tau$ -open, and conjugation gives the  $\tau$ -open subgroup

$$s \text{Fix}(A) s^{-1} = \text{Fix}(s[A]).$$

Finite intersections give open stabilizers of finite unions of these image sets. If  $C$  is a subset of such a union  $D$ , then  $\text{Fix}(C)$  contains the open subgroup  $\text{Fix}(D)$ , and is itself open as a union of its cosets. Thus every  $\text{Fix}(C)$  with  $C \in \mathcal{J}^{\text{sym}}$  is  $\tau$ -open. Translating these identity neighborhoods proves  $\tau_{\mathcal{J}^{\text{sym}}} \subseteq \tau$ .  $\square$

**Theorem 70.18** (The bounded-prefix group envelope). *For every infinite  $\mu$ , the coarsest group topology finer than  $\tau_b$  is*

$$\tau_{<\mu} = \tau_{[\mu]^{<\mu}}.$$

*For regular  $\mu$ , it equals  $\tau_b$ . For singular  $\mu$ ,*

$$\tau_b \subsetneq \tau_{\leftrightarrow} \subsetneq \tau_{<\mu}.$$

*Proof.* Every small set  $A \subseteq \mu$  is the image of a bounded initial ordinal under a permutation: take a bijection  $|A| \rightarrow A$  and extend it over the two complements, both of size  $\mu$ . Conversely, images of bounded sets have size less than  $\mu$ . Therefore

$$(\mathcal{J}_b)^{\text{sym}} = [\mu]^{<\mu},$$

and Theorem 70.17 applies. At regular  $\mu$ , small and bounded are equivalent.

For every  $\mu$ , the two-sided bounded topology contains the forward one. A two-sided bounded requirement at  $p$  is enforced by forward agreement on

$$\alpha \cup p^{-1}[\alpha],$$

which has size less than  $\mu$ . Thus  $\tau_{\leftrightarrow} \subseteq \tau_{<\mu}$ .

Suppose  $\mu$  singular. Choose an involution  $s$  exchanging a bounded set of size  $\text{cf } \mu$  with a disjoint cofinal set of the same size. At  $s$ , an inverse requirement on the bounded set has no forward-prefix neighborhood enforcing it, by the transposition proof of Theorem 70.2. Hence  $\tau_b \neq \tau_{\leftrightarrow}$ .

At the identity, however, fixing  $\alpha$  automatically fixes the inverse on  $\alpha$ . Thus the  $\tau_{\leftrightarrow}$  and  $\tau_b$  identity neighborhood bases coincide. Let  $C$  be an unbounded set of size  $\text{cf } \mu < \mu$ . Its stabilizer is  $\tau_{<\mu}$ -open, but contains no bounded-prefix identity neighborhood: beyond any prescribed  $\beta$  one can swap a point of  $C$  with another point. It is not a  $\tau_{\leftrightarrow}$  neighborhood of the identity. Hence  $\tau_{\leftrightarrow} \neq \tau_{<\mu}$ .  $\square$

**Proposition 70.19** (Why two-sided bounded control is not enough). *At singular  $\mu$ ,  $\tau_{\leftrightarrow}$  does not make  $S_\mu$  a topological group.*

*Proof.* Use the permutation  $s$  from Theorem 70.18, with  $s[\alpha]$  unbounded for some  $\alpha$ . At the identity, every two-sided bounded neighborhood contains  $\text{Fix}(\beta)$  for some  $\beta$ . Choose a transposition  $t$  supported outside  $\beta$  that moves a point of  $s[\alpha]$ . Then  $t$  belongs to that input neighborhood, but  $t \circ s$  disagrees with  $s$  below  $\alpha$ . Right translation by  $s$  is not continuous at the identity.  $\square$

The envelope theorem gives a canonical answer to a natural formulation of the problem: retain all original prefix-open sets, keep ordinary permutation composition, and add no more open sets than group continuity forces. Its answer is *not* the original order topology and is *not* merely inverse-prefix control. It is control on all sets of positions with cardinality less than  $\mu$ .

## 70.5 Exact character and the singular cardinal penalty (source 28)

For a topological space, the character at a point is the least size of a local neighborhood base. For a poset,  $\text{cof}$  denotes the least size of a cofinal subset. Neither should be confused with the ordinal cofinality of the enumeration cardinal, although all three occur here.

*Note 70.20* (Source 28, Proposition 8.1, “Character of the forward space”). *Every point of  $(S_\mu, \tau_b)$  has character  $\text{cf } \mu$ . The forward space is metrizable exactly when  $\text{cf } \mu = \omega$ . This is [proposition 62.7](#) and [note 69.10](#), by the same argument (“Strictness follows by swapping two coordinates outside  $\gamma$ , one of them  $\gamma$ ”).*

**Theorem 70.21** (Character of the canonical envelope). *For every infinite cardinal  $\mu$ ,*

$$\chi(S_\mu, \tau_{<\mu}) = \text{cof}([\mu]^{<\mu}, \subseteq).$$

*For singular  $\mu$ ,*

$$\mu^+ \leq \chi(S_\mu, \tau_{<\mu}) \leq \mu^{<\mu}.$$

*In particular, the canonical group envelope is not first countable at any singular  $\mu$ .*

*Proof.* A cofinal family  $\mathcal{A} \subseteq [\mu]^{<\mu}$  gives the identity base  $\{\text{Fix}(A) : A \in \mathcal{A}\}$ . For the reverse inequality, let  $\mathcal{U}$  be a local base at the identity, and choose  $A_U$  small with  $\text{Fix}(A_U) \subseteq U$ . Given any small  $A$ , choose  $U \subseteq \text{Fix}(A)$ . Then

$$\text{Fix}(A_U) \subseteq \text{Fix}(A) \implies A \subseteq A_U.$$

Indeed, a point of  $A \setminus A_U$  could be transposed with a different point outside  $A_U$ , contradicting the inclusion. Thus the  $A_U$  form a cofinal family. Homogeneity of the topological group gives the formula at every point.

The upper bound is the number of small subsets,  $\mu^{<\mu}$ . To prove the strict lower bound at singular  $\mu$ , put  $q = \text{cf } \mu$  and suppose a family  $(A_\xi)_{\xi < \mu}$  were cofinal. Choose increasing infinite cardinals  $\kappa_i < \mu$ ,  $i < q$ , cofinal in  $\mu$ . For each  $i$ , the union

$$T_i = \bigcup \{A_\xi : \xi < \kappa_i, |A_\xi| \leq \kappa_i\}$$

has size at most  $\kappa_i$ , so choose  $x_i \in \mu \setminus T_i$ . The set  $C = \{x_i : i < q\}$  has size less than  $\mu$ . For any fixed  $\xi < \mu$ , choose  $i$  sufficiently large that  $\xi < \kappa_i$  and  $|A_\xi| \leq \kappa_i$ . Then  $x_i \notin A_\xi$ , and hence  $C \not\subseteq A_\xi$ . This contradicts cofinality of the family. A shorter family could have been padded to length  $\mu$ , so the cofinality is strictly greater than  $\mu$ .  $\square$

**Example 70.22** (A countably based order with a very large group envelope). Take  $\kappa = \beth_\omega$  and  $X = \mathbf{No}_{<\kappa}$ . The cardinal  $\kappa$  is a singular strong limit of cofinality  $\omega$ , and  $2^{<\kappa} = \kappa$ . Thus the minimal enumeration order has a metrizable order topology with local character  $\omega$ . Its canonical group envelope has character at least  $\beth_\omega^+$ . No additional hypothesis such as the generalized continuum hypothesis is needed for this example: strong limit follows because every  $\lambda < \beth_\omega$  is below some  $\beth_n$ , and  $2^\lambda \leq \beth_{n+1} < \beth_\omega$ .

*Remark 70.23* (What the character bound does not say). Character is not monotone under arbitrary refinement of a topology. In particular, the discrete topology is a finer metrizable group topology and has character 1. The theorem says that the *coarsest* group refinement has large character. It does not exclude all other finer metrizable group topologies. Nor does it claim that a different, artificially transported group law could not be placed on the underlying space. The fixed operations throughout are ordinary permutation composition and inversion.

**Proposition 70.24** (Equal global invariants can conceal different local geometry). *Both  $(S_\mu, \tau_b)$  and  $(S_\mu, \tau_{<\mu})$  have density and weight equal to  $\mu^{<\mu}$ .*

*Proof.* There are  $\mu^{<\mu}$  short injective prefixes, giving an upper bound for the weight of  $\tau_b$ ; choosing one completion of each gives the same bound for density. There are also at most  $\mu^{<\mu}$  small-domain partial injections, giving both upper bounds for  $\tau_{<\mu}$ .

For every cardinal  $\lambda < \mu$ , all injections from a fixed initial segment of size  $\lambda$  into  $\mu$  give pairwise disjoint nonempty cylinders in either topology. There are  $\mu^\lambda$  such injections: an arbitrary function  $a : \lambda \rightarrow \mu$  can be coded injectively as  $\xi \mapsto (\xi, a(\xi))$ , followed by a fixed identification  $\lambda \times \mu \cong \mu$  when  $\lambda > 0$ . Every dense set must meet every cylinder. Taking the supremum over  $\lambda < \mu$  gives density at least  $\mu^{<\mu}$ , and weight is at least density.  $\square$

Thus density and weight alone cannot detect the topology change. The local character and the continuity of right translations do detect it.

## 70.6 Three uniform completions, kept separate (source 28)

Uniform completeness depends on a chosen family of agreement requirements, not only on the induced topology. This is already visible for permutations of  $\omega$ : permutations can stabilize at every forward coordinate while one label escapes to arbitrarily late positions. The following results organize the analogous phenomena at arbitrary cardinalities.

### 70.6.1 Forward completion for an arbitrary coordinate ideal

For admissible  $\mathcal{J}$ , put on  $\mathcal{I}_\mu(\mu)$  the uniformity with basic entourages

$$E_A = \{(h, k) : h \restriction A = k \restriction A\}, \quad A \in \mathcal{J}.$$

Its restriction to  $S_\mu$  is the forward  $\mathcal{J}$ -uniformity.

**Theorem 70.25** (The forward ideal completion). *The injection space is complete for this uniformity, and  $S_\mu$  is a dense uniform subspace. Hence  $\mathcal{I}_\mu(\mu)$  is its Hausdorff uniform completion.*

*Proof.* A Cauchy filter determines, for each  $A \in \mathcal{J}$ , a unique stabilized restriction  $q_A$  on  $A$ : an  $E_A$ -small nonempty filter member lies in the cylinder determined by one such restriction, and two different cylinders are disjoint. Taking control on  $A \cup B$  proves compatibility of  $q_A$  and  $q_B$ . Since singletons belong to  $\mathcal{J}$ , the union determines a function  $h : \mu \rightarrow \mu$ . Control on each two-element set proves injectivity. The filter contains the cylinder of  $h \upharpoonright A$  for every  $A \in \mathcal{J}$ , hence converges to  $h$ .

Every small-domain partial injection extends to a permutation, because both unused domain and unused range have cardinality  $\mu$ . Therefore every basic cylinder in the injection space meets  $S_\mu$ . The agreement entourage restricts exactly to those on  $S_\mu$ , proving density and uniform embedding. Completeness and Hausdorffness give the completion assertion.  $\square$

This proof uses stabilization of an entire allowed control set, not merely separate eventual stabilization at each coordinate. For uncountable control sets those are distinct conditions.

**Theorem 70.26** (Forward completion of the bounded subgroup). *For the bounded-prefix uniformity, the Hausdorff completion of  $H_\mu$  is*

$$\mathcal{I}_\mu^b = \{h \in \text{Inj}(\mu, \mu) : h[A] \text{ is bounded whenever } A \text{ is bounded}\}.$$

*For every infinite  $\mu$ , the subgroup  $H_\mu$  is not complete for this forward uniformity.*

*Proof.* In the full injection completion from Theorem 70.25, a failure of boundedness is witnessed by an entire prefix with unbounded range. Its cylinder excludes  $\mathcal{I}_\mu^b$ , so that subspace is closed and complete. Each prefix of a boundedness-preserving injection has bounded domain and bounded range; Lemma 70.9 completes it inside  $H_\mu$ . Conversely, no prefix with unbounded range can occur in an element of  $H_\mu$ . Hence the closure of  $H_\mu$  in the injection completion is exactly  $\mathcal{I}_\mu^b$ .

For a concrete missing point, send each natural number  $n$  to  $n + 1$  and fix every coordinate in  $\mu \setminus \omega$ . This is a boundedness-preserving injection omitting 0. When  $\mu = \omega$ , bounded sets are finite and the assertion is immediate; when  $\mu > \omega$ , the changed coordinates lie in the bounded set  $\omega$ . Thus the complete closure strictly contains  $H_\mu$ .  $\square$

There is no conflict between this theorem and complete metrizability of  $H_\mu$  when  $\text{cf } \mu = \omega$ . A complete compatible metric can induce the same topology as an incomplete forward metric while defining a different uniformity.

### 70.6.2 Two-sided small-set completeness

On  $S_\mu$ , define

$$E_A^{\leftrightarrow} = \{(p, q) : p \upharpoonright A = q \upharpoonright A \text{ and } p^{-1} \upharpoonright A = q^{-1} \upharpoonright A\}, \quad |A| < \mu.$$

**Theorem 70.27** (Completeness of the canonical group envelope). *The two-sided small-set uniformity is complete, induces  $\tau_{<\mu}$ , and is the two-sided group uniformity of  $(S_\mu, \tau_{<\mu})$ . Thus the canonical envelope is a complete topological group in the two-sided sense.*

*Proof.* A Cauchy filter determines coherent stabilized forward and inverse restrictions. As in Theorem 70.25, their unions are injections  $h, g : \mu \rightarrow \mu$ . If  $h(\xi) = \eta$ , take a nonempty filter member on which the forward value at  $\xi$  and the inverse value at  $\eta$  are both stabilized. Every permutation in that member witnesses  $g(\eta) = \xi$ . Conversely,  $g(\eta) = \xi$  implies  $h(\xi) = \eta$ . Hence  $g = h^{-1}$ , and  $h$  is a permutation. Stabilization on each whole small control set proves convergence in the stated uniformity.

At a fixed  $p$ , inverse agreement on  $A$  is enforced by forward agreement on  $p^{-1}[A]$ , which is small. Thus adding inverse requirements does not change the topology  $\tau_{<\mu}$ .

Finally, the two group-uniform conditions associated with  $\text{Fix}(A)$  are

$$p^{-1}q \in \text{Fix}(A), \quad qp^{-1} \in \text{Fix}(A).$$

The first is equivalent to forward agreement on  $A$ . The second is equivalent to agreement of the inverses on  $A$ : it says  $q(p^{-1}(a)) = a$  for every  $a \in A$ . Their intersection is  $E_A^{\leftrightarrow}$ . Finite unions combine different control sets, identifying the uniformities exactly.  $\square$

| Control convention                       | Completion or completeness                                            | Singular-cardinal warning                                        |
|------------------------------------------|-----------------------------------------------------------------------|------------------------------------------------------------------|
| Forward bounded prefixes                 | Full injection space; for $H_\mu$ , boundedness-preserving injections | Surjectivity can be lost.                                        |
| Forward arbitrary small sets             | Full injection space, with small-set control                          | Coordinatewise convergence alone is weaker.                      |
| Forward and inverse bounded prefixes     | Complete on the full permutation set                                  | The induced topology is still not a group topology.              |
| Forward and inverse arbitrary small sets | Complete two-sided group uniformity                                   | Its topology is $\tau_{<\mu}$ , not the original order topology. |
| Dedekind cuts of the numerical order     | Also fills cylinder edges and alphabet gaps                           | Not a uniform completion of either preceding kind.               |

For the last row, even a full injective word cannot represent the lower edge of a first-label cylinder. If  $X$  is thick and  $x \in X$ , consider the lower cut consisting of exhaustive words with first label below  $x$ . An injection starting below  $x$  lies below some words in that cut, one starting above  $x$  lies above the entire  $x$ -cylinder, and one starting at  $x$  has exhaustive words with that same first label below it. None gives exactly the cylinder-edge cut. This is the elementary reason the forward injection boundary is only part of the order-completion boundary (source 24, [proposition 65.4](#)).

## 70.7 What the group results say about surreal lexicography (source 28)

### 70.7.1 Changing labels versus changing positions

A bijection  $a : X \rightarrow Y$  acts on exhaustive enumerations by  $f \mapsto a \circ f$ . It takes prefix cylinders to prefix cylinders, and is therefore always a homeomorphism of the prefix spaces. If both alphabets are thick, it is a homeomorphism of their order topologies. It is an order isomorphism exactly when  $a$  is increasing: sufficiency follows from first disagreement, and necessity follows by choosing exhaustive words with prescribed distinct first labels.

By contrast, a permutation of positions acts by  $f \mapsto f \circ s$ . Theorem [70.2](#) shows that this is a forward homeomorphism precisely when  $s \in H_\mu$ . The distinction is conceptual: relabelling does not change which positions have been inspected, but reordering positions can move a bounded inspection set to an unbounded one.

**Proposition 70.28** (Exact filtration invariance). *The position changes that preserve the bounded-prefix topology in both directions are exactly the automorphisms of the bounded-set ideal, namely  $H_\mu$ . The topology  $\tau_{<\mu}$  is invariant under every position permutation. For singular  $\mu$ , it is the coarsest topology that contains the prefix topology and is a group topology for all position permutations.*

*Proof.* The first assertion is Theorem 70.2(ii) applied to  $s$  and  $s^{-1}$ . Every permutation preserves cardinality, so it preserves the small-set ideal and acts homeomorphically for  $\tau_{<\mu}$ . The final assertion is Theorem 70.18.  $\square$

### 70.7.2 The permutation structure is relative to a baseline

The set  $\text{Bij}(\mu, X)$  is not intrinsically a group under composition: its members have domain  $\mu$  and codomain  $X$ , so  $f \circ g$  need not even be typed. Fixing  $e : \mu \rightarrow X$  gives the group law

$$f *_e g = f \circ e^{-1} \circ g,$$

with identity  $e$ . The usual right action of  $\text{Sym}(\mu)$  on enumerations is intrinsic, but choosing an identity for a group law is auxiliary. It is useful to regard the enumeration space as a *torsor*, a space on which the permutation group acts freely and transitively, before selecting a baseline.

The subgroup  $H_\mu$  then corresponds to enumerations that send bounded position sets into bounded portions of the baseline label filtration  $e[\alpha]$ , and whose inverses have the same property. Its placement inside the surreal enumeration space depends on that label filtration. Self-normalization is a precise theorem about this specified action; it is not a claim that numerical order alone canonically chooses  $H_\mu$ .

### 70.7.3 Concrete cutoff consequences

For  $\mathbf{No}_{<\kappa}$  and  $\mu = 2^{<\kappa}$ , the following conclusions are immediate from the proved theorems. The minimal order is dense without endpoints, has size  $2^\mu$ , and contains every linear order of size at most  $\mu$ . Its ordinal and reverse-ordinal spectra stop exactly at  $\mu^+$ . Its local order-topological character is cf  $\mu$ . After choosing a baseline, the boundedness-preserving subgroup is maximal in the sense of Theorem 70.4, and, when  $\mu$  is singular, is self-normalizing and nowhere dense. The least group refinement has character  $\text{cof}([\mu]^{<\mu})$  and is two-sided complete.

These conclusions are insensitive to whether the birthday cutoff is a subfield. Arithmetic closure is not needed. Conversely, the statements do not automatically apply to an arbitrary sparse subset of  $\mathbf{No}$  with its numerical order. Prefix topology still makes sense there, but its agreement with the order topology required thickness.

### 70.7.4 Context from earlier topological classifications

At regular  $\mu$ , the predecessor manuscript constructs a homeomorphism

$$\mathcal{W}_\mu(X) \cong_{\text{top}} (\mu^{<\mu})^\mu$$

with the bounded topology (source 24, theorem 66.2). Its tree forces the least not-yet-used label to appear at each stage. Regularity keeps the union of fewer than  $\mu$  intermediate short prefixes short. At singular  $\mu$ , that specific construction can reach full length before all coverage requirements have been imposed. This is why a regular argument cannot simply be copied.

At the countable thick cutoff, the same predecessor proves that the topology is ordinary Baire-space topology, while the Dedekind completion is a real line with continuum many omitted points. It is therefore not order-isomorphic to the usual irrationals, whose real completion omits only countably many points. This is another warning that topology alone does not classify the numerical order. The bounded-topology setting is part of the broader generalized descriptive-set-theoretic landscape studied in [61]; the present ideal arguments neither assume nor establish a general classification of all such spaces.

## 71 The class analogue: global prefix completion and its limits (source 24; sources 26 and 28)

[merge] Source 24’s Sections 9–11, with source 26’s Sections 11–12 and source 28’s Sections 11–12. The class layer re-proves Part IV: the core  $\mathcal{P}_{\text{bd}}(b)$  (the three sources’  $\mathcal{C}_b$ ), its prefix completion, its density and universality, the diagonal theorem and direct comparison; these are notes. New are source 24’s small-net rigidity, its global branch-completion scheme and its two-sided global completion, the corresponding remarks of sources 26 and 28, and source 28’s observation that every set of ordinal coordinates is bounded, so that the singular obstruction of [section 69](#) does not occur globally. All statements are GBC schemes about supplied class parameters; source 24’s  $\mathfrak{E}$ ,  $\mathfrak{I}$  are printed  $\mathfrak{W}_{\text{sl}}$ ,  $\mathfrak{J}$ .

### 71.1 Global prefix completion (source 24)

We now work in GBC with the fixed baseline  $b : \text{Ord} \rightarrow \mathbf{No}$ . Besides the virtual domain  $\mathfrak{W}_{\text{sl}}$  of class bijections, write  $\mathfrak{J}$  for the virtual domain of class injections  $h : \text{Ord} \rightarrow \mathbf{No}$ . Both have a well-defined first-disagreement comparison of individual members: a nonempty class of ordinals has a least member, since any one witness bounds a nonempty set in which the least witness can be found.

A set-sized injective prefix is an actual set  $p : \alpha \rightarrow \mathbf{No}$ . The expression “[ $p$ ]” means the predicate that a given class word extends  $p$ . It does not introduce a class with those class words as its members. This distinction is harmless for ordinary pairwise proofs and indispensable for statements about all words.

#### 71.1.1 A genuinely class-sized core made from set codes

A permutation of  $\text{Ord}$  is *set supported* when its moved coordinates form a set. Such a permutation is the identity above some ordinal. Code it canonically by a permutation of the least initial segment containing its support, extended by the identity outside that segment. The identity has the empty code. The collection of these codes is an ordinary class of sets. Evaluating a code as  $b \circ \pi$  gives an exhaustive surreal enumeration. Denote the ordered class of canonical codes by  $\mathcal{P}_{\text{bd}}(b)$ .

*Note 71.1* (Source 24, Lemma 9.1 and Propositions 9.2 and 9.3). Lemma 9.1 (“Global prefix extension with a reserve”): *every set-sized injective prefix  $p : \alpha \rightarrow \mathbf{No}$  extends to the evaluation of a code in  $\mathcal{P}_{\text{bd}}(b)$ ; the extension can be selected uniformly from  $p$  and the fixed baseline and global-choice parameters.* This is [lemma 19.4](#), by a balanced reserve: with  $q = b^{-1} \circ p$  and  $S = \alpha \cup \text{ran } q$ , a disjoint block  $R$  of size  $\nu \geq |S|$  makes  $D \setminus \alpha$  and  $D \setminus \text{ran } q$  equinumerous for  $D = S \cup R$ . Source 24 comments: “The reserve is not cosmetic. A naive instruction to ‘close every partial-injection chain’ can fail for an infinite chain with unequal endpoint behavior . . . Earlier work optimizes the size of that reserve; optimality is unnecessary here” (source 17’s [theorem 49.7](#)). Proposition 9.2 (“Prefix density and numerical density”): *every set-prefix cylinder in  $\mathfrak{W}_{\text{sl}}$  or  $\mathfrak{J}$  contains a core evaluation; a core evaluation lies strictly between any two distinct injections, and on either side of each, which is [proposition 19.25](#) with the density in [theorem 19.10](#).* Source 24: “The existing report proves more: with its explicit uniform set-cut convention, this core realizes all set-sized separated cuts and is order-isomorphic to the surreal line” ([corollary 19.15](#)). “The results below need only the prefix extension and density just proved. In particular, the fact that a dense core is a surreal line should not be turned into the assertion that the entire virtual enumeration domain is an ordinary copy of  $\mathbf{No}$ .” Proposition 9.3 (“Ordinary class-order universality, recalled”): *in GBC, every linear order carried by a class of sets admits a class order embedding into  $\mathbf{No}$ , and hence into  $\mathcal{P}_{\text{bd}}(b)$  and the virtual domain  $\mathfrak{W}_{\text{sl}}$ ; the variable-carrier set-word orders also contain such an image, even when words are*

required to be numerically increasing, which is [propositions 5.13](#) and [19.20](#); source 24 uses the set-cut property, “not an assertion about arbitrary class cuts”, and a first-label embedding  $\mathbf{No} \rightarrow \mathcal{P}_{\text{bd}}(b)$ , and adds: “The qualifier ‘carried by a class of sets’ is essential. The virtual domain of *all* class enumerations is not such a carrier, so the proposition does not embed that whole higher-order domain into  $\mathbf{No}$ . This universality statement is part of the predecessor framework; it is included to connect the new completion theory to the original embedding question.”

### 71.1.2 Set-indexed nets cannot make nontrivial global progress

A *uniformly set-indexed family of class words* is given by one class relation  $F(i, \xi, x)$ , where  $i$  belongs to a fixed set  $I$ , and the  $i$ th section defines a class word  $f_i$ . A directed order on  $I$  makes it a net. Forward Cauchyness means

$$\forall \alpha \in \text{Ord} \exists i_0 \in I \forall i, j \geq i_0 \quad f_i \upharpoonright \alpha = f_j \upharpoonright \alpha.$$

All restrictions displayed here are sets. This is a formula about the one class relation  $F$ , not a quantification over a set of proper-class objects.

**Theorem 71.2** (Small-net rigidity). *Every uniformly set-indexed forward-Cauchy net in  $\mathfrak{J}$  is eventually constant. Every uniformly set-indexed net converging in the prefix sense to a specified class word is eventually equal to that word. In particular, both statements hold for  $\mathfrak{M}_{\text{sl}}$  and for core evaluations.*

*Proof.* For each pair  $i, j \in I$  whose sections differ, let  $\delta(i, j)$  be their least disagreement, and set  $\delta(i, j) = 0$  when the sections are equal. This is a class function on the set  $I \times I$ . Class Replacement gives a set of its values. Thus

$$\Gamma = \sup\{\delta(i, j) + 1 : i, j \in I\}$$

is an ordinal. Two sections in this family agreeing below  $\Gamma$  are identical. Cauchyness at  $\Gamma$  makes all sections in a tail identical, proving eventual constancy.

For convergence to a specified word  $h$ , apply the same argument to the set of first disagreements between  $h$  and the sections not equal to it. A bound on those disagreements, together with convergence, makes every sufficiently late section equal to  $h$ .  $\square$

**Corollary 71.3** (No set-sized accumulation pattern). *Relative to the prefix-neighborhood predicates, any uniformly set-indexed collection of distinct global words is discrete and has no accumulation point, even at a word outside the collection. Every set of core codes is a closed discrete subset of the core’s order topology.*

*Proof.* For a specified word  $h$ , bound the first disagreements with all indexed words other than  $h$ . The corresponding prefix neighborhood of  $h$  excludes them all. On the core, prefix cylinders form the order-topology base by the same argument as [Lemma 62.5](#), using [note 71.1](#) for completions.  $\square$

This is a foundationally meaningful difference from the countable case. A sequence indexed by ordinary  $\omega$ , or a net indexed by any set, cannot successively explore every ordinal-length prefix in the global problem. Nontrivial global approximation must have a proper-class index range or be interpreted externally in a larger universe.

### 71.1.3 The correct global branch-completion statement

**Definition 71.4** (A coherent prefix system). A coherent prefix system is one class relation specifying, for every ordinal  $\alpha$ , a set injection  $p_\alpha : \alpha \rightarrow \mathbf{No}$ , with

$$p_\beta \upharpoonright \alpha = p_\alpha \quad (\alpha < \beta).$$

**Theorem 71.5** (Global branch completion, stated as a scheme). *A coherent prefix system has a unique union  $h : \text{Ord} \rightarrow \mathbf{No}$  that is a class injection. Conversely, every class injection determines such a system. For each specified injection  $h$ , there is a uniformly Ord-indexed net of core codes whose evaluations converge forward to  $h$ . It has a limit in  $\mathfrak{W}_{\text{sl}}$  exactly when  $h$  is exhaustive.*

*Proof.* Elementary class comprehension forms the union relation. Coherence proves that it is a function on all ordinals; injectivity is witnessed in a single set prefix for any proposed pair of coordinates. The reverse construction is restriction of a class function to each set ordinal, with Class Replacement ensuring that each restriction is a set.

For each  $\alpha$ , apply the uniform extension procedure in [note 71.1](#) to  $h \upharpoonright \alpha$ . Let  $c_\alpha$  be the resulting core code and  $f_\alpha$  its evaluation. For every  $\beta$ , all  $\alpha \geq \beta$  satisfy  $f_\alpha \upharpoonright \beta = h \upharpoonright \beta$ . This is forward convergence. Any other forward limit must share every set prefix with  $h$ , hence must equal  $h$ . Therefore a limit in the exhaustive domain exists exactly when  $h$  itself is exhaustive.  $\square$

This theorem is the global analogue of [Theorem 65.1](#), but its formulation is deliberately different. It does not form the collection of all Cauchy filters on a nonexistent ordinary space of all class words. It proves a uniform reconstruction statement about each supplied class-coded system. In a larger-universe set model, it can be read as an ordinary completion theorem; within two-sorted class theory it is a scheme with class parameters.

### 71.1.4 Inverse stabilization restores exhaustiveness

For a global enumeration  $f$ , its inverse is a class function  $f^{-1} : \mathbf{No} \rightarrow \text{Ord}$ . Relative to  $b$ , a two-sided prefix comparison requires agreement of  $f, g$  below a set ordinal  $\alpha$  and agreement of  $f^{-1}, g^{-1}$  on  $b[\alpha]$ .

**Theorem 71.6** (Two-sided global completion). *Let  $(f_\gamma)_{\gamma \in \text{Ord}}$  be a uniformly class-coded net of exhaustive global enumerations. Suppose that for every set ordinal  $\alpha$ , both the forward restrictions below  $\alpha$  and the inverse restrictions on  $b[\alpha]$  are eventually pairwise equal. Then there is a unique exhaustive global enumeration  $f$  to which the net converges in both senses.*

*At each specified enumeration, forward and two-sided neighborhood predicates generate the same topology. No elementary transfinite recursion principle beyond GBC is needed for this reconstruction.*

*Proof.* For each ordinal  $\xi$ , define  $h(\xi)$  to be the unique eventual value of  $f_\gamma(\xi)$ . For each surreal  $x$ , define  $g(x)$  to be the unique eventual value of  $f_\gamma^{-1}(x)$ . The assumed stabilization makes these values exist; they are defined by an elementary formula using the class parameter for the net. Elementary class comprehension therefore gives both graphs.

If  $h(\xi) = x$ , choose a stage beyond the stabilization thresholds for that forward coordinate and that inverse coordinate. Since every row is a bijection,  $g(x) = \xi$ . The converse gives  $h(g(x)) = x$ . Thus  $h$  and  $g$  are inverse class bijections. Stabilization of entire set prefixes, not just individual coordinates, is part of the hypothesis and gives convergence in both senses. Uniqueness follows from agreement on all set prefixes.

For compatibility at a fixed  $f$ , the preimage  $f^{-1}[b[\alpha]]$  is a set of ordinals by Class Replacement, hence bounded by some ordinal  $\beta$ . Agreement with  $f$  below  $\beta$  fixes the inverse on  $b[\alpha]$ . This is exactly the forward-to-inverse neighborhood implication. The other implication is immediate.

The construction selected eventual values by a formula. It did not perform a recursion with proper-class previous values; consequently no appeal to ETR is hidden in this argument.  $\square$

The global theorem behaves like the regular-cardinal case: every *set* of ordinal positions is bounded. The singular set case differs because a set of cardinality less than  $\mu$  need not be bounded in  $\mu$ . This one quantifier distinction explains both the continuity obstruction and the apparent contrast between small-net rigidity and nontrivial external approximations.

## 71.2 Comparison beyond ordinal words, and the foundations ledger (source 24)

*Note 71.7* (Source 24, Section 10: Definition 10.1, Lemma 10.2, Theorem 10.3 and Example 10.4). Source 24 gives “the direct comparison theorem because it is the cleanest way to include the unrestricted interpretation without assuming an inappropriate class-order-type calculus”. Its common labelled initial segment  $I(R, S)$ , its maximality lemma and its Theorem 10.3 (“Elementary lexicographic comparison of all class well-orders”): *for distinct class well-orders  $R, S$  of a labelled class  $X$  with a fixed linear order  $<_X$ ,  $R <_{\text{lex}} S$  iff  $a <_X b$  for the first residual labels; this is a strict linear comparison, it agrees with first-disagreement comparison for ordinal-indexed enumerations, and it uses elementary class comprehension, not general class well-order comparability or ETR*, are [theorem 14.2](#) and [theorem 14.7](#), by the same proof. Source 24: “This theorem reprises a central construction in the earlier report, with the logical dependencies exposed. It is included here as a tool, not presented as a new resolution of an old open problem.” Its Example 10.4 (“A genuinely proper-class prefix”: a set-like well-order of  $\mathbf{No} \setminus \{u < v\}$  followed by  $u, v$  or by  $v, u$ ) is the family of [theorem 16.2](#); source 24 adds that “non-set-like orders have tail geometry invisible to the first Ord-long set-like part . . . Therefore our cylinder topology, completion, and regular-cardinal Baire theorems should not be transferred wholesale to the unrestricted order.”

[merge] Source 24’s Section 11, “Paradox-free foundations and the size ledger”.

### 71.2.1 Four different levels of collection

The safest practice is to attach a size declaration to every carrier and every family. The following ledger separates constructions that are often written with deceptively similar notation.

| Object                                                    | Legitimate status                                                      | What must not be inferred                                                |
|-----------------------------------------------------------|------------------------------------------------------------------------|--------------------------------------------------------------------------|
| $\mathcal{W}_\mu(X), \mathcal{I}_\mu(X)$ for set $X, \mu$ | Sets in ZFC; ordinary topology, filters, and powersets apply.          | They need not be sets inside a smaller chosen universe.                  |
| All set-length surreal words                              | A definable class of set graphs.                                       | This class is not a set; its powerclass is not an ordinary class.        |
| The support core $\mathcal{P}_{\text{bd}}(b)$             | A class of canonical set codes with a uniform evaluation relation.     | Its dense image does not exhaust all global enumerations.                |
| All class enumerations or all class well-orders           | A virtual domain, a higher-sort domain, or a set in an external model. | Proper classes do not become members of a same-level class in GBC or KM. |

The first two levels are enough to prove many order embeddings. The third supplies a practical surrogate for global prefixes. The fourth is needed only when one insists on quantifying over, or making functions whose arguments are, arbitrary global enumerations as objects.

*Note 71.8* (Source 24, Theorem 11.1, “No uniform class of set codes exhausts the global words”). In GBC, let  $A$  be a class of sets and let one class relation uniformly assign a global enumeration  $f_a : \text{Ord} \rightarrow \mathbf{No}$  to each  $a \in A$ ; this family cannot exhaust  $\mathfrak{W}_{\text{sl}}$ . This is [theorem 19.37](#), by the same pair-swap diagonal on the blocks  $\{2 \cdot \alpha, 2 \cdot \alpha + 1\}$ . Source 24: “This gives a concrete reason that  $\mathcal{P}_{\text{bd}}(b)$  is a core rather than an exhaustive parametrization. Density is a local statement about each prefix or each interval. Exhaustive coding would be a global surjectivity statement, and the diagonal argument forbids it. There is no contradiction between a surreal-sized dense core and a larger virtual domain.” Its Example 11.2 below is the inconsistency of unrestricted cuts recorded in the foundations report (`found:prop:allcuts`, formalized as `noUnrestrictedCuts`; [section 1.5](#)).

### 71.2.2 Set-like recursion versus recursion with class-valued stages

Several constructions above are sometimes described informally as “transfinite recursion,” but they do not all require the same principle. Recursion of set-length along a set ordinal is ordinary set recursion. A uniform Ord-length construction whose stage values and previous histories are sets can be described by its unique set-length initial solutions, then assembled by elementary class comprehension. This is different from a recursion in which the value at each stage is itself an arbitrary proper class.

The latter is the setting of elementary transfinite recursion principles for classes. Their nontrivial strength is reflected, for example, in the equivalence between suitable clopen class-game determinacy and ETR studied by Gitman and Hamkins [22]. It is therefore not valid to invoke arbitrary class recursion while claiming to work only in GBC.

In source 24, the common-prefix formula is elementary; the supported extension procedure takes set parameters to set codes; coherent-prefix unions are given class relations; and eventual-value reconstruction is an elementary definition from a supplied net. None of these arguments assumes an unrestricted proper-class recursion theorem. A future construction of an automorphism by class-length back-and-forth should be audited anew, rather than inheriting this conclusion merely because it also mentions prefixes.

### 71.2.3 An external inaccessible-universe model

There is a transparent way to turn the virtual global picture into an ordinary set-sized one. Work externally in ZFC and assume a strongly inaccessible cardinal  $\Theta$ . Let

$$M = V_\Theta, \quad \mathcal{X} = \mathcal{P}(V_\Theta).$$

Interpret sets as members of  $M$  and classes as all external subsets of  $V_\Theta$ . This full class model satisfies the class-comprehension and replacement requirements of KM with Global Choice: regularity bounds the ranks of images of internal sets, and strong inaccessibility ensures that the required internal sets and powersets lie below  $\Theta$ .

Its ordinals are externally the ordinals below  $\Theta$ , and its surreal class is externally  $\mathbf{No}_{<\Theta} = \mathbf{No}_{<\Theta}$ , of size  $\Theta$ . Consequently its full set-like global enumeration domain is externally the ordinary set

$$\text{Bij}(\Theta, \mathbf{No}_{<\Theta}) = \mathcal{W}_\Theta(\mathbf{No}_{<\Theta}).$$

Theorem 66.2 applies to it. In this model  $\Theta^{<\Theta} = \Theta$ , so the external topological presentation is  $\Theta^\Theta$  with the bounded topology. The arbitrary internal class well-orders, because all subclasses are available, correspond externally to all genuine well-orders of the set  $\mathbf{No}_{<\Theta}$ , not merely its minimal-length slice.

There is no conflict with Theorem 71.2. An internal set-indexed net has an index set in  $V_\Theta$  and hence fewer than  $\Theta$  indices. An external  $\Theta$ -indexed net need not have an internal set of indices and can make nontrivial progress. The distinction is exactly the one the theorem requires.

The inaccessible hypothesis is a sufficient external modeling device, not an axiom claimed to follow from ZFC, and not a prerequisite for the elementary set-sized results. Other class models can be used, but their available classes and their external size must then be specified.

#### 71.2.4 Definable classes, class models, and higher universes

There are three complementary formalization routes.

**Schematic definable classes.** In a set-theoretic metatheory, work with explicitly supplied formulas and set parameters defining the relevant classes. Each theorem is a schema about such definitions. This is efficient for fixed examples and elementary comparison. It does not yield a single internal truth predicate for all formulas or an internal enumeration of all semantic classes. Syntax codes are not automatically an exhaustive semantic universe.

**A two-sorted class model.** Specify a model  $(M, \mathcal{X})$  of GBC or a stronger theory. Every assertion about “all global enumerations” means all such class relations belonging to  $\mathcal{X}$ . Enlarging  $\mathcal{X}$  while preserving  $M$  can add new branches and new enumerations. A set-coded core can remain unchanged, but this does not make every assertion about all classes absolute. The previous cut-reconstruction work addresses more refined preservation questions (sources 17 and 14; section 48); here we use only the explicit parameter-relative interpretation.

**A universe hierarchy.** In a type-theoretic or Grothendieck-universe setting, collect the small surreals at one level and their large relations at the next. Their functions and cuts can then be ordinary objects at a sufficiently high level. This is often the easiest route for a proof assistant. It remains essential not to identify a type with a type containing all of its own higher-universe relations. Moving to a higher universe resolves a size problem; erasing the universe distinction recreates it.

**Example 71.9** (Why all class cuts cannot be filled by surreals). Every surreal is below some ordinal surreal: compare its sign sequence with a longer all-plus sequence. Thus the lower class consisting of all ordinal surreals has no surreal upper bound. The separated class cut with that lower side and empty upper side has no surreal separator. The familiar set-cut interpolation property is therefore not a theorem about arbitrary class-indexed cuts. The word “set” or “small” in such a theorem is a mathematical hypothesis, not bookkeeping.

### 71.3 Global well-orders without a class of classes (source 26)

#### 71.3.1 Set-like versus unrestricted class well-orders

Work in GBC. A class relation  $R$  on a class  $C$  is a class well-order when it is a strict linear order and every nonempty admitted subclass has an  $R$ -least element. It is *set-like* when

$$\text{Pred}_R(x) = \{y \in C : yRx\}$$

is a set for each  $x \in C$ . For a proper class, a set-like class well-order has a unique ordinal-class enumeration: the position of  $x$  is the set ordinal  $\text{otp}(\text{Pred}_R(x), R)$ . Its range of positions is an unbounded initial segment of  $\text{Ord}$ , hence all of  $\text{Ord}$ .

Fix a baseline class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . Global choice supplies such a bijection. Set-like surreal well-orders can be represented by other class bijections  $e : \text{Ord} \rightarrow \mathbf{No}$ . Their labels at the first differing ordinal determine their comparison. In contrast, an unrestricted class well-order can have type  $\text{Ord} + 1$  or  $\text{Ord} + \text{Ord}$ , after a suitable class bijection of its carrier with  $\mathbf{No}$ . It cannot be represented by an exhaustive Ord-word: the tail beyond the initial proper-class segment would be lost.

The repository proves the equivalence, over its convention for GB without set choice, between the existence of a class well-order of  $\mathbf{No}$  and global choice ([theorem 13.1](#)). We do not repeat the full weak-choice coding proof. All global constructions below explicitly assume GBC, so no additional choice claim is concealed in the selection of  $b$ .

The expressions “all set-like class well-orders” and “all class well-orders” below denote predicates on class variables. In two-sorted GB or KM, a class has *sets* as members. Stronger class comprehension in KM does not turn classes into allowable members of another class. An actual collection whose elements are class relations needs a higher sort, external semantics, or a separately specified coding restriction.

*Note 71.10* (Source 26, Section 11: Definition 11.1, Lemma 11.2, Theorem 11.3, Example 11.4, Lemma 11.5, Proposition 11.6 and Theorem 11.7). Source 26 prints “a useful earlier result”, with a proof “to expose its precise logical strength”: the common labelled prefix  $D_{R,S}$ , its Lemma 11.2 and its Theorem 11.3 (“A virtual linear order of all labelled class well-orders”), which are [theorems 14.2](#) and [14.7](#) and source 24’s [note 71.7](#). Its Example 11.4 (“A genuine adjacent pair”: a set-like enumeration of  $\mathbf{No} \setminus \{a, b\}$  followed by  $a, b$  or by  $b, a$ , two unrestricted well-orders of type  $\text{Ord} + 2$  that are adjacent) is [theorem 16.2](#); the example “also demonstrates why a topology using only set-length initial prefixes cannot distinguish every unrestricted tail: both orders have the same prefix at every ordinal position, yet they are distinct.” Its Lemma 11.5 (“Prefix extension with an explicit reserve”) is source 24’s [note 71.1](#) ([lemma 19.4](#)); “the previous report proves considerably more about this core ... The reserve lemma is the only part needed for the approximation arguments below.” It adds “a direct simple embedding of the numerical surreal order into the code class”: swap baseline position 0 with position  $b^{-1}(x)$ , so that the enumeration starts with  $x$ . Its Proposition 11.6 (“Class-order universality, with the coding boundary explicit”) is [propositions 5.13](#) and [19.20](#), with the remark that “the recursion here is set-valued ... It is not an ETR assertion producing a new proper class at every stage”; “This is an order-theoretic universality statement, not a claim that  $\mathcal{P}_{\text{bd}}(b)$  exhausts all global well-orders.” Its Theorem 11.7 (“Diagonal obstruction”): *no uniformly Ord-indexed family of class bijections  $\text{Ord} \rightarrow \mathbf{No}$  contains every such bijection; consequently, in GBC, no ordinary class of set codes with a uniform evaluation relation codes all set-like global surreal well-orders*, which is [theorem 19.37](#), by the same pair swap; “The conclusion is not an inconsistency in global well-orders. It is a limitation on a proposed uniform coding at the wrong logical level.”

*Note 71.11* (Source 26, Theorem 12.1, “Small-net rigidity”). *In GBC, every uniformly set-indexed prefix-Cauchy net of class Ord-words is eventually constant as a family of class functions.* This is source 24’s [theorem 71.2](#), by the same Class Replacement bound on the set of first disagreements. Source 26 observes that stating the scheme needs no “topology whose points are classes ... as a third-sort object”.

Class-indexed approximation is different. Given a class injection  $h : \text{Ord} \rightarrow \mathbf{No}$ , for every ordinal  $\alpha$  apply [note 71.10](#) to  $h \upharpoonright \alpha$  and choose a support-code extension uniformly. This Ord-indexed family stabilizes to  $h$  on each set prefix. The limit can fail to be exhaustive. For example, relative to a baseline, shift the finite ordinal positions by one and leave positions at least  $\omega$  fixed; the resulting injection omits exactly the first baseline label.

If forward and inverse prefixes both stabilize for a uniformly coded family of bijections, their

unions are mutually inverse. Indeed, when a stabilized forward value is  $h(\xi) = x$ , take a common sufficiently late stage at which that coordinate and the inverse coordinate  $x$  have stabilized. The bijection at that stage witnesses  $g(x) = \xi$ . The converse is the same. This is a reconstruction scheme for admitted class graphs, not the creation of a completed class whose elements are all class graphs.

### 71.3.2 A fixed class relation versus an enlarged class part

A model of class theory is written  $(M, \mathcal{X})$ , where  $M$  supplies the sets and  $\mathcal{X}$  the admitted classes. The class part need not consist of every externally available subset of  $M$ . A definition using an external collection of all subsets can therefore change the meaning of a supposed internal theorem.

There is, however, an important preservation fact for an *old fixed relation*. In GBC, internal well-foundedness of a fixed strict class relation is equivalent to the absence of a set-coded descending  $\omega$ -sequence. One direction is immediate from the range of such a sequence. Conversely, from a nonempty class with no minimal element, global choice selects a predecessor at each point, and recursion on  $\omega$  followed by Class Replacement yields a descending sequence that is a set.

Consequently, when  $(M, \mathcal{X})$  and  $(M, \mathcal{Y})$  both satisfy the relevant GBC assumptions, have the same sets, and an old relation  $R$  belongs to both class parts, enlarging the class part does not change whether that old relation is internally well-founded. What can change is *which relations exist*, which uniform families and cuts are admitted, and which prospective limits are available. The repository's reviewed scope correction makes this distinction explicit (this report's README, review notes). External well-foundedness of a nonstandard model is a different question: an external descending sequence need not be a sequence coded in  $M$ .

### 71.3.3 Higher universes are a legitimate alternative, not a size eraser

A universe-relative treatment can fix a strongly inaccessible  $\Theta$  and view

$$(V_\Theta, \mathcal{P}(V_\Theta))$$

from an ambient universe. Its internally proper classes are externally sets. The internal surreal sign carrier is represented externally by signs of length below  $\Theta$ , and global relations become external relations on that set. It is then legitimate to take an external set of those relations. What is illegitimate is to move that set back down and call it an internal class whose members are internal proper classes.

In type theory, the analogous safeguard is explicit universe levels. A carrier for ordinal-length signs lives above the universe of its ordinal lengths, while every fixed birthday-bounded fragment can be small in that lower universe. A type of all predicates on the carrier lives at a higher level again. These level changes can formalize the objects without paradox, but they alter which families count as small and which cut-filling theorem is applicable.

A singular birthday fragment such as  $\mathbf{No}_{<\beth_\omega}$  is a perfectly sound set-level alphabet. It is not a replacement for the inaccessible model just described. Regularity, replacement closure, power sets, and externally full class parts must be checked for a proposed model rather than inferred from an evocative notation.

### 71.3.4 Where stronger recursion principles actually enter

The direct common-prefix comparison in [note 71.10](#) does not need elementary transfinite recursion. Ordinary set-valued recursion used to select one surreal at each stage is also distinct from a recursion that constructs an entire new class at each stage. The latter is the setting in which ETR becomes

a substantive additional principle. Gitman and Hamkins identify its strength over GBC through clopen class-game determinacy [22].

A formal development should therefore state the exact recursion rule and the sort of its values. Invoking KM for every global argument overstates some dependencies; treating arbitrary class-valued recursion as an automatic consequence of elementary comprehension understates others. The present manuscript confines itself to elementary comparison, set-valued recursive constructions, and explicitly uniform family schemes. No theorem here assumes that all higher-order cuts can be filled.

## 71.4 Source 28's global sections

[merge] Source 28's Sections 11 and 12 re-prove the global layer; their one new point is printed whole: every set of ordinal coordinates is bounded, so the singular obstruction of sections 69 and 70 has no global counterpart.

### 71.4.1 The virtual enumeration domain

Work in GBC, and fix a class bijection  $b : \text{Ord} \rightarrow \mathbf{No}$ . Such a baseline can be obtained by globally choosing well-orderings of the set-sized birthday levels and listing the new surreals level by level. Every proper initial part of this listing is a set. The merged repository report analyzes the precise equivalence with Global Choice over its stated weak base theory (theorem 13.1); the arguments here assume the baseline rather than silently selecting one in bare GB.

Let  $\mathfrak{W}_{\text{sl}}$  mean the virtual domain of all class bijections  $f : \text{Ord} \rightarrow \mathbf{No}$ . It is notation for the objects over which class variables range under a stated predicate, not a declaration that those proper classes are members of an ordinary class. For two specified distinct class words, the first disagreement exists: choose one ordinal witness, and find the least witness inside the set of ordinals at most that one. Their numerical lexicographic comparison is therefore an elementary class-theoretic assertion.

A uniformly indexed family is represented by a single relation

$$F(i, \xi, x),$$

whose  $i$ th section is the graph of the relevant word. Quantifying over the set or class index  $i$  does not turn each section into a set. This representation is sufficient for the global prefix and continuity arguments below.

### 71.4.2 Every set of ordinal coordinates is bounded

**Proposition 71.12** (Why the global case has no singular-coordinate obstruction). *For every specified class permutation  $s : \text{Ord} \rightarrow \text{Ord}$ , both  $s$  and  $s^{-1}$  send bounded sets of ordinals to bounded sets. Forward and two-sided set-prefix neighborhood predicates agree at each specified global enumeration. Left and right translations and inversion satisfy the corresponding continuity formulas.*

*Proof.* A bounded collection of ordinals is a set. By Class Replacement, its image and inverse image under a specified class permutation are sets of ordinals. Every such set has an ordinal bound. The proofs of Theorem 70.2 now apply to each allowed control set, with set-sized images and inverse images. In particular, to enforce inverse agreement on  $b[\alpha]$  at  $f$ , it suffices to enforce forward agreement below an ordinal bounding the set  $f^{-1}[b[\alpha]]$ .  $\square$

This is a statement about formulas and specified class parameters, not an ordinary topology carried by a class whose elements are all the global enumerations. The analogy with regular cardinals is exact at the relevant quantifier: every *set* of ordinal coordinates is bounded. At singular  $\mu$ , a subset of cardinality less than  $\mu$  may instead be unbounded in  $\mu$ .

*Note 71.13* (Source 28, Lemma 11.2, Proposition 11.3, Theorem 11.4, Proposition 11.5, Lemma 12.1 and Theorem 12.2). Source 28’s Lemma 11.2 (“Global prefix extension by a set-supported code”) is [lemma 19.4](#) and source 24’s [note 71.1](#); its Proposition 11.3 (“Universality for ordinary class carriers”; “every set ordinal and every ordinary class linear order, including class well-orders such as  $\text{Ord} + 1$  and  $\text{Ord} + \text{Ord}$ , is included”) is [propositions 5.13](#) and [19.20](#); its Theorem 11.4 (“The diagonal obstruction, explicitly typed”:  $g_C = b \circ s_C$  with  $s_C$  exchanging the two members of pair  $i$  exactly when  $i \in C$ , decoded by one elementary formula  $D$ , and the diagonal class  $C_* = \{i : \neg D(i, i)\}$ ; “No truth predicate for arbitrary formulas is used”) is [theorem 19.37](#); its Proposition 11.5 (“Set-indexed prefix-Cauchy nets are eventually constant”) is source 24’s [theorem 71.2](#), its third proof in the batch; its Lemma 12.1 and Theorem 12.2 (“Direct lexicography beyond set-like orders”) are [theorem 14.2](#) and [theorem 14.7](#). Source 28 adds that a dense core of set codes “must not be confused with an exhaustive parametrization of the whole virtual domain”; that the coherent-branch approximations are “the appropriate global analogues of forward completion; they do not require a class containing all Cauchy filters” on  $\mathfrak{W}_{\text{sl}}$ ; that a supplied class-indexed net stabilizing forward prefixes and inverse restrictions to  $b[\alpha]$  reconstructs mutually inverse class maps by the two-coordinate argument of [theorem 70.27](#), with no “general recursion with previously constructed proper classes as values”; and, of unrestricted orders, that “an order with type  $\text{Ord} + 1$  cannot be exhaustively represented by an order-preserving list with domain  $\text{Ord}$ ”, that two orders sharing a common initial segment with complement  $\{a, b\}$  are adjacent, that relation coding gives a different order already on two labels, and that “numerical lexicography is not compatible with merely quotienting presentations by their unlabelled order types”.

## 71.5 Foundations, models and paradox avoidance (source 28)

[merge] Source 28’s Section 13, printed whole; it states for the group results what sources 24 and 26 state above for theirs.

### 71.5.1 Set approximations are ordinary mathematics

For a fixed set alphabet  $X$ , well-order relations lie in  $\mathcal{P}(X \times X)$ , and the spaces  $\text{Bij}(\mu, X)$  and  $\text{Inj}(\mu, X)$  are sets. Their topologies, filters, completions, and permutation subgroups are standard set-sized objects. This is the cleanest setting for formalizing the new theorems. A birthday cutoff specifies both the carrier and the relevant cardinal parameters explicitly.

One should not replace  $\mu = 2^{<\kappa}$  by  $\kappa$  merely because  $\kappa$  is the birthday bound. One should also distinguish subsets of size less than  $\mu$  from subsets belonging to a particular inner model. The first is a cardinal condition in the ambient set theory; the second is a membership condition relative to a foundational model.

### 71.5.2 Two-sorted class theory

In a model  $(M, \mathcal{X})$  of class theory, the sets are the elements of  $M$  and the available classes are the elements of the external collection  $\mathcal{X}$ . Internally, a class is a predicate on sets, not an element that can be inserted into an ordinary set or class. A formula may assert that a class variable is a bijection  $\text{Ord}^M \rightarrow \mathbf{No}^M$ , and may compare two such variables. It may not silently collect every one of those class variables into another ordinary class.

Global Choice supplies useful baseline listings and uniform choices of set-coded extensions. It is not a license for an exhaustive class list of all class bijections: [Note 71.13](#) rules that out. Stronger comprehension in KM still does not erase the type distinction between sets and classes.

Elementary comprehension is enough for the common-prefix definition, the diagonal construction, and the eventual-value reconstruction of a supplied stabilized net. General recursions in which earlier values are themselves proper classes require separate analysis. Gitman and Hamkins [22] distinguish elementary transfinite recursion over well-founded class relations from the strength of GBC and relate it to clopen class-game determinacy. We do not use that stronger recursion principle in the proofs just listed.

### 71.5.3 Larger universes and full external collections

There is a second rigorous approach: place the smaller theory inside a larger set universe. Conditionally, let  $\Theta$  be strongly inaccessible and take  $M = V_\Theta$ , with the full external collection of subclasses of  $M$ . The objects called proper classes inside  $M$  are sets externally. One may then form, externally, the set of all internal class enumerations and put an ordinary topology on it.

This is a relative model construction with a stated additional hypothesis, not a proof in bare ZFC that such an inaccessible exists. The external indexing ordinal is  $\Theta$ , and the surreals built from sign sequences of length less than  $\Theta$  form an external set of size  $\Theta$ . Since  $\Theta$  is regular, the singular-coordinate obstruction disappears for external subsets of size less than  $\Theta$ . But a general external subset of size  $\Theta$  is not an internal set-sized control object, so no claim about arbitrary external cuts follows from internal set-cut interpolation.

A Grothendieck-universe or dependent-type-theoretic presentation makes the same size distinction syntactic: words small in one universe form a type in a larger universe. The larger type is not automatically all-surreal mathematics at the same universe level.

### 71.5.4 Changing the available classes

If  $(M, \mathcal{X}) \subseteq (M, \mathcal{Y})$  have the same sets but more available classes in  $\mathcal{Y}$ , two old ordinal-class words retain their first-disagreement comparison. Their graphs and numerical labels have not changed. New class words can nevertheless appear, along with new approximation systems and new uniform families. An old proof that a class relation is a well-order must also be assessed relative to the intended available subclasses; internal and unrestricted external well-foundedness are not interchangeable.

In an externally countable model, an external countable sequence may be cofinal in  $\text{Ord}^M$ , despite the absence of such an internal set sequence. Thus the small-net rigidity theorem does not prohibit external approximations indexed by a set that is not an internal set of indices with the required internal uniform coding. Its quantifiers were internal and explicit.

### 71.5.5 Definable orders and syntactic codes

One can restrict to class orders defined by specified formulas with set parameters, but “all definable classes” is not automatically an internally evaluable class-coded family. A uniform evaluator for arbitrary definitions would require an appropriate satisfaction predicate. A safer construction fixes a single formula  $\varphi(i, \xi, x)$  and varies the set parameter  $i$ , or works externally with formula codes and an explicitly provided satisfaction relation. The diagonal obstruction applies to any genuinely uniform exhaustive family once the required evaluations are available.

The same caution applies to definability claims motivated by the Kanovei–Shelah construction [16]. Their published index set consists of functions from the continuum cardinal to  $\mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters, ordered lexicographically. These functions need not be injective. That construction motivates definable lexicographic indexing, but it is not literally the order of all well-order relations on the reals or on the surreals.

### 71.5.6 A short paradox checklist

Before using an assertion about “all” surreal well-orders, specify the carrier, its size level, whether labels are retained, the permitted enumeration domains, and the comparison rule. For a completion argument, specify the topology or uniformity and the index size of the approximation. For a class construction, identify one uniform relation representing any claimed family, and say whether the statement is internal or external. For a recursion, identify the type of its values and the size of its previous history.

The apparent paradoxes arise when one of these specifications is suppressed. In particular, a class can contain codes for some class functions without containing every class function as an element; realizing every set cut does not mean realizing every class cut; and a universe-polymorphic construction does not collapse all its universe levels into one.

## 72 What this Part answers

[merge] Dated notes, 3 October 2026. Each item names the question, where it is asked, and the result that answers it. Where the question index of [section 113](#) or the status notes of Part VI ([section 33](#)) say otherwise, these notes supersede them; questions of the batch-81 and batch-83 sources are named by their numbers in those sources.

- (a) *Source 12’s question on all fixed enumeration types* ([research question 113.11](#)), *source 08’s question 4*, and *Part VI’s open boundary* ([section 31.3](#); [section 33](#), item (e)): the embedded binary cubes are determined for every fixed type,  $\mathbb{B}_\theta \hookrightarrow \mathcal{W}_\alpha(\mathbf{No}_{<\kappa})$  iff  $\theta \leq \varrho_{\text{lo}} + \lfloor \log_2(n!) \rfloor$  ([theorem 64.11](#)); the equimorphism type and the binary coding length are determined whenever the two computed weights agree, in particular when every residual cardinal is regular, singular strong limit or above  $\kappa$  ([theorem 64.7](#) and [corollary 64.13](#)), hence for every type when  $\mu \leq \aleph_\omega$  ([corollary 64.8](#)), at every cutoff  $\kappa < \aleph_\omega$  in ZFC ([corollary 64.20](#)) and for every type under GCH ([note 64.18](#)). **Open:** the least coding length when a singular non-strong-limit residual cardinal at most  $\kappa$  makes  $\varrho_{\text{lo}} < \varrho_{\text{up}}$ ; source 19 asks it as its Question 14.1 (“The remaining coding gap”), and sources 29 and 30 ask it again (their Questions 13.1 and 12.1). The same results answer the fixed-type questions of sources 15–18 ([research questions 113.46](#), [113.58](#), [113.69](#) and [113.83](#)) in the same extent.
- (b) *Source 12’s question on the order topology, isomorphism invariants and degrees of homogeneity of the minimal slice* ([research question 113.13](#); Part VI left the isomorphism type and homogeneity open, [section 33](#), item (b)): answered further. The topology is determined at every regular  $\mu = 2^{<\kappa}$ , as the bounded-topology space  $(\mu^{<\mu})^\mu$  ([corollary 66.3](#)); the minimal surreal slice is metrizable exactly when  $\text{cf } \mu = \omega$  and completely metrizable exactly when  $\kappa = \omega$  ([theorem 69.27](#)); at  $\kappa = \omega$  it is homeomorphic to Baire space, has completion  $\mathbb{R}$  with continuum many omitted points in every interval, is not isomorphic to the irrationals ([note 67.1](#)), is strongly finitely homogeneous with  $2^{\aleph_0}$  automorphisms, and its proper prefix cylinders are not definable in the pure order ([theorem 67.8](#) and [corollary 67.9](#)). The weights and all point characters of the finite-tail and  $\mu + \omega$  strata of every thick alphabet are determined ([theorems 63.4](#), [63.9](#) and [63.15](#)). **Open:** the order type of the minimal slice at uncountable  $\kappa$ , and its topology at singular  $\mu$  (source 24’s question “A singular replacement for the exhaustion tree”). Source 15’s question on the finer topology of bounded slices ([research question 113.52](#)) is answered in the same extent for local bases and the cardinal invariants; source 18’s question on the arrangement of gaps ([research question 113.82](#)) in part, by the normal forms of the completion with its realized points ([theorem 65.11](#)); source 17’s question on isomorphism after

- the invariant calculation (research question 113.71) is not settled, but at  $\kappa = \omega$  the placement of the omitted cuts is an invariant beyond the topology (corollary 67.5 and theorem 67.10).
- (c) *Part VI's disclaimer after the fusion theorem* (“The theorem does not claim a complete metrizability”, after theorem 30.5) and *source 17's question “Beyond the proved fusion length”* (research question 113.72: “When  $q = \omega$ , determine complete metrizability and more precise descriptive topological properties”): answered for the minimal slices. When  $q = \omega$  the slice is completely metrizable exactly when  $\mu = \omega$ ; at uncountable  $\mu$  of countable cofinality it is not Borel in its injection completion, no nonempty open subspace is completely metrizable, and for  $\mu > \mathfrak{c}$  every zero-dimensional separable metrizable space is a closed subspace (theorems 69.17 and 69.18 and corollary 69.21). The least size of a family of dense open sets with nondense intersection remains open (source 24's and source 26's questions “Dense-open intersection thresholds”).
  - (d) *Source 24's Question 13.1* (complete metrizability at uncountable countable cofinality) and *source 28's Question 1*: **answered** negatively in ZFC (notes 69.7 and 70.13). Source 28's Question 3 (descriptive complexity of the one-sided loci): in part (theorem 69.23 and proposition 69.24).
  - (e) *Source 24's question “The boundedness-preserving subgroup”* (its closure properties, normalizers, topological-group structures on larger natural subgroups, and recovery of the bounded-set ideal): answered in the natural permutation action by source 28:  $H_\mu$  is the largest subgroup containing the finitary permutations on which the prefix topology is a group topology (theorem 70.4), it is self-normalizing at singular  $\mu$  (theorem 70.6), its forward closure is  $H_\mu^+$ , nowhere dense at singular  $\mu$  (theorem 70.10), and the bounded ideal is recovered from the group with its action (proposition 70.8). Source 24's question “Uniformities with an exhaustion interpretation”: in part (theorems 70.18 and 70.27). Abstract automorphisms of  $H_\mu$  remain open (source 28's question “Abstract automorphisms versus the natural normalizer”).
  - (f) *Source 22's Question 12.4* (“Descriptive topology when cofinalities are countable”): answered for the minimal lengths (theorem 69.18) and for the countable lengths  $\omega + n$ : metrizable exactly when  $n \leq 1$ , completely metrizable exactly when  $n = 0$ , the split space at  $\omega + 2$  separable, first countable, meagre and not metrizable (theorems 68.8 and 68.9). Its Question 12.2 (when are  $Q_n(X)$  and  $Q_m(X)$  isomorphic) remains open at  $\mu = \omega$ , where  $Q_n(D) = E_n$ ; the orders  $P_{\omega+n}$  themselves are pairwise nonisomorphic (corollary 68.7).
  - (g) *The reals report's question “Other ground orders”* (lwo:sec:research; section 33, item (g)): answered further. For  $X = \mathbf{No}_{<\kappa}$  and  $\alpha = \lambda + n$  with  $\lambda$  a limit, outside the open case of item (a) the display  $\mathcal{W}_{\lambda+n}(X) \simeq_e \mathbb{B}_\lambda \times_{\text{lex}} n!$  holds exactly when the weighted length  $\varrho_{\text{lo}}$  equals  $\lambda$  (theorem 64.7 and note 64.12); the weight of every finite-tail stratum  $\mathcal{W}_{\mu+n}(X)$  is determined for every infinite alphabet (corollary 63.12). The gap spectrum of the full order  $\mathcal{W}(X)$  stays open.

Sources 24, 26 and 28 present their singular theorems as answers to questions of the sources they read; items (c)–(e) record which. Source 22 says its table is “now treated as proved”; for density and cellularity that was source 16's result (note 63.5).

## Part XI

# Across birthday cutoffs: restrictions, coherent limits and birthday spectra

[merge] (3 October 2026.) This Part belongs to the batch-83 addition of twelve further manuscripts, sources 19–30; its notation is that of [sections 1.3](#) and [1.3.1](#) with the batch-83 addendum ([section 1.3.2](#)), and the conventions fixed below. The set-sized Parts (I, VI and X) hold the birthday cutoff fixed. This Part prints what sources 19, 20, 21 and 29 prove about *changing* the cutoff: how the enumeration orders at two cutoffs are related by maps, how the orders at all cutoffs fit together into class well-orders of **No**, and what the cutoff itself, initial cardinal or not, leaves visible in the alphabet and in its enumeration strata.

- Restriction to a smaller carrier is order preserving for the native order in exactly three degenerate cases (source 19, [section 73](#)).
- Restriction-coherent profiles along all ordinal cutoffs are exactly the class well-orders of **No**; two labels decide every later local comparison, so eventual local comparison is the native order on the inverse limit; local ranks and a club of strong-limit cutoffs detect set-likeness; and the append-tail maps form a coherent direct system whose limit is the bounded-support core (source 20, [section 74](#)).
- Within one cardinality band, a single baseline gives exactly composing fixed-slot embeddings of the minimal slices (source 21, [section 75](#)).
- The binary cube  $\mathbb{B}_\beta$  embeds in  $\mathbf{No}_{<\theta}$  exactly when  $\beta < \theta$ , so the birthday alphabets are strictly ordered by embeddability even where their cardinality is constant (source 29, [section 76](#)).
- At a cutoff  $\theta$  that is not an initial cardinal, the minimal slice has exact cardinal invariants, coding rank  $\mu = 2^{|\theta|}$ , global cofinality  $\text{cf } \lambda$  ( $\theta = \lambda + n$ ), and is not isomorphic to any interval or ray of itself (source 21, [section 77](#)); every enumeration length at such a cutoff has a coding sandwich, an exact cube spectrum and an exact birthday threshold, and on the countable band all lengths are classified up to equimorphism without CH (source 29, [section 78](#)).

[Section 79](#) records which questions the Part answers.

The four sources' sections printed here are complementary, so there is no base to choose; one clause is proved twice, the coding rank  $\mu$  of the minimal slice at a noninitial cutoff (source 21's [theorem 77.4](#), and source 29's [corollary 78.9](#) at  $\alpha = \mu$ ), by different arguments, and both are printed as parts of larger theorems. Sources 19 and 20 (pin d5bd4a67b) and source 21 (pin 109aaca15) were written independently of one another and before Parts VI–VIII were written; source 29 (pin 7ff7736ec) read the delivered manuscripts of sources 19, 21 and 20 (its “earlier residual analysis”, “earlier structure” and “earlier limits” manuscripts) and credits them. Where source 29's Section 5 re-proves source 19's residual-tail lemmas for initial cardinal cutoffs, printed in Part X ([section 64](#)), the shared statements are recorded in notes and only the noninitial statements are printed in full; its Corollary 4.2 is recorded as a note to Parts I and VI. Source 19's restriction theorem refines source 15's three-label theorem of Part VII ([theorem 38.5](#)); source 20's eventual comparison explains why that obstruction does not prevent a native order on the inverse limit.

**Conventions of this Part.** [merge] All sums and products of ordinals are ordinal operations. For every ordinal  $\alpha$ ,  $\mathbf{No}_{<\alpha} = \{x \in \mathbf{No} : \text{bd}(x) < \alpha\}$ ; source 20's  $X_\alpha$  and source 29's  $X_\theta$  are printed this way. When the cutoff is an infinite initial cardinal it is written  $\kappa$  and  $\mu = 2^{<\kappa}$ , as in Parts VI–X.

When the cutoff is an infinite ordinal  $\theta$  that is *not* an initial cardinal (sources 21 and 29), both sources put  $\kappa = |\theta|$  and  $\mu = |\mathbf{No}_{<\theta}| = 2^\kappa$ , and this Part keeps their letters in those sections. *False reading:* there,  $\kappa < \theta$  is not the cutoff, and  $\mu = 2^\kappa$ , not  $2^{<\kappa}$ . In this Part  $\theta$  is a cutoff ordinal, never the regular cardinal that [section 1.3.1](#) writes  $\theta$  for source 18. Renamed symbols: source 19's restriction map  $r_Y$  and source 20's  $\rho_{\beta\alpha}$  are printed  $\pi_Y$ ,  $\pi_{\beta\alpha}$  (since  $r = \text{cf } \kappa$  and  $\rho_\kappa$  is source 15's minimal-slice coding rank); source 20's local ranks  $r_\alpha(x)$  are printed  $\text{lr}_\alpha(x)$ ; source 20's class  $A_R$  of minimum-type cutoffs is printed  $\text{Min}_R$  (source 16 writes  $A_R$  for the largest set final segment, [corollary 52.7](#)); source 20's core  $\mathcal{C}_b$  is printed  $\mathcal{P}_{\text{bd}}(b)$ , since its codes are normalized permutations of an ordinal ([section 1.3](#)); source 21's  $d$ ,  $c$  and  $\text{br}$  are printed  $\text{d}$ ,  $\text{cell}$  and  $\ell_2$  (its “least ordinal length of a fixed-length binary lexicographic cube into which the order embeds” is exactly  $\ell_2$ ); source 29's  $D_{\rho,m}$  and  $\otimes_{\text{lex}}$  are printed  $\mathbb{B}_\rho \times_{\text{lex}} m$  and  $\times_{\text{lex}}$ , its  $\ell_2$  is  $\ell_2$ , its termination symbol  $\dagger$  is **end** (Conway sign order  $- < \text{end} < +$ ), its layer weights  $r(\lambda)$ ,  $u_\kappa(\lambda)$  are printed  $\text{wt}(\lambda)$ ,  $\text{wt}_\kappa^+(\lambda)$ , and its weighted lengths  $R$ ,  $U$  are printed  $\varrho_{\text{lo}}$ ,  $\varrho_{\text{up}}$  (the letters  $r$ ,  $R$  are taken by  $\text{cf } \kappa$  and by raw well-orders). Displayed equations keep their source numbers as (SNN.*n*). Labels: **swo:rs:** (19), **swo:lm:** (20), **swo:fu:** (21, keeping its internal **bs:**), **swo:bw:** (29, keeping its internal **bs:** and **ns:**); text written for this Part has labels **swo:xi:**.

### 73 Exactly when restriction preserves the native order (source 19)

[merge] Source 19's Section 6, printed whole. Its restriction map  $r_Y$  is printed  $\pi_Y$ . “The earlier manuscripts” of its first sentence are, at this point of the report, source 15's three-label theorem ([theorem 38.5](#)) and the reversal  $021 < 102$ ,  $21 > 12$  printed with it in Part VII; source 19 cites sources 15, 16 and 18 as unrefereed prior manuscripts, which are now sources of this report. The two theorems are consistent: source 15's concerns all three two-label restrictions of a three-label carrier at once, under any choice of order on each target, while [theorem 73.1](#) concerns one specified restriction between native orders, and its exceptional case  $\{a < z < b\} \rightarrow \{a, b\}$  is the one restriction of source 15's carrier that is monotone.

The earlier manuscripts exhibit reversals under carrier restriction and show that no linearization can make all two-label restrictions monotone. There is also an exact answer for one specified restriction with the native numerical lexicographic orders on its source and target.

**Theorem 73.1** (Classification of monotone restrictions). *Let  $(X, <)$  be a linearly ordered set and  $Y \subseteq X$ . Compare the well-orders of each fixed labelled carrier by their ordinal enumerations, using the inherited label order at the first disagreement. The map*

$$\pi_Y : \mathcal{W}(X) \longrightarrow \mathcal{W}(Y), \quad R \longmapsto R \upharpoonright Y,$$

*is nondecreasing if and only if one of the following holds:*

1.  $|Y| \leq 1$ ;
2.  $Y = X$ ;
3.  $X = \{a < z < b\}$  and  $Y = \{a, b\}$ .

*For an infinite carrier  $X$  of cardinality  $\mu$ , every proper restriction retaining at least two labels already has a reversal on the minimal slice  $\mathcal{W}_\mu(X)$ .*

*Proof.* Each finite word displayed below is followed by the same fixed well-order of the unused labels. Both relevant comparisons are decided inside the displayed words.

Suppose  $a < b$  belong to  $Y$  and  $z \notin Y$ . If  $z < a$ , use

$$R = (z, b, a), \quad S = (a, b, z).$$

Then  $R < S$ , while their restrictions start with  $(b, a)$  and  $(a, b)$ , respectively, so  $\pi_Y(R) > \pi_Y(S)$ . If  $b < z$ , the pair

$$R = (b, a, z), \quad S = (z, a, b)$$

has exactly the same property. Therefore monotonicity requires every omitted label to lie between every pair of retained labels.

If  $Y$  contains  $a_0 < a_1 < a_2$ , any omitted  $z$  violates this requirement. For  $z < a_1$ , use the pair  $a_1 < a_2$ ; for  $a_1 < z$ , use the pair  $a_0 < a_1$ . These alternatives are exhaustive because  $z$  is omitted. Consequently, a proper monotone restriction retaining at least two labels must have  $Y = \{a, b\}$ , with every omitted label in  $(a, b)$ .

If two labels  $u < v$  are omitted, then  $a < u < v < b$ . The four-label pair

$$R = (u, b, a, v), \quad S = (v, a, b, u)$$

satisfies  $R < S$  because  $u < v$ , whereas the restrictions again begin  $(b, a)$  and  $(a, b)$ . There can therefore be only one omitted label, and the only remaining proper case is  $X = \{a < z < b\}$ .

For this exceptional case the six enumerations, in increasing lexicographic order, are

$$(a, z, b), (a, b, z), (z, a, b), (z, b, a), (b, a, z), (b, z, a).$$

The first three restrict to  $(a, b)$  and the last three to  $(b, a)$ , so restriction is nondecreasing. The singleton and identity cases are immediate.

Finally, if  $X$  is infinite, choose the common unused tail to have type  $\mu$ . Every displayed finite prefix followed by this tail has type  $n + \mu = \mu$ . Thus all reversals occur already in  $\mathcal{W}_\mu(X)$ .  $\square$

The same finite gadgets work for a supplied proper-class carrier in GBC: append a fixed set-like enumeration of the unused labels. They produce set-like global witnesses. In that setting the statement is interpreted as a theorem about supplied classes and explicit witnesses, not as the assertion that all class well-orders form an ordinary class of objects.

This sharpens the obstruction to a backwards system of birthday cutoffs. Whenever  $\mathbf{No}_{<\kappa} \subsetneq \mathbf{No}_{<\lambda}$  are infinite, unrestricted carrier restriction fails to be monotone, even on the minimal source slice. Forward extension maps, or specially constrained families of enumerations, must supply any coherent order-preserving system.

*Remark 73.2* (Finite verification). The accompanying script `check_restrictions.py` checks every subset of each carrier of size  $0 \leq n \leq 7$  and every adjacent pair in the lexicographic list of its permutations. It checks 695,228 adjacent comparisons. All cases agree with [theorem 73.1](#); the respective numbers of monotone subsets are 1, 2, 4, 6, 6, 7, 8, 9. The JSON report records the counts and sample reversals. This finite regression check does not replace the proof for arbitrary carriers.

[merge] The script ships as `code/19-residual-check_restrictions.py` and its recorded output as `data/19-residual-restriction_checks.json`. The counts 1, 2, 4, 6, 6, 7, 8, 9 are those of  $n = 0, 1, \dots, 7$  and agree with the theorem: for  $n \geq 4$  the monotone subsets are the empty set, the  $n$  singletons and  $X$  itself, and for  $n = 3$  the extra subset  $\{a, b\}$  is added.

[merge] The “forward extension maps” of the last paragraph are what the next two sections construct: source 20’s append-tail maps ([theorem 74.8](#)) and source 21’s fixed-slot insertions ([theorem 75.1](#)). Source 20’s [theorem 74.3](#) shows that the reversals of [theorem 73.1](#) disappear in the limit: for a fixed pair of well-orders, every sufficiently large restriction compares them as the originals are compared. Source 19 also records the restriction theorem as an attractive first formalization target and states that it “does not forbid carefully designed enlargement embeddings” (its results ledger).

## 74 Birthday limits: gluing, stabilization, and two different completions (source 20)

[merge] Source 20’s Section 4, printed whole. It is the only source of the batch to treat all ordinal cutoffs at once. Renamed:  $X_\alpha$  is printed  $\mathbf{No}_{<\alpha}$ ; the restriction maps  $\rho_{\beta\alpha}$  are printed  $\pi_{\beta\alpha}$ ; the local ranks  $r_\alpha(x)$  are printed  $\text{lr}_\alpha(x)$ ; the class  $A_R$  of minimum-type cutoffs is printed  $\text{Min}_R$ ; the core  $\mathcal{C}_b$  is printed  $\mathcal{P}_{\text{bd}}(b)$ ; and the ordinal  $r = \text{otp}(R)$  in the proof of [theorem 74.8](#) is printed  $\zeta$ . Its citations of the repository are replaced by cross-references to the results meant. Its first paragraph is accurate at this report’s head: the correction of “coherent” to “uniform” is the one recorded in [remarks 13.4](#) and [113.15](#) (3 October 2026). The nonmonotone example of its second subsection is source 15’s ([section 38](#)).

The distinction between uniformly chosen local well-orders and restriction-coherent local well-orders is mathematically consequential. The current repository explicitly corrects an earlier use of “coherent” in its global-choice argument: the recursively constructed orders on  $V_\alpha$  are uniform, but need not extend one another ([remark 13.4](#)). Here we study genuine restriction coherence and obtain an exact local-to-global description. We also show that the native lexicographic comparison is eventually recoverable from every increasing exhaustion, even though individual restriction maps need not preserve it.

Write

$$\mathbf{No}_{<\alpha} = \{x \in \mathbf{No} : \text{bd}(x) < \alpha\}.$$

These are increasing sets, their union is  $\mathbf{No}$ , and every set of surreal labels is contained in some  $\mathbf{No}_{<\alpha}$ . The last fact follows by applying Replacement to birthdays and then taking a strict ordinal upper bound. For  $\alpha \leq \beta$ , restriction gives a set map

$$\pi_{\beta\alpha} : \mathcal{W}(\mathbf{No}_{<\beta}) \longrightarrow \mathcal{W}(\mathbf{No}_{<\alpha}), \quad R \longmapsto R \upharpoonright \mathbf{No}_{<\alpha}^2.$$

A *uniform coherent profile* is one class function  $\alpha \mapsto R_\alpha$ , with set-valued entries, such that  $R_\alpha \in \mathcal{W}(\mathbf{No}_{<\alpha})$  and  $\pi_{\beta\alpha}(R_\beta) = R_\alpha$  whenever  $\alpha \leq \beta$ . This is a class of set-coded local relations, not a class containing global class relations as members.

### 74.1 Local well-foundedness reflects to the whole class

**Theorem 74.1** (Coherent birthday gluing in GB). *Every uniform coherent profile determines a unique strict class well-order  $R$  of  $\mathbf{No}$  with  $R \upharpoonright \mathbf{No}_{<\alpha}^2 = R_\alpha$  for all  $\alpha$ . Conversely, the restrictions of every supplied class well-order form such a profile. These constructions are inverse, uniformly in the supplied class parameters. Set-likeness is not required.*

*Proof.* Define  $xRy$  when  $xR_\alpha y$  at any stage containing  $x, y$ . Coherence makes this independent of the stage. Every finite collection of labels is contained in a common stage, so irreflexivity, transitivity, and linearity follow from the corresponding local properties. Elementary class comprehension supplies  $R$ .

It remains to prove that every nonempty available subclass  $A$  has a least element. Suppose otherwise and fix  $x_0 \in A$ . Given  $x_n$ , let  $\beta_n$  be the least ordinal such that

$$A \cap \mathbf{No}_{<\beta_n} \cap \{y : yRx_n\} \neq \emptyset.$$

Such an ordinal exists because  $A$  has no least element. A nonempty subclass of the ordinals has a least member, by restricting to an ordinal containing one witness. The displayed intersection is a set

by separation with class parameters. Let  $x_{n+1}$  be its unique  $R_{\beta_n}$ -least member. This is a uniquely specified set-valued recursion along  $\omega$ , available in GB; no global choice of witnesses is needed.

Class Replacement makes  $\{x_n : n < \omega\}$  a set. Its birthdays are bounded, so the entire strictly descending sequence lies in one  $\mathbf{No}_{<\gamma}$ . This contradicts the well-foundedness of  $R_\gamma$ . Uniqueness follows because every pair of labels occurs at a stage. The converse is immediate, and local restrictions are sets by separation with the supplied relation as a class parameter.  $\square$

Thus the inverse-limit notation

$$\{(R_\alpha)_{\alpha \in \text{Ord}} : \pi_{\beta\alpha}(R_\beta) = R_\alpha\} \longleftrightarrow \{R : R \text{ is a class well-order of } \mathbf{No}\} \quad (74.1a)$$

expresses a correspondence between predicates on supplied classes. It does not assert that either side is an ordinary GB class of members. In a larger universe in which the relevant classes are objects, it becomes a literal inverse-limit bijection, subject to that universe's well-foundedness interpretation.

**Proposition 74.2** (The sharp set-filtration criterion). *Work in ZFC. Let  $\lambda > 0$  and let  $(Y_\alpha)_{\alpha < \lambda}$  be an increasing ordinal-indexed family of sets with union  $Y$ . The following are equivalent:*

1. *Every countable subset of  $Y$  is contained in some  $Y_\alpha$ .*
2. *Every coherent family of well-orders on the  $Y_\alpha$  has a well-ordered union.*

*In particular, (2) holds if  $\text{cf}(\lambda) > \omega$ . If  $\text{cf}(\lambda) = \omega$  and the family is not eventually constant, there is a coherent counterexample.*

*Proof.* For (1) $\Rightarrow$ (2), an ill-founded linear union would admit a descending  $\omega$ -sequence, whose countable range would lie in one well-ordered stage.

Suppose (1) fails. Choose a countable set with no bounded stage of containment. Its stage indices give a countable cofinal sequence in  $\lambda$ . Recursively choose increasing cofinal indices  $\alpha_n$  and distinct labels  $y_n \notin Y_{\alpha_n}$ , enlarging  $\alpha_{n+1}$  so that it contains all previously chosen labels. For each fixed  $\alpha$ , only finitely many  $y_n$  belong to  $Y_\alpha$ : eventually  $\alpha_n \geq \alpha$ . Order  $\{y_n : n < \omega\}$  by  $\dots R y_2 R y_1 R y_0$ , and place it before a fixed well-order of its complement in  $Y$ . Every restriction to  $Y_\alpha$  consists of a finite initial block followed by a well-order, so it is a well-order. The union contains the descending sequence  $y_0, y_1, \dots$

If  $\text{cf}(\lambda) > \omega$ , countably many stage indices are bounded. If  $\text{cf}(\lambda) = \omega$  and no stage already equals the union, the same recursive choice of new labels produces a countable unbounded subset. This proves the final assertions.  $\square$

The familiar reverse- $\omega$  union of finite orders is therefore a real obstruction, but it does not refute birthday gluing along all ordinals. In the class theorem every set-sized witness has bounded birthdays. The proof also explains why Class Replacement matters: an arbitrary external branch through a small model's stages need not be an admissible class of a GB realization.

## 74.2 Native lexicography survives as an eventual comparison

Individual restriction maps are not monotone for native enumeration lexicography. On  $0 < 1 < 2$ ,

$$021 <_{\text{lex}} 102, \quad 21 >_{\text{lex}} 12 \quad \text{after restriction to } \{1, 2\}.$$

Nevertheless, each comparison has an unexpectedly small persistent witness.

**Theorem 74.3** (Two labels determine every sufficiently large restriction). *Let  $R, S$  be distinct well-orders of the same linearly ordered set or class of labels. There are distinct labels  $a, b$  such that every subcarrier  $Y$  containing  $a, b$  satisfies*

$$R \upharpoonright Y^2 <_{\text{lex}} S \upharpoonright Y^2 \iff a < b \iff R <_{\text{lex}} S.$$

*The assertion includes proper-class common prefixes and is provable in GB for supplied class well-orders.*

*Proof.* Let  $C$  be the largest common labelled initial segment of  $R, S$ . The elementary common-prefix construction for class well-orders provides  $C$ ; it does not compare abstract class order types (lemma 14.1 and theorem 14.7). Put

$$a = \min_R(\mathbf{No} \setminus C), \quad b = \min_S(\mathbf{No} \setminus C),$$

with the indicated carrier substituted for  $\mathbf{No}$  in the general case. These labels differ, since otherwise  $C$  could be extended by that common next label. In the restrictions to  $Y$ , the set or class  $C \cap Y$  is still an initial segment of both orders, and their orders on it agree. Their next labels are still  $a, b$ , because those labels belong to  $Y$  and were the least available labels outside  $C$ . The first unequal labels of the restrictions therefore coincide with those of the original pair. This is exactly the displayed comparison.  $\square$

The number two is optimal: restrictions to a one-element carrier cannot differ. The theorem is a persistence statement for restrictions of a fixed pair. It does not say that knowing only the orientation of one pair determines the comparison of arbitrary other orders.

**Corollary 74.4** (Native order on the coherent inverse limit). *For two coherent birthday profiles with global unions  $R, S$ ,*

$$R <_{\text{lex}} S \iff \exists \alpha \forall \beta \geq \alpha \ R_\beta <_{\text{lex}} S_\beta.$$

*For distinct profiles, the local comparisons are eventually strict and constant. Consequently eventual local comparison gives exactly the native global lexicographic order, despite the failure of monotonicity of individual bonding maps.*

*Proof.* Choose a cutoff containing the two labels from theorem 74.3. Every later cutoff has the same comparison. Equality of the global orders is equivalent to equality at every stage. Applying the same argument to the opposite strict comparison establishes the converse.  $\square$

This result is independent of the birthday filtration. Any increasing exhaustion of the carrier eventually contains the two decisive labels. Thus changing the exhaustion leaves the eventual order unchanged. There is also a stronger finiteness statement.

**Theorem 74.5** (Only finitely many changes of decisive labels). *Fix two well-orders  $R, S$  and any uniform increasing ordinal-indexed family of subcarriers. Once their restrictions are distinct, the pair of first unequal labels changes only finitely many times. In particular, the native lexicographic signs change only finitely often. There is no uniform finite bound on the number of changes, even for birthday restrictions of well-orders of  $\mathbf{No}$ .*

*Proof.* For  $Y \subseteq Z$  on which the restrictions differ, write  $(a_Y, b_Y)$  and  $(a_Z, b_Z)$  for their first unequal labels. The pair on  $Y$  is reversed:

$$a_Y R b_Y, \quad b_Y S a_Y.$$

Neither label can lie in the common labelled prefix  $C_Z$ . For if one did, initiality in the order putting the other one first would force both into  $C_Z$ , contradicting agreement there. Consequently

$$a_Z \leq_R a_Y, \quad b_Z \leq_S b_Y.$$

Each coordinate can strictly decrease only finitely many times. Otherwise, recursively taking the least later index with a strict decrease would produce a descending  $\omega$ -sequence in one of the given well-orders. In the class setting this is again a set-valued recursion with ordinal choices and Class Replacement. The union of the two finite sets of change indices is finite.

To obtain any prescribed finite sequence of strict comparison signs, choose strictly increasing positive ordinals  $\gamma_i$  and take  $a_i = -\gamma_i < b_i = \gamma_i$ , for  $0 \leq i \leq n$ . Both labels in a pair have the same birthday  $\gamma_i$ . In both global orders put these pairs before all other labels, with the pair blocks in decreasing order of  $i$ . Within the  $i$ th pair choose opposite orientations for  $R, S$ , selecting the orientation in  $R$  to give the prescribed sign. Append the same set-like birthday-respecting baseline on the remaining labels. At a cutoff containing pairs  $0, \dots, i$  and no later pair, the first unequal labels are exactly the  $i$ th pair. Both global orders are well-orders. Arbitrarily long finite alternating patterns follow.  $\square$

### 74.3 Detecting set-likeness from local ordinal ranks

For a profile and a label  $x$ , at every sufficiently large stage put

$$\text{lr}_\alpha(x) = \text{otp}(\{y \in \mathbf{No}_{<\alpha} : yR_\alpha x\}, R_\alpha).$$

These are set ordinals, even if the global predecessor class is proper. Coherence makes  $\text{lr}_\alpha(x)$  nondecreasing, because an ordered subset of an ordinal has order type at most that ordinal.

**Theorem 74.6** (Rank stabilization is exactly set-likeness). *For the global union  $R$  of a coherent profile and each label  $x$ , the following are equivalent:*

1. *the global predecessor class  $P_x = \{y : yRx\}$  is a set;*
2.  *$P_x$  is contained in a birthday cutoff;*
3. *the ordinals  $\text{lr}_\alpha(x)$  are bounded by one set ordinal;*
4.  *$\text{lr}_\alpha(x)$  is eventually constant.*

*Thus  $R$  is set-like exactly when every local rank profile eventually stabilizes. The theorem holds in GB.*

*Proof.* The first two conditions are equivalent by boundedness of birthdays and separation. If  $P_x \subseteq \mathbf{No}_{<\delta}$ , then every later local predecessor set is exactly  $P_x$ , proving (2) $\Rightarrow$ (4). Monotonicity gives (4) $\Rightarrow$ (3).

For (3) $\Rightarrow$ (1), suppose  $P_x$  is proper and all ranks are at most  $\theta$ . Using the global well-order supplied by [theorem 74.1](#), recursively select the least unused predecessor through  $\theta + 1$  stages. Each earlier range is a set and cannot exhaust  $P_x$ , so the recursion continues. It gives an increasing sequence of type  $\theta + 1$ . Its range, together with  $x$ , lies in one birthday cutoff. That local predecessor order then has type at least  $\theta + 1$ , contradicting its asserted bound  $\theta$ . Only set-valued recursion along a set ordinal was used.  $\square$

Coherence alone therefore does not impose set-likeness. For example, take a birthday-respecting set-like baseline on  $\mathbf{No} \setminus \{0\}$  and place 0 last. Its type is  $\text{Ord} + 1$ . All birthday restrictions are well-orders and cohere, but  $\text{lr}_\alpha(0)$  is unbounded. Local ordinal ranks diagnose the proper predecessor class without treating its order type as an ordinal.

#### 74.4 A club dichotomy for minimum enumeration types

For an infinite strong-limit cardinal  $\kappa$ , the birthday carrier  $\mathbf{No}_{<\kappa}$  has cardinality  $\kappa$ . Indeed every earlier stage has cardinality below  $\kappa$ , their  $\kappa$ -indexed union has cardinality at most  $\kappa$ , and the ordinal labels below  $\kappa$  give the reverse inequality. Thus  $\kappa$  is the least possible well-order type of this carrier. Define the class

$$\text{Min}_R = \{\kappa : \kappa \text{ is an infinite strong-limit cardinal and } \text{otp}(R \upharpoonright \mathbf{No}_{<\kappa}^2) = \kappa\}.$$

A class  $C \subseteq \text{Ord}$  is *club* if it is unbounded and contains every ordinal limit point of itself. A class is *stationary* if it meets every available club class. These are predicates on classes, not collections of classes regarded as ordinary members.

**Theorem 74.7** (Club reflection detects set-likeness). *In GBC, every class well-order  $R$  of  $\mathbf{No}$  satisfies exactly one of the following alternatives.*

1.  $R$  is set-like, and a club of infinite strong-limit cardinals  $\kappa$  satisfies:  $\mathbf{No}_{<\kappa}$  is an  $R$ -initial segment and has order type  $\kappa$ . In particular,  $\text{Min}_R$  contains a club.
2.  $R$  is not set-like, and there are a fixed label  $x$  and a club of infinite strong-limit cardinals  $\kappa$  such that  $x \in \mathbf{No}_{<\kappa}$  and  $\text{lr}_\kappa(x) \geq \kappa$ . Consequently  $\text{otp}(R \upharpoonright \mathbf{No}_{<\kappa}^2) > \kappa$ , and  $\text{Min}_R$  misses that club.

Hence  $R$  is set-like if and only if  $\text{Min}_R$  is stationary, equivalently if and only if  $\text{Min}_R$  contains a club. In particular, minimum type at every infinite strong-limit cutoff forces set-likeness.

*Proof.* We first record an explicit closure construction. Let  $h : \text{Ord} \rightarrow \text{Ord}$  be nondecreasing, with  $h(\alpha) > \alpha$ . The class

$$C_h = \{\kappa : \kappa \text{ is a nonzero limit ordinal and } (\forall \alpha < \kappa) h(\alpha) < \kappa\}$$

is club. For unboundedness, start above any prescribed ordinal and iterate  $\alpha_{n+1} = h(\alpha_n)$ ; its supremum belongs to  $C_h$ . Class Replacement justifies this set-sized iteration. Closure follows by bounding each fixed  $h(\alpha)$  below a member of  $C_h$  preceding the proposed limit. If each  $h(\alpha)$  is an infinite cardinal and exceeds  $2^{|\alpha|}$ , every member of  $C_h$  is a strong-limit cardinal: cardinals are cofinal below it, and its smaller power-set cardinals are bounded strictly below it.

If  $R$  is set-like, let  $f : \text{Ord} \rightarrow \mathbf{No}$  be its enumeration. Define  $h(\alpha)$  to be the least infinite cardinal strictly exceeding

$$\alpha, \quad 2^{|\alpha|}, \quad \sup_{\xi < \alpha} (\text{bd}(f(\xi)) + 1), \quad \sup_{x \in \mathbf{No}_{<\alpha}} (f^{-1}(x) + 1).$$

All the suprema concern sets by Class Replacement, and  $h$  is nondecreasing. For  $\kappa \in C_h$ , forward birthday closure gives  $f[\kappa] \subseteq \mathbf{No}_{<\kappa}$ . Conversely, each  $x \in \mathbf{No}_{<\kappa}$  already lies in some  $\mathbf{No}_{<\alpha}$  with  $\alpha < \kappa$ , so inverse closure gives  $f^{-1}(x) < \kappa$ . Thus  $f[\kappa] = \mathbf{No}_{<\kappa}$ , proving the first alternative, including initiality.

If  $R$  is not set-like, choose  $x$  with proper predecessor class  $P_x$ . Its first Ord-long segment has an increasing enumeration  $f : \text{Ord} \rightarrow P_x$ . Concretely, each set-length initial enumeration is obtained by repeatedly selecting the least unused predecessor; uniqueness makes these set-valued constructions uniform. Define  $h$  as above, omitting the inverse term and adding the fixed bound  $\text{bd}(x) + 1$ . For  $\kappa \in C_h$ , the label  $x$  and the increasing sequence  $f[\kappa]$  lie in  $\mathbf{No}_{<\kappa}$ . This sequence has type  $\kappa$  and precedes  $x$ , so  $\text{lr}_\kappa(x) \geq \kappa$ , and the whole local order has strictly larger type.

Finally, two club classes intersect in a club: alternate their least points above successive bounds and take the supremum of the resulting  $\omega$ -sequence. Closure places that supremum in both classes. This proves the stationary reformulation.  $\square$

**Unboundedly many minimum types do not suffice.** The stationary qualification is sharp. Let

$$P = \{\beth_{\beta+1} : \beta \in \text{Ord}\}, \quad Q = \mathbf{No} \setminus (P \cup \{0\}),$$

and order the carrier by  $P$ , in increasing  $\beta$ -order, followed by 0, followed by a birthday-respecting well-order of  $Q$ . This class well-order  $R$  is not set-like at 0. For any ordinal  $\alpha$ , put  $\lambda = \alpha + \omega$  and  $\kappa = \beth_\lambda$ . Then  $\kappa$  is strong-limit and  $\lambda < \kappa$ . For infinite  $\alpha$ , the ordinal  $\alpha + \omega$  is not an initial cardinal, whereas  $\beth_\lambda \geq \lambda$  is one; for finite  $\alpha$ , use  $\beth_\omega > \omega$ . The intersection  $P \cap \mathbf{No}_{<\kappa}$  has exactly type  $\lambda$ . Removing these fewer than  $\kappa$  labels and 0 leaves  $|Q \cap \mathbf{No}_{<\kappa}| = \kappa$ . Its birthday-respecting order has type  $\kappa$ : each earlier birthday segment has type below  $\kappa$ , while their union has cardinality  $\kappa$ . Consequently

$$\text{otp}(R \upharpoonright \mathbf{No}_{<\kappa}^2) = \lambda + 1 + \kappa = \kappa.$$

The cardinals  $\beth_{\alpha+\omega}$  are unbounded, so  $\text{Min}_R$  is unbounded, yet [theorem 74.7](#) supplies a club disjoint from it.

## 74.5 Coherent append-tail maps and their direct limit

Work now in GBC and choose a baseline well-order  $B$  which orders labels first by birthday and then by a chosen well-order of each birthday layer. It is set-like. Let  $b : \text{Ord} \rightarrow \mathbf{No}$  be its unique enumeration. Every  $\mathbf{No}_{<\alpha}$  is an initial segment of  $B$ ; write  $t_\alpha = \text{otp}(B \upharpoonright \mathbf{No}_{<\alpha})$ , so  $b[t_\alpha] = \mathbf{No}_{<\alpha}$ .

For  $\alpha \leq \beta$  define

$$j_{\alpha\beta}(R) = R + (B \upharpoonright (\mathbf{No}_{<\beta} \setminus \mathbf{No}_{<\alpha})).$$

The plus sign means ordered concatenation on the disjoint carriers.

**Theorem 74.8** (The direct system is precisely the bounded-support core). *The maps  $j_{\alpha\beta}$  are native lexicographic order embeddings, satisfy*

$$j_{\beta\gamma}j_{\alpha\beta} = j_{\alpha\gamma}, \quad \pi_{\beta\alpha}j_{\alpha\beta} = \text{id},$$

*and their direct limit identifies with the bounded-support core  $\mathcal{P}_{\text{bd}}(b)$ : the global enumerations which equal  $b$  at every sufficiently large ordinal. The identification is induced by*

$$J_\alpha(R) = R + (B \upharpoonright (\mathbf{No} \setminus \mathbf{No}_{<\alpha})).$$

*Proof.* The first disagreement of two well-orders on the same carrier occurs before the appended tail. Neither exhaustive enumeration can be a proper prefix of the other. Thus appending the common tail preserves and reflects comparison. Birthday compatibility of  $B$  puts  $\mathbf{No}_{<\beta} \setminus \mathbf{No}_{<\alpha}$  before  $\mathbf{No}_{<\gamma} \setminus \mathbf{No}_{<\beta}$ , proving the composition identity. The retraction identity is immediate.

Let  $\zeta = \text{otp}(R)$ , and choose an infinite initial cardinal  $\kappa > \zeta, t_\alpha$ . If  $f$  enumerates  $J_\alpha(R)$ , then on the appended tail

$$f(\zeta + \delta) = b(t_\alpha + \delta).$$

For every  $\gamma \geq \kappa$  both  $\zeta + \gamma = \gamma$  and  $t_\alpha + \gamma = \gamma$ : write  $\gamma = \kappa + \varepsilon$  and use  $\zeta + \kappa = t_\alpha + \kappa = \kappa$ . Hence  $f(\gamma) = b(\gamma)$  for every  $\gamma \geq \kappa$ . Each  $J_\alpha(R)$  therefore belongs to  $\mathcal{P}_{\text{bd}}(b)$ .

Conversely, let  $f$  equal  $b$  beyond  $\kappa$ , and let  $R_f$  be its induced order. The two bijections necessarily have  $f[\kappa] = b[\kappa]$ . Choose  $\alpha$  with  $b[\kappa] \subseteq \mathbf{No}_{<\alpha}$ , so  $t_\alpha \geq \kappa$ . Then  $f[t_\alpha] = b[t_\alpha] = \mathbf{No}_{<\alpha}$ ; on the complementary tail,  $f$  agrees with  $b$ . Consequently

$$R_f = J_\alpha(R_f \upharpoonright \mathbf{No}_{<\alpha}^2).$$

Finally, two local objects have the same global extension exactly when their images agree at a common later stage. This proves the asserted direct-limit identification.  $\square$

There is no need to make a proper equivalence class of stage codes into a member of another class. One can use the core's unique set-supported permutation codes, or choose the least stage at which a direct-limit object is represented. The direct limit is consequently an ordinary class order. The repository's core theorem identifies it with **No** under the stated choice assumptions ([corollary 19.15](#) and [note 19.16](#)).

The same stage spaces thus support two sharply different constructions:

| maps                               | limit                                          | comparison                   |
|------------------------------------|------------------------------------------------|------------------------------|
| $\pi_{\beta\alpha}$ by restriction | all supplied class well-orders                 | eventual native comparison   |
| $j_{\alpha\beta}$ by appending $B$ | $\mathcal{P}_{\text{bd}}(b) \cong \mathbf{No}$ | compatible native embeddings |

The inverse-limit side includes non-set-like orders; the direct-limit side consists of eventual perturbations of one baseline. Each local order has a direct-limit extension, so every bounded observation of a global class well-order is already realized in the core.

*Note 74.9* ([merge]; the append-tail maps and the earlier remarks on extension). The maps  $j_{\alpha\beta}$  are the operation  $R \mapsto R + Q$  with a fixed well-order  $Q$  of the new labels, which source 15 records as an order embedding in [section 38](#) (subsection on restrictions and extensions), there for one pair of carriers. New in source 20 is the coherence: one birthday-respecting baseline makes all of them compose exactly along all ordinal cutoffs, with  $\pi_{\beta\alpha}$  as a left inverse, and the direct limit is identified with the core. Naively appended tails need not preserve the minimal enumeration type ([research question 113.19](#) warns of this); here no minimality is claimed: the stage spaces are the full spaces  $\mathcal{W}(\mathbf{No}_{<\alpha})$  of all lengths. The fixed-slot construction of [theorem 75.1](#) keeps the minimal type instead, at the price of a fixed cardinality band.

## 74.6 A monotone inverse system using relation tables

There is also a literal monotone inverse system, obtained by changing the comparison. In GBC, well-order the pair layer

$$L_\gamma = \{(x, y) : \max(\text{bd}(x), \text{bd}(y)) = \gamma\}$$

for every  $\gamma$ , and concatenate these layer orders in increasing  $\gamma$ . The resulting scan  $Q$  of  $\mathbf{No}^2$  is set-like. Its restriction to  $\mathbf{No}_{<\alpha}^2$  is an initial segment of some ordinal length  $s_\alpha$ . The lengths are continuous at limit cutoffs and cofinal in Ord.

**Proposition 74.10** (Birthday table quotients). *Order each  $\mathcal{W}(\mathbf{No}_{<\alpha})$  by the characteristic table of its strict relation, scanned by  $Q \upharpoonright \mathbf{No}_{<\alpha}^2$ , with  $0 < 1$ . Every  $\pi_{\beta\alpha}$  is then a weakly order-preserving surjection with convex fibers. The append-tail maps  $j_{\alpha\beta}$  are order embeddings for these table orders as well. The coherent inverse-limit comparison is exactly global first-difference table comparison under  $Q$ .*

*Proof.* Restriction removes a final segment of the table. Prefix restriction of binary lexicographic words is weakly monotone, and all words with a fixed prefix form a convex set. Intersecting with the allowed well-order tables preserves convexity. Surjectivity follows by appending the baseline on the complementary carrier. The same argument shows that an append-tail map preserves the first differing bit of its input tables. For two global tables, their first differing pair belongs to some  $\mathbf{No}_{<\alpha}^2$ ; every later restriction has the same first differing bit. Finally, [theorem 74.1](#) identifies the compatible local well-order tables with the supplied global well-orders.  $\square$

These table orders depend on the chosen scans inside pair layers. They are a separate interpretation of lexicography. Their monotone restriction property does not imply that they agree with

native enumeration comparison. Native comparison instead has the stronger intrinsic interpretation of [theorem 74.3](#) and [corollary 74.4](#), and requires no scan of pairs.

[merge] Relation-table orders are source 15’s and source 16’s scan orders ([section 38](#), its subsection on relation tables, and [theorem 38.2](#)); [proposition 74.10](#) is the first statement about how they behave under change of cutoff. It answers in part source 15’s question “Coherent restricted filtrations” (its Question 13.9), which asks for restricted families on which restriction is monotone: a change of comparison achieves it for all well-orders at once.

## 74.7 The existence of a branch is already a choice principle

Over GB with set-level AC, each  $\mathcal{W}(\mathbf{No}_{<\alpha})$  is nonempty and every restriction map is surjective. It still takes a uniform class to provide a full coherent profile. By [theorem 74.1](#) and the repository’s equivalence between global choice and a class well-order of **No** ([theorem 13.1](#)),

$$\text{a full coherent birthday profile exists} \iff \text{Global Choice.}$$

The forward implication uses the glued well-order; the reverse implication restricts a birthday-respecting baseline. Thus nonempty set stages and surjective bonding maps do not by themselves supply a uniform class branch under the weaker stated assumptions. This pinpoints an actual foundational requirement, rather than attributing the difficulty to an informal “size paradox.”

[merge] [Theorem 13.1](#) is proved over GB without set choice, so the displayed equivalence holds over GB itself, not only over GB + AC: the forward implication uses [theorem 74.1](#) (GB), and the reverse one a class bijection  $\text{Ord} \rightarrow \mathbf{No}$ , which GC supplies over GB. Source 20’s finite diagnostics (code/20-limits-finite\_diagnostics.py, recorded run data/20-limits-finite\_diagnostics\_results.json) check [theorem 74.3](#) on every restricted carrier and the coordinatewise monotonicity in the proof of [theorem 74.5](#) on every nested pair of carriers, for all pairs of permutations of carriers of sizes two to five: 58,255 decisive-pair restriction checks and 609,862 nested-witness checks over 7,432 permutation pairs, with the nonmonotone example  $021 < 102$ ,  $21 > 12$  reproduced. In source 20’s words they are “finite operational diagnostics”; they establish no transfinite or class-theoretic statement of this section.

## 75 Coherent embeddings within a cardinality band (source 21)

[merge] Source 21’s Section 6, printed whole. Its “proposed direction in the repository” is [research question 113.19](#); the cited noncardinal theorem is [theorem 77.4](#) ([section 77](#) below) and the cited topology proposition is source 21’s [note 62.13](#), printed in Part X. Source 20’s append-tail system ([theorem 74.8](#)), written independently, is the other coherent system of this Part; the two are compared in [note 74.9](#) and [section 79](#). Displayed equation (4) of source 21 is (S21.4).

Another proposed direction in the repository is compatibility between birthday cutoffs ([research question 113.19](#)). Appending an arbitrary tail generally changes the enumeration type. Within a fixed cardinality band, one baseline on an upper alphabet gives embeddings that keep the minimal type and compose exactly.

**Theorem 75.1** (Coherent insertion into fixed slots). *Let  $(X_i)_{i \in I}$  be a set-indexed nested family of ordered subsets of an ordered set  $Y$ , with  $|X_i| = |Y| = \mu$  infinite. Fix a bijection  $b : \mu \rightarrow Y$ . There are order embeddings*

$$J_{ij} : \mathcal{W}_\mu(X_i) \hookrightarrow \mathcal{W}_\mu(X_j) \quad (X_i \subseteq X_j)$$

*such that  $J_{ii}$  is the identity and  $J_{jk} \circ J_{ij} = J_{ik}$  whenever  $X_i \subseteq X_j \subseteq X_k$ .*

Each map is a homeomorphism onto its image for the prefix topologies. Its image is closed, and is clopen when the inserted positions are bounded in  $\mu$ ; if those positions are unbounded, the image is nowhere dense. These are also assertions about the order topologies whenever the relevant prefix and order topologies coincide.

*Proof.* Put  $A_i = b^{-1}[X_i] \subseteq \mu$ . A subset of the initial ordinal  $\mu$  having cardinality  $\mu$  has order type exactly  $\mu$ : its order type is at most  $\mu$  and cannot be smaller. Let  $a_i : \mu \rightarrow A_i$  be its unique increasing enumeration. For  $X_i \subseteq X_j$ , define

$$u_{ij} = a_j^{-1} \circ a_i : \mu \longrightarrow \mu, \quad D_{ij} = \mu \setminus u_{ij}[\mu].$$

Thus  $u_{ij}$  is increasing and cofinal. Set

$$J_{ij}(f)(\eta) = \begin{cases} f(\xi), & \eta = u_{ij}(\xi), \\ b(a_j(\eta)), & \eta \in D_{ij}. \end{cases} \quad (\text{S21.4})$$

Every old label occurs once in an old slot, and every new label occurs once in its fixed baseline slot, so the result is a bijection onto  $X_j$ . If  $f, g$  first disagree at  $\xi$ , their images first disagree at  $u_{ij}(\xi)$ : earlier variable slots agree, all inserted slots are fixed, and the numerical comparison at that disagreement is unchanged. Hence  $J_{ij}$  is an order embedding.

The slot maps satisfy  $u_{jk} \circ u_{ij} = u_{ik}$ . Under either successive insertion or direct insertion, the oldest labels retain the same ambient slots in  $\mu$ , and each additional label has its value prescribed by  $b$ . This proves the required equality of functions, rather than merely an isomorphism between two choices of extension. The identity assertion is immediate.

For continuity, fix a target prefix length  $\beta < \mu$ . The source coordinates whose slots are below  $\beta$  form a proper initial segment  $\delta < \mu$ , because  $u_{ij}$  is increasing and cofinal. Agreement on that source prefix therefore implies agreement on the entire target prefix; the other entries there are fixed. Conversely, for  $\delta < \mu$ , knowledge of the target prefix of length  $u_{ij}(\delta)$  determines all source coordinates below  $\delta$ . Both directions use genuine bounds below  $\mu$ ; no regularity of  $\mu$  is required. The map and its inverse on its image are continuous for the prefix topologies.

The image consists exactly of the target permutations satisfying

$$g(\eta) = b(a_j(\eta)) \quad (\eta \in D_{ij}).$$

Indeed these fixed positions contain exactly  $X_j \setminus X_i$ , so bijectivity forces the remaining positions to enumerate  $X_i$ . A violation is witnessed by a single coordinate and hence by a prefix neighborhood; the image is closed. If  $D_{ij}$  is bounded, a sufficiently long prefix checks all its conditions, so the image is open as well.

If  $D_{ij}$  is unbounded, take any cylinder meeting the image. Beyond its prescribed prefix choose an inserted position and a distinct later position, and swap their entries. The result remains in the cylinder but violates a fixed-position condition. The image therefore has empty interior and, being closed, is nowhere dense.  $\square$

**Corollary 75.2** (A bounded surreal system). *Let  $\Theta$  be a set ordinal and let  $I$  be a set of cutoffs  $\theta \leq \Theta$  such that*

$$|\mathbf{No}_{<\theta}| = |\mathbf{No}_{<\Theta}| = \mu \quad (\theta \in I).$$

*A single baseline enumeration of  $\mathbf{No}_{<\Theta}$  gives the coherent minimal-length system of [theorem 75.1](#) for all these cutoffs.*

In particular, for a fixed infinite cardinal  $\kappa$ , every cutoff  $\kappa < \theta \leq \kappa^+$  has alphabet cardinality  $2^\kappa$ . Use the single upper alphabet  $Y = \mathbf{No}_{<\kappa^+}$ , whose cardinality is  $2^{<\kappa^+} = 2^\kappa$ . Thus the construction works throughout this entire set-sized band, including its upper endpoint. The topology statements are then statements about order topology by [theorem 77.4](#) and [note 62.13](#). The distinction between a clopen image and a nowhere dense image records the placement of the new labels in the chosen baseline; it is not determined by their numerical order alone.

The restriction to one set-sized upper alphabet and one cardinality band is substantive. The proof gives no assertion that a single baseline works simultaneously across changing minimal cardinal lengths or across all proper-class birthday cutoffs. Those compatibility questions require additional constructions and an explicit foundational level.

[merge] Here  $\kappa$  is a cardinal of the band, not a cutoff of the convention of Part VI; the cutoffs  $\theta$  of the band are noninitial except its upper endpoint  $\kappa^+$ , and at the endpoint “ $\mu$ ” is  $2^{<\kappa^+} = 2^\kappa$  in either convention. The two coherent systems of this Part are complementary. Source 20’s append-tail maps ([theorem 74.8](#)) run along all ordinal cutoffs and compose exactly, but act on the full spaces  $\mathcal{W}(\mathbf{No}_{<\alpha})$  and change the enumeration length; source 21’s fixed-slot maps keep the minimal length  $\mu$ , are homeomorphisms onto closed images, but live in one cardinality band below one set-sized upper alphabet. Which of these maps preserve finite condensation, coding ranks or canonical cylinders, the further properties that [research question 113.19](#) asks about, is not stated by either source.

## 76 The exact binary spectrum of a birthday alphabet (source 29)

[merge] Source 29’s Section 4, printed whole. Its  $X_\theta$  is printed  $\mathbf{No}_{<\theta}$ , its  $D_{\rho,m}$  is printed  $\mathbb{B}_\rho \times_{\text{lex}} m$  and its  $\otimes_{\text{lex}}$  is printed  $\times_{\text{lex}}$ , its  $\ell_2$  is  $\ell_2$ , and its termination symbol  $\dagger$  is printed **end**; its displayed equations (1)–(4) are (S29.1)–(S29.4). The fusion lemma ([lemma 76.1](#)) is the cylinder fusion mechanism of [lemmas 31.1](#) and [31.5](#) and of source 19’s [lemma 64.3](#), stated in its cleanest form; it is printed because every later proof of this Part’s last three sections uses it. Its Corollary 4.2 is recorded in [note 76.2](#). Everything from [proposition 76.3](#) on is new against the repository and the rest of batch 83: the repository and its sources had determined the cube spectra of the binary cubes themselves and of the enumeration strata, but not of the birthday alphabets  $\mathbf{No}_{<\theta}$ .

The numerical order used as the alphabet already has a rigid embedding hierarchy. This remains true when increasing the birthday bound does not change the cardinality of the alphabet. We first determine that hierarchy; the result will then distinguish information retained by the alphabet from information retained by the lexicographic order of its enumerations.

Throughout this section all lengths are set ordinals. Write

$$\mathbf{No}_{<\theta} = \bigcup_{\xi < \theta} \{-, +\}^\xi, \quad \mathbb{B}_\beta = (\{0, 1\}^\beta, <_{\text{lex}}).$$

The order on  $\mathbf{No}_{<\theta}$  is numerical surreal order: at the first disagreement, termination lies strictly between minus and plus. This is the standard sign-sequence description of the surreals [12]. The symbol  $\simeq_e$  denotes order embeddings in both directions, not order isomorphism. For a positive finite integer  $m$ , put

$$\mathbb{B}_\rho \times_{\text{lex}} m = \mathbb{B}_\rho \times_{\text{lex}} \{0, \dots, m-1\}.$$

Every addition or multiplication of lengths below is ordinal arithmetic.

### 76.1 Binary fusion and finite capacity

The following elementary fusion argument is useful both for the native alphabet and for spaces of its enumerations. A full cylinder consists of all extensions of a fixed initial binary word, with every

later coordinate and every displayed final factor retained.

**Lemma 76.1** (Equal-length fusion). *Let  $\rho$  be an ordinal, let  $K$  be a nonempty linear order, and let*

$$f : \mathbb{B}_\rho \times_{\text{lex}} K \longrightarrow \mathbb{B}_\rho$$

*be nondecreasing. There is an  $s \in \mathbb{B}_\rho$  such that  $f$  is constant on  $\{s\} \times K$ .*

*Proof.* At stage  $\xi \leq \rho$  retain a full source cylinder whose first  $\xi$  bits are fixed and on which the first  $\xi$  target bits are constant. Suppose  $\xi < \rho$ . With the earlier target bits fixed, the next target bit is nondecreasing on that cylinder. If the lower source child maps entirely to 0 at that bit, retain it. Otherwise some point of the lower child maps to 1, so the whole upper child maps to 1; retain the upper child. At limit stages take unions of the fixed prefixes. After  $\rho$  stages the entire factor  $K$  survives over a single source word, and every target bit is fixed.  $\square$

*Note 76.2* (Source 29, Corollary 4.2, “Cube hierarchy and finite factors”). *For ordinals  $\beta, \gamma, \rho$  and positive finite integers  $m, n$ ,*

$$\mathbb{B}_\beta \hookrightarrow \mathbb{B}_\gamma \iff \beta \leq \gamma, \quad (\text{S29.1})$$

$$\mathbb{B}_\rho \times_{\text{lex}} m \hookrightarrow \mathbb{B}_\rho \times_{\text{lex}} n \iff m \leq n. \quad (\text{S29.2})$$

*If  $\rho = 0$  or  $\rho$  is an infinite limit ordinal, the least ordinal length of a binary cube containing  $\mathbb{B}_\rho \times_{\text{lex}} m$  is  $\ell_2(\mathbb{B}_\rho \times_{\text{lex}} m) = \rho + \lceil \log_2 m \rceil$ .*

[merge] (S29.1) is [lemma 6.4](#) (reals report `two:thm:cube-strict`; source 15’s [lemma 31.1](#)); (S29.2) and the coding length are [lemma 31.5](#) for nonzero limit  $\rho$  (the case  $\rho = 0$  is the count of finite chains), and source 19’s [note 64.12](#) proves the same. Source 29 derives all three from [lemma 76.1](#): for (S29.1), if  $\beta > \gamma$ , split the source after its first  $\gamma$  bits; the remaining factor has at least two points, and fusion of the composite with the target word makes them equal. For (S29.2), fusion of the composite with the projection to  $\mathbb{B}_\rho$  leaves all  $m$  source points over one target binary word, so they inject into its  $n$ -point fibre. For the coding length, coding the finite factor in  $j = \lceil \log_2 m \rceil$  bits gives the upper bound; a target length below  $\rho$  is excluded by the  $\mathbb{B}_\rho$  suborder, and a target length  $\rho + i$ ,  $i < j$ , has fibres of only  $2^i < m$  points, excluded by (S29.2). The proof is the argument of [lemma 31.5](#). New in the statement is only that (S29.2) is stated for every ordinal  $\rho$ , not only for nonzero limits.

## 76.2 The finite part of a birthday bound

Every ordinal  $\theta$  has a unique expression

$$\theta = \lambda + n, \quad n < \omega,$$

where  $\lambda = 0$  or  $\lambda$  is an infinite limit ordinal. A finite tail has an exact effect on the native alphabet.

**Proposition 76.3** (Finite terminal trees). *If  $n \geq 1$  and  $\lambda = 0$  or  $\lambda$  is an infinite limit ordinal, then*

$$\mathbf{No}_{<\lambda+n} \simeq_e \mathbb{B}_\lambda \times_{\text{lex}} (2^n - 1).$$

*Proof.* Consider the strings whose length is at least  $\lambda$ . Each is a length- $\lambda$  sign word followed by a finite sign word of length less than  $n$ . The latter words, with centered termination, form a finite linear order of size

$$1 + 2 + \cdots + 2^{n-1} = 2^n - 1.$$

Thus this subset of  $\mathbf{No}_{<\lambda+n}$  is actually isomorphic to  $\mathbb{B}_\lambda \times_{\text{lex}} (2^n - 1)$ , proving one embedding.

For  $\lambda = 0$  this is the whole alphabet. Suppose therefore that  $\lambda$  is an infinite limit. The relevant identities are

$$2 \cdot \lambda = \lambda, \quad 2 \cdot \xi + 2 < \lambda \quad (\xi < \lambda). \quad (\text{S29.3})$$

Indeed  $\lambda = \omega \cdot \delta$  for some nonzero ordinal  $\delta$ , and left multiplication by 2 fixes this product. Strict inequality for the proper partial lengths follows because  $\xi + 1 < \lambda$ . The factor 2 in (S29.3) is on the left; no cardinal multiplication is being substituted here.

Replace each minus sign by 00 and each plus sign by 11. If a string  $x$  has length  $\xi < \lambda$ , append the termination block 01, then pad with zeros to length  $\lambda$ , and assign it finite fiber rank 0. If  $x$  has length  $\lambda + j$ , with  $j < n$ , double its first  $\lambda$  signs to form its length- $\lambda$  binary block, and assign its finite tail its rank in the  $(2^n - 1)$ -point centered tail order.

The first binary blocks separate any two short strings and every short string from every long string. At a termination disagreement the decisive comparison is precisely

$$00 < 01 < 11.$$

Different long prefixes also compare correctly. Long strings sharing their first  $\lambda$  signs compare by their finite tail ranks. Consequently this is an order embedding of the entire alphabet into  $\mathbb{B}_\lambda \times_{\text{lex}} (2^n - 1)$ .  $\square$

The full sign level  $\lambda + n$  has  $2^n$  points over each length- $\lambda$  prefix, whereas the available finite subtree has only  $2^n - 1$ . Thus [note 76.2](#) immediately gives

$$\mathbb{B}_{\lambda+n} \not\hookrightarrow \mathbf{No}_{<\lambda+n}. \quad (\text{S29.4})$$

The limit case requires a different argument: there is no final finite fiber in which to count points.

### 76.3 Fusion at a limit birthday

**Proposition 76.4** (The missing full-height cube). *For every infinite limit ordinal  $\lambda$ ,*

$$\mathbf{No}_{<\lambda} \hookrightarrow \mathbb{B}_\lambda, \quad \mathbb{B}_\lambda \not\hookrightarrow \mathbf{No}_{<\lambda}.$$

*Proof.* The first embedding is the short-string code from [proposition 76.3](#): double signs, append 01, and pad with zeros to length  $\lambda$ .

Suppose for a contradiction that  $e : \mathbb{B}_\lambda \hookrightarrow \mathbf{No}_{<\lambda}$ . Recursively construct binary prefixes  $p_\xi$ , for  $\xi \leq \lambda$ , of length  $2 \cdot \xi$ . Require that the images of all extensions of  $p_\xi$  share  $\xi$  actual surreal signs; in particular, none of these common coordinates is a termination symbol.

At a stage  $\xi < \lambda$ , the earlier target signs are fixed. The target symbol at coordinate  $\xi$  is therefore a nondecreasing function on the retained source cylinder with values in

$$- < \text{end} < +.$$

A nondecreasing map to a three-point chain becomes constant on a full binary subcylinder after at most two source-bit choices. To see this precisely, process the two threshold functions indicating whether the symbol is at least **end** and whether it is  $+$ . For each threshold, the one-bit child rule in the proof of [lemma 76.1](#) makes its value constant while retaining a full child cylinder. If fewer than two choices suffice, fix additional arbitrary bits. The resulting prefix has length  $2 \cdot (\xi + 1)$ .

The constant target symbol cannot be **end**. Since the earlier actual signs are common, termination at  $\xi$  would make every image the same length- $\xi$  surreal. The retained source cylinder still has at

least two elements by (S29.3), contradicting injectivity. Its next common symbol is therefore minus or plus, as required.

At a limit stage  $\xi < \lambda$ , take the union of the preceding prefixes. Its length is

$$\sup_{\eta < \xi} 2 \cdot \eta = 2 \cdot \xi < \lambda,$$

and every earlier chosen target sign persists. At the final stage  $p_\lambda$  is a full source word because  $2 \cdot \lambda = \lambda$ . Its image has an actual sign at every coordinate below  $\lambda$ . That image has birthday at least  $\lambda$ , contrary to membership in  $\mathbf{No}_{<\lambda}$ .  $\square$

**Theorem 76.5** (Exact native birthday spectrum). *For all ordinals  $\beta, \theta$ ,*

$$\mathbb{B}_\beta \hookrightarrow \mathbf{No}_{<\theta} \iff \beta < \theta.$$

*Proof.* If  $\beta < \theta$ , the strings of exactly length  $\beta$  form the required copy of  $\mathbb{B}_\beta$ . The empty alphabet at  $\theta = 0$  contains no such cube. For positive  $\theta$ , nonembedding at  $\beta = \theta$  is (S29.4) or proposition 76.4. Every larger cube contains  $\mathbb{B}_\theta$  by fixing its later coordinates, so larger  $\beta$  are excluded as well.  $\square$

**Corollary 76.6** (A strict hierarchy on every birthday band). *For all ordinals  $\theta, \eta$ ,*

$$\mathbf{No}_{<\theta} \hookrightarrow \mathbf{No}_{<\eta} \iff \theta \leq \eta.$$

*Proof.* Inclusion proves sufficiency. If  $\theta > \eta$ , the exact sign level  $\eta$  embeds  $\mathbb{B}_\eta$  into  $\mathbf{No}_{<\theta}$ . An embedding of that alphabet into  $\mathbf{No}_{<\eta}$  would contradict theorem 76.5.  $\square$

For an infinite initial cardinal  $\kappa$ , every noninitial cutoff  $\kappa < \theta < \kappa^+$  has alphabet cardinality  $2^\kappa$ . Nevertheless, corollary 76.6 distinguishes all these cutoffs under order embeddability. This distinction will disappear from the equimorphism type of several corresponding enumeration strata.

## 76.4 Coding length versus embedded cubes

**Corollary 76.7** (Exact native binary coding lengths). *Let  $\ell_2(L)$  be the least ordinal  $\rho$  such that  $L \hookrightarrow \mathbb{B}_\rho$ . Then  $\ell_2(\mathbf{No}_{<0}) = 0$ . For every nonzero limit  $\lambda$ ,*

$$\ell_2(\mathbf{No}_{<\lambda}) = \lambda.$$

*For  $n \geq 1$  and  $\lambda = 0$  or an infinite limit,*

$$\ell_2(\mathbf{No}_{<\lambda+n}) = \lambda + \lceil \log_2(2^n - 1) \rceil = \begin{cases} \lambda, & n = 1, \\ \lambda + n, & n \geq 2. \end{cases}$$

*Proof.* At a limit, proposition 76.4 supplies the upper code. Every proposed shorter target  $\mathbb{B}_\rho$  is excluded because  $\mathbb{B}_{\rho+1} \hookrightarrow \mathbf{No}_{<\lambda}$  and  $\mathbb{B}_{\rho+1} \not\hookrightarrow \mathbb{B}_\rho$ . At a successor cutoff use proposition 76.3 and note 76.2.  $\square$

For example,  $\mathbf{No}_{<\omega}$  and  $\mathbf{No}_{<\omega+1}$  both have least binary coding length  $\omega$ , but only  $\mathbf{No}_{<\omega+1}$  contains  $\mathbb{B}_\omega$ . At a limit birthday, all shorter cubes occur and their supremum is not attained. At the next birthday that full cube appears without increasing the least coding length. The two numerical invariants therefore answer different questions.

| Birthday bound       | Native alphabet information                                                | Least binary code |
|----------------------|----------------------------------------------------------------------------|-------------------|
| $\omega$             | cubes exactly of length $< \omega$                                         | $\omega$          |
| $\omega + 1$         | $\mathbf{No}_{<\omega+1} \simeq_e \mathbb{B}_\omega$                       | $\omega$          |
| $\omega + 2$         | $\mathbf{No}_{<\omega+2} \simeq_e \mathbb{B}_\omega \times_{\text{lex}} 3$ | $\omega + 2$      |
| $\omega + 3$         | $\mathbf{No}_{<\omega+3} \simeq_e \mathbb{B}_\omega \times_{\text{lex}} 7$ | $\omega + 3$      |
| $\omega \cdot 2$     | cubes exactly of length $< \omega \cdot 2$                                 | $\omega \cdot 2$  |
| $\omega \cdot 2 + 1$ | $\mathbf{No}_{<\omega \cdot 2+1} \simeq_e \mathbb{B}_{\omega \cdot 2}$     | $\omega \cdot 2$  |

These arguments use only set-sized sign strings, ordinal recursion, and canonical choices between two binary children. The native spectrum and strict hierarchy can consequently be developed in ZF; no enumeration of an arbitrary unordered set is needed. This makes them particularly suitable as an initial formalization target before the choice-dependent permutation constructions in the next section.

[merge] “The next section” of source 29 is printed as [section 78](#). The proposition on finite terminal trees is printed with  $\mathbb{B}_\lambda \times_{\text{lex}} (2^n - 1)$  where source 29’s typeset text has a stray double comma in the subscript of  $D$ ; no change of meaning. At  $\theta = \omega$  the theorem gives the countable alphabet  $\mathbf{No}_{<\omega}$  (order-isomorphic to the dyadic rationals) all finite cubes and no infinite one, consistent with  $\ell_2(\mathbf{No}_{<\omega}) = \omega$ . The repository’s earlier statements about birthday alphabets concern initial cardinal cutoffs: their cardinality  $\mu = 2^{<\kappa}$  and their cuts ([section 29](#)). The cardinality  $|\mathbf{No}_{<\theta}| = 2^\kappa$  is constant on each band  $\kappa < \theta \leq \kappa^+$ , while [corollary 76.6](#) separates every two cutoffs of the band by embeddability.

## 77 Noncardinal birthday cutoffs (source 21)

[merge] Source 21’s Section 5, printed whole. It keeps its letters  $\kappa = |\theta|$  and  $\mu = |\mathbf{No}_{<\theta}|$  (conventions of this Part: here  $\mu = 2^\kappa$ , not  $2^{<\kappa}$ ); its  $d$ ,  $c$  and  $\text{br}$  are printed  $\text{d}$ ,  $\text{cell}$  and  $\ell_2$  (its definition of  $\text{br}$  is that of  $\ell_2$ ); its displayed equation (3) is (S21.3). The question it answers in part is [research question 113.12](#) (“the repository explicitly asks”), which Part VI left open for noncardinal cutoffs ([section 33](#), items (b) and (g)). Some clauses are instances of results printed earlier:  $|P| = 2^\mu$  is [theorem 6.1](#); the formula  $\text{d} = \text{cell} = \mu^{<\mu}$  of [theorems 77.1](#) and [77.4](#) is the case  $\alpha = \mu$  of source 16’s [theorem 27.2](#), which needs no hypothesis on  $X$ ; the point characters of  $\mu$  are those that source 17 computes for initial cardinal cutoffs ([theorem 30.2](#), where  $q = \text{cf } \mu$ ). New are the sufficient condition of [theorem 77.1](#), its verification at every noncardinal cutoff, the coding rank, the global cofinality of  $\lambda$  and [corollary 77.5](#). Source 29 obtains the coding rank again, for every enumeration length, in [corollary 78.9](#).

The repository explicitly asks what survives when the birthday bound is an arbitrary ordinal rather than an initial cardinal ([research question 113.12](#)). There is a useful simplification in that case: the alphabet becomes strictly larger than the length of any of its monotone chains. This determines several exact invariants without any additional cardinal-arithmetic hypothesis.

### 77.1 A general permutation lemma

For an infinite initial cardinal  $\mu$  and an ordered set  $X$  of cardinality  $\mu$ , write  $\mathcal{W}_\mu(X)$  for the bijections  $\mu \rightarrow X$  in enumeration lexicographic order. For an injection  $p : \delta \rightarrow X$ , where  $\delta < \mu$ , put

$$C_p = \{f \in \mathcal{W}_\mu(X) : f \upharpoonright \delta = p\}.$$

The *prefix topology* has these cylinders as a base. Throughout this section, cellularity means the supremum of the sizes of pairwise disjoint families of nonempty open sets; the supremum need not be attained.

**Theorem 77.1** (Short monotone chains in the alphabet). *Suppose that  $X$  contains neither an increasing nor a decreasing sequence of order type  $\mu$ . Then  $P = \mathcal{W}_\mu(X)$  is dense without endpoints, and its order topology equals its prefix topology. The cylinders are clopen, and*

$$d(P) = \text{cell}(P) = \mu^{<\mu}.$$

*Every  $f \in P$  has left cofinality and right coinitiality exactly  $\text{cf}(\mu)$ .*

*Proof.* Define the feasible downward and upward divergence positions by

$$\begin{aligned} D^-(f) &= \{i < \mu : \exists j > i [f(j) < f(i)]\}, \\ D^+(f) &= \{i < \mu : \exists j > i [f(j) > f(i)]\}. \end{aligned}$$

If  $D^-(f)$  were bounded, a final part of  $f$  would be strictly increasing. Every final interval of the initial ordinal  $\mu$  has order type  $\mu$ , so this contradicts the hypothesis. Thus  $D^-(f)$  is cofinal in  $\mu$ , and the same argument applies to  $D^+(f)$ . At any feasible position, swap  $f(i)$  with the corresponding later value. This produces a bijection whose first disagreement with  $f$  occurs at  $i$ , in the desired direction.

For  $f < g$ , an upward swap of  $f$  beyond their first disagreement gives  $f < h < g$ . The same construction in both directions shows that every point is internal to each of its prefix cylinders. Since cylinders are convex, they are open; their complements are unions of other cylinders of the same length, so they are closed. Conversely, a prefix longer than the first disagreements with the endpoints of an order neighborhood lies inside that neighborhood. The two topologies therefore agree.

Choose a cofinal subset of  $D^-(f)$  of size  $\text{cf}(\mu)$  and one downward swap at each of its positions. These permutations are cofinal below  $f$ , since a later first disagreement brings a point closer to  $f$  from below. Any family of fewer than  $\text{cf}(\mu)$  points below  $f$ , however, has bounded disagreement positions; a downward swap beyond that bound lies above the entire family. The left character is exactly  $\text{cf}(\mu)$ . Reverse inequalities for the right character.

There are  $\mu^{<\mu}$  prefixes, so one completion per prefix gives a dense set of at most that size. Every prefix extends: its range has size less than  $\mu$ , its complement has size  $\mu$ , and the remaining coordinate interval has order type  $\mu$ . At level  $\delta < \mu$  there are exactly  $\mu^{|\delta|}$  injective prefixes. For the lower bound, encode an arbitrary function  $h : \delta \rightarrow \mu$  as the injection  $i \mapsto \langle h(i), i \rangle$  using a fixed injection  $\mu \times \delta \rightarrow \mu$ . Their cylinders form a disjoint open family of that size. Taking the supremum over  $\delta$  and using  $\text{cell}(P) \leq d(P)$  proves the formula.  $\square$

*Remark 77.2.* The hypothesis is sufficient, not necessary. It fails for  $X = \mathbb{Q}$  and  $\mu = \omega$ , even though the conclusion holds there because deleting a finite prefix leaves a dense alphabet without endpoints. It should not be silently substituted for that different argument.

**Lemma 77.3** (Finite-alphabet obstruction). *If  $|\tau| = \kappa$  is infinite and  $A$  is a finite linear order, then the lexicographic order on  $A^\tau$  contains no increasing or decreasing sequence of length  $\kappa^+$ .*

*Proof.* Suppose  $(x_\eta)_{\eta < \kappa^+}$  is strictly increasing. Recursively make each coordinate constant on a final segment. Once all coordinates below  $\beta$  have stabilized, their stabilization indices have a common upper bound below  $\kappa^+$ , since  $|\beta| \leq \kappa$  and  $\kappa^+$  is regular. Beyond that bound, coordinate  $\beta$  is

nondecreasing and takes only finitely many values, so it too eventually stabilizes. After  $\tau$  steps a single final segment has every coordinate constant, a contradiction. Reverse the alphabet order for decreasing sequences.  $\square$

[merge] This lemma is the finite-alphabet case of the stabilization argument used for source 19's [proposition 64.5](#) (no increasing  $\kappa^+$ -sequence in  $\mathbb{B}_\kappa$ ); it is stated here for every finite alphabet and every index ordinal of cardinality  $\kappa$ .

## 77.2 Exact invariants at an arbitrary noninitial bound

**Theorem 77.4** (Noncardinal cutoff). *Let  $\theta$  be an infinite ordinal that is not an initial cardinal, and put*

$$\kappa = |\theta|, \quad X = \mathbf{No}_{<\theta}, \quad \mu = |X|.$$

*Then  $\mu = 2^\kappa > \kappa$ . For  $P = \mathcal{W}_\mu(X)$  one has*

$$|P| = 2^\mu, \quad \ell_2(P) = \mu, \quad d(P) = \text{cell}(P) = \mu^{<\mu},$$

*where  $\ell_2$  is the least ordinal length of a fixed-length binary lexicographic cube into which the order embeds. The order  $P$  is dense without endpoints, its order topology is its prefix topology, and every point has left and right character  $\text{cf}(\mu)$ .*

*Write uniquely  $\theta = \lambda + n$ , where  $\lambda$  is a nonzero limit ordinal and  $n < \omega$ . Then*

$$\text{cf}(P) = \text{ci}(P) = \text{cf}(\lambda).$$

*Proof.* Since  $\kappa < \theta$ , all sign sequences of length  $\kappa$  lie in  $X$ . Thus  $|X| \geq 2^\kappa$ . There are  $\kappa$  possible lengths below  $\theta$ , each contributing at most  $2^\kappa$  sequences, proving  $\mu = 2^\kappa$ . Pad a sign sequence to length  $\theta$  with a symbol 0, ordered  $- < 0 < +$ . This embeds the numerical order of  $X$  into the lexicographic order on  $\{-, 0, +\}^\theta$ : the padding symbol reproduces the centered termination convention for surreal signs. By [lemma 77.3](#),  $X$  has no monotone sequence of length  $\kappa^+$ . As  $\mu \geq \kappa^+$ , [theorem 77.1](#) applies.

The number of bijections of an infinite  $\mu$ -set is  $2^\mu$ . The upper bound is  $\mu^\mu = 2^\mu$ ; independent swaps in a partition into pairs give the lower bound. To obtain the binary-rank upper bound, encode the three padding symbols as 00, 01, 10, respectively. This embeds  $X$  into binary words of fixed length  $\tau = 2 \cdot \theta$ . Here  $|\tau| = \kappa < \mu$ , so  $\tau < \mu$  and  $\tau \cdot \mu = \mu$ . Concatenating the entry codes of a permutation therefore embeds  $P$  into  $2^\mu$  with its lexicographic order.

Conversely, partition  $X$  into  $\mu$  pairs, order each pair numerically, and let each bit choose one of the pair's two enumeration orders. Since  $2 \cdot \mu = \mu$ , this embeds the lexicographic cube  $2^\mu$  into  $P$ . That cube contains every linear order  $L$  of cardinality at most  $\mu$ : index its elements by distinct coordinates and send  $t \in L$  to the characteristic function of its strict lower set, assigning 0 elsewhere. For  $s < t$ , these characteristic functions are nested, differ at the coordinate for  $s$ , and compare in the correct direction at their first disagreement. Thus, for every infinite  $\alpha < \mu$ , the order  $P$  contains the ordinal  $|\alpha|^+$ , whereas  $2^\alpha$  does not by [lemma 77.3](#). Finite target lengths are excluded by cardinality. The binary rank is exactly  $\mu$ .

It remains to compute the global cofinalities. In fact this argument works for every infinite birthday bound. If  $n = 0$ , the all-plus words  $+^\beta$ , for  $\beta < \lambda$ , are cofinal in  $X$ . A family of fewer than  $\text{cf}(\lambda)$  words has birthdays bounded below  $\lambda$ , so a longer all-plus word dominates the family. Hence  $\text{cf}(X) = \text{cf}(\lambda)$ . Whenever an alphabet  $Y$  has no maximum,

$$\text{cf}(\mathcal{W}_\mu(Y)) = \text{cf}(Y), \tag{S21.3}$$

because cofinal first entries give cofinal permutations, and the first entries of a cofinal family of permutations must be cofinal in  $Y$ .

If  $n > 0$ , let  $B$  consist of the words in  $X$  extending  $+^\lambda$ . These form a finite final block of the numerical alphabet, of size

$$|B| = 1 + 2 + \cdots + 2^{n-1} = 2^n - 1.$$

Every word outside  $B$  terminates or first has a minus sign below  $\lambda$ , and hence lies below every member of  $B$ . The complement  $Y = X \setminus B$  has no maximum. The words  $+^\beta$ ,  $\beta < \lambda$ , are cofinal in it. For the converse bound assign to each  $y \in Y$  its first disagreement or termination position relative to  $+^\lambda$ . Fewer than  $\text{cf}(\lambda)$  such positions are bounded below  $\lambda$ ; a longer all-plus word then dominates the corresponding family. Thus  $\text{cf}(Y) = \text{cf}(\lambda)$ .

The cylinder beginning by listing  $B$  in decreasing numerical order is a final convex suborder of  $P$ . Deleting this finite prefix leaves coordinate order type  $\mu$ , so that cylinder is isomorphic to  $\mathcal{W}_\mu(Y)$ . Equation (S21.3) gives  $\text{cf}(P) = \text{cf}(\lambda)$ . Negating all signs proves the matching coinitality formula.  $\square$

**Corollary 77.5** (Failure of interval self-similarity). *At every noncardinal cutoff of theorem 77.4, the whole order  $P$  is not isomorphic to any nonempty bounded open interval of itself, nor to either proper open ray.*

*Proof.* König's theorem gives

$$\text{cf}(P) = \text{ci}(P) = \text{cf}(\lambda) \leq \kappa < \text{cf}(2^\kappa) = \text{cf}(\mu).$$

Every interval  $(a, b)$  has cofinality and coinitality  $\text{cf}(\mu)$ , by the point-character calculation. A proper open ray has one of these endpoint characters. The corresponding invariant of  $P$  is strictly smaller.  $\square$

For example, the cutoffs  $\omega + 1$ ,  $\omega \cdot 2$ , and  $\omega^2$  all have  $\mu = 2^{\aleph_0}$ . Their minimal permutation orders have global cofinalities  $\omega$  and point characters  $\text{cf}(2^{\aleph_0}) > \omega$ . Moving from cutoff  $\omega$  to cutoff  $\omega + 1$  already changes the point character from countable to uncountable. These calculations answer part of the repository's proposed question, while leaving full cut spectra, saturation, and isomorphism classifications open. No historical novelty claim is attached to these deductions.

[merge] Two remarks on the comparison with initial cardinal cutoffs. First, at an initial cardinal cutoff  $\kappa$  the global cofinality is  $r = \text{cf } \kappa$  and the point characters are  $(q, q)$ ,  $q = \text{cf } \mu$  (theorem 30.2), with  $r \leq q$  (note 29.9). The argument of corollary 77.5 therefore applies at an initial cardinal cutoff exactly when  $r < q$ ; at a noncardinal cutoff the corresponding inequality  $\text{cf } \lambda < \text{cf } \mu$  holds always, by König's theorem. Second, at an initial cardinal cutoff the coding rank is  $\rho_\kappa$ , which differs from  $\mu$  exactly at singular strong limits (theorem 8.3); at a noncardinal cutoff it is always  $\mu$ , because  $\mathbf{No}_{<\theta}$  codes into binary words of the fixed length  $2 \cdot \theta < \mu$ . Source 29's corollary 76.6 shows that the noncardinal cutoffs of one band are nevertheless pairwise distinguished by their alphabets, while theorem 77.4 sees of the cutoff only  $\kappa$  and  $\text{cf } \lambda$ .

## 78 All enumeration lengths at a noninitial birthday bound (source 29)

[merge] Source 29's Section 5, printed whole except for four lemmas that source 19 proves for initial cardinal cutoffs in its Section 5 (printed in Part X, section 64) and that hold verbatim, for any alphabet, at noninitial cutoffs; these are recorded in notes carrying source 29's labels (notes 78.3,

78.4, 78.6 and 78.7). Source 29 credits all four to source 19 (“the earlier residual analysis”). Its main-prefix lemma and residual reduction (lemma 78.1 and proposition 78.2) are source 19’s lemma 64.2 and theorem 64.4 transferred to noninitial cutoffs, where the proof is simpler (no singular scheduler is needed for the main prefix); they are printed in full because their statements are new. The coding sandwich, the exact cube and birthday capacity, the coding bounds and the countable-band classification (theorems 78.5 and 78.8 and corollaries 78.9 and 78.10) are new; at initial cardinal cutoffs the corresponding statements are source 19’s theorems 64.7 and 64.11 and corollary 64.13, except the native birthday threshold (S29.13), which is new at every cutoff. Renamed (conventions of this Part):  $D_{\rho,m}$  is  $\mathbb{B}_{\rho} \times_{\text{lex}} m$ ; the layer weights  $r(\lambda)$ ,  $u_{\kappa}(\lambda)$  are  $\text{wt}(\lambda)$ ,  $\text{wt}_{\kappa}^+(\lambda)$ ; the weighted lengths  $R$ ,  $U$  are  $\varrho_{\text{lo}}$ ,  $\varrho_{\text{up}}$ ;  $\ell_2$  is  $\ell_2$ . Displayed equations (5)–(13) are (S29.5)–(S29.13). Its first sentence’s “fixed-length results” of the repository are theorem 31.2 (Part VI).

The repository’s fixed-length results include the minimum stratum and finite tails after a whole-cardinality prefix (theorem 31.2). The earlier residual analysis goes further for initial birthday bounds: it treats arbitrary smaller residual alphabets and obtains an exact embedded-cube spectrum, while retaining a specific upper coding gap at singular non-strong-limit residual cardinals (source 19, section 64). We now extend that analysis to every noninitial birthday cutoff. The residual fusion and singular scheduler are inherited mechanisms; the work here is to verify their hypotheses for the new alphabets and draw the resulting sharp birthday-embedding consequences.

Work in ZFC. Fix an infinite ordinal  $\theta$  which is not an initial cardinal, and put

$$\kappa = |\theta|, \quad X = \mathbf{No}_{<\theta}, \quad \mu = |X| = 2^{\kappa}. \quad (\text{S29.5})$$

The last equality follows because every sign word of length  $\kappa$  belongs to  $X$ , and there are only  $\kappa$  possible lengths, each contributing at most  $2^{\kappa}$  words. In particular  $\kappa < \mu$ . An admissible enumeration type is an ordinal  $\alpha$  of cardinality  $\mu$ , and  $\mathcal{W}_{\alpha}(X)$  denotes the bijections  $\alpha \rightarrow X$  ordered by their first numerical disagreement.

## 78.1 Main prefixes and variable residual alphabets

Write

$$\alpha = \mu \cdot \gamma + \zeta, \quad 0 < \gamma < \mu^+, \quad \zeta < \mu.$$

The difference between an injection of length  $\mu \cdot \gamma$  and a bijection of that length is essential: a proper prefix of the full enumeration may leave a smaller alphabet, with numerical order depending on the prefix.

**Lemma 78.1** (Noninitial main-prefix package). *Every lexicographically ordered family of injective prefixes  $p : \mu \cdot \gamma \rightarrow X$  embeds into  $\mathbb{B}_{\mu \cdot \gamma}$ . For every  $Y \subseteq X$  with  $|Y| < \mu$ ,*

$$\mathbb{B}_{\mu \cdot \gamma} \hookrightarrow \mathcal{W}_{\mu \cdot \gamma}(X \setminus Y).$$

*Proof.* Pad every sign word to length  $\theta$  with a termination symbol ordered between minus and plus, and encode the three symbols by 00, 01, 11. This embeds  $X$  into  $\mathbb{B}_{\tau}$ , where  $\tau = 2 \cdot \theta$  has cardinality  $\kappa$ . Thus  $0 < \tau < \mu$  and  $\tau \cdot \mu = \mu$ . Concatenating the fixed entry codes over  $\gamma$  successive  $\mu$ -blocks yields an order-preserving code of length  $\mu \cdot \gamma$ . Exhaustiveness is never used.

The complement  $X \setminus Y$  has cardinality  $\mu$ . Partition it into pairs indexed by  $\mu \cdot \gamma$ , orient each pair numerically, and let its corresponding bit choose the order in which the two labels are listed. Every label appears exactly once. The resulting enumeration has length  $2 \cdot (\mu \cdot \gamma) = \mu \cdot \gamma$ , and its first changed bit gives its first changed label in the same order direction.  $\square$

**Proposition 78.2** (Exact residual reduction). *For every nonempty linear order  $K$ ,*

$$\begin{aligned} \mathbb{B}_{\mu \cdot \gamma} \times_{\text{lex}} K &\hookrightarrow \mathcal{W}_{\mu \cdot \gamma + \zeta}(X) \\ \iff \exists Y \subseteq X (|Y| = |\zeta| \text{ and } K &\hookrightarrow \mathcal{W}_{\zeta}(Y)). \end{aligned}$$

*Proof.* There is an actual lexicographic-sum decomposition

$$\mathcal{W}_{\mu \cdot \gamma + \zeta}(X) \cong \sum_p \mathcal{W}_{\zeta}(X \setminus \text{ran } p), \quad (\text{S29.6})$$

where  $p$  ranges over the injective main prefixes whose omitted set has cardinality  $|\zeta|$ . The projection onto this prefix order is nondecreasing, and [lemma 78.1](#) embeds its range into  $\mathbb{B}_{\mu \cdot \gamma}$ . Apply [lemma 76.1](#) to the composition with a proposed product embedding. The whole factor  $K$  survives in one target fiber, proving necessity.

Conversely, fix a suitable  $Y$ . Use [lemma 78.1](#) to enumerate the fixed complement  $X \setminus Y$  according to the main binary factor, then append the chosen  $K$ -indexed permutations of  $Y$ .  $\square$

This reduction applies to arbitrary product embeddings. It does not assume that an embedding respects the displayed fibers. In particular, it prevents a variable residual alphabet from being replaced silently by a preferred copy of a birthday fragment.

[merge] The decomposition (S29.6) is source 19's (6) and, for the minimal length, the set-level fibre identity of sources 21 and 22 printed in Part X; the class version is source 16's [equation \(S16.12\)](#).

## 78.2 The finitely many residual cardinal layers

Repeated left division of  $\zeta$  by its current infinite initial cardinal gives a finite expression

$$\zeta = \lambda_0 \cdot \eta_0 + \cdots + \lambda_{s-1} \cdot \eta_{s-1} + n, \quad (\text{S29.7})$$

where

$$\mu > \lambda_0 > \cdots > \lambda_{s-1} \geq \omega, \quad 0 < \eta_i < \lambda_i^+, \quad n < \omega.$$

There cannot be infinitely many layers, since their cardinals would form an infinite strictly decreasing sequence of ordinals. When  $\zeta$  is finite,  $s = 0$ .

Define the two weights

$$\text{wt}(\lambda) = \begin{cases} \lambda \cdot \lambda, & \lambda \text{ singular strong limit,} \\ \lambda, & \text{otherwise,} \end{cases} \quad (\text{S29.8})$$

$$\text{wt}_{\kappa}^+(\lambda) = \begin{cases} \lambda \cdot \lambda, & \lambda \leq \kappa \text{ and } \lambda \text{ singular,} \\ \lambda, & \text{otherwise.} \end{cases} \quad (\text{S29.9})$$

Finally set

$$\varrho_{\text{lo}} = \mu \cdot \gamma + \sum_{i < s} \text{wt}(\lambda_i) \cdot \eta_i, \quad \varrho_{\text{up}} = \mu \cdot \gamma + \sum_{i < s} \text{wt}_{\kappa}^+(\lambda_i) \cdot \eta_i. \quad (\text{S29.10})$$

Both are nonzero limit ordinals, and  $\varrho_{\text{lo}} \leq \varrho_{\text{up}}$ . Their difference, when present, is an ordinal difference in coding cost; their cardinalities are both  $\mu$ .

*Note 78.3* (Source 29, Lemma 5.3, “Entry codes and regular blocks”). *Every linear order of infinite cardinality  $\lambda$  admits a prefix-free, order-preserving binary entry code with positive code lengths below  $\lambda$ . If  $\lambda$  is regular, concatenating these codes over a block of  $\lambda \cdot \eta$  entries has length exactly  $\lambda \cdot \eta$ .* The first sentence is source 19's [lemma 64.1](#) and the second the coding half of its [lemma 64.6](#), by

the same argument: insert the alphabet, in an enumeration of length  $\lambda$ , into  $\mathbf{No}_{<\lambda}$  by simplest separators (the birthday bound for a surreal cut, [12]), double minus and plus to 00 and 11 and append 01; regularity keeps every proper partial sum of fewer than  $\lambda$  code lengths below  $\lambda$ , and positivity makes the full sum  $\lambda$ . The code is source 15's entry code (lemma 31.1) applied after the insertion.

*Note 78.4* (Source 29, Lemma 5.4, “Inherited singular strong-limit scheduler”). *If  $\lambda$  is singular strong limit and  $0 < \eta < \lambda^+$ , then  $\mathbb{B}_{\lambda \cdot \lambda \cdot \eta} \hookrightarrow \mathcal{W}_{\lambda \cdot \eta}(\mathbf{No}_{<\lambda})$ .* This is the lower half of theorem 31.2 at the cutoff  $\lambda$  (there  $\mu = \lambda$  and  $\rho_\lambda = \lambda \cdot \lambda$ ), and source 29 says “We recall the construction from the earlier residual analysis”: the row scheduler of lemma 31.3 in the form given in the proof of source 19's lemma 64.2. Its steps, as source 29 recalls them: the sign cones with prefixes  $+^i \frown -$ ,  $i < \lambda$ , are pairwise disjoint copies of  $\mathbf{No}_{<\lambda}$ , indexed by  $\lambda \cdot \eta$ , and their complement (containing the  $\lambda$  all-plus words) is a fixed filler row placed first ( $1 + \lambda = \lambda$ ); row-column pairs are scheduled first by  $\max(i, j)$ , then lexicographically, which has order type  $\lambda$  even for singular  $\lambda$  and lets the first entry of the first varying row decide the comparison; this embeds  $(\mathbf{No}_{<\lambda})_{\text{lex}}^{\lambda \cdot \eta}$ . Finally, with  $\delta = \text{cf } \lambda$  and positive lengths  $(\tau_j)_{j < \delta}$  summing to  $\lambda$ , a binary word of length  $\lambda$  is encoded by  $\delta$  consecutive entries of sign lengths exactly  $\tau_j$ , so that  $\delta \cdot (\lambda \cdot \eta) = \lambda \cdot \eta$  entries carry  $\lambda \cdot \lambda \cdot \eta$  bits.

**Theorem 78.5** (Noninitial coding sandwich). *With (S29.5)–(S29.10),*

$$\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} n! \hookrightarrow \mathcal{W}_\alpha(X) \hookrightarrow \mathbb{B}_{\varrho_{\text{up}}} \times_{\text{lex}} n!.$$

*Proof.* For the upper embedding, code the main prefix in length  $\mu \cdot \gamma$  using lemma 78.1. At the start of a residual layer its remaining alphabet has cardinality  $\lambda_i$ : the remaining coordinate interval has that cardinality, and the enumeration is bijective.

At a regular layer, note 78.3 gives cost  $\lambda_i \cdot \eta_i$ . At a singular layer with  $\lambda_i \leq \kappa$ , pad its entry codes to length  $\lambda_i$ , giving cost  $\lambda_i \cdot \lambda_i \cdot \eta_i$ . If  $\lambda_i > \kappa$ , use the fixed global code of length  $\tau = 2 \cdot \theta$ . Now  $\tau < \lambda_i$ , so  $\tau \cdot \lambda_i = \lambda_i$ , and the cost is only  $\lambda_i \cdot \eta_i$ .

Choose one entry code for each possible residual alphabet. These are set-indexed choices. Two enumerations agreeing through a layer boundary have the same residual alphabet and use the same code. If they disagree earlier, their comparison has already been decided. The conditional codes therefore concatenate to an order-preserving code of length  $\varrho_{\text{up}}$ . After that prefix, the last  $n$  labels are determined as a set; append the rank of their permutation among its  $n!$  possibilities.

For the lower embedding, reserve disjoint fixed alphabets for the residual layers and a fixed  $n$ -element terminal set. If a residual  $\lambda < \mu$  is singular strong limit, necessarily  $\lambda \leq \kappa$ : otherwise strong limit would imply  $2^\kappa < \lambda$ , contradicting  $\lambda < \mu = 2^\kappa$ . Thus a copy of  $\mathbf{No}_{<\lambda}$  lies in a finite-prefix cone of  $X$ . All its sign lengths stay below  $\lambda \leq \kappa < \theta$ . Finitely many distinct prefixes make the alphabets for different such layers disjoint. Apply note 78.4 at each of them.

For every other residual layer reserve an arbitrary set of the required cardinality and orient pairs to realize  $\mathbb{B}_{\lambda_i \cdot \eta_i}$ . The union of all reserved sets has cardinality below  $\mu$ , so lemma 78.1 realizes the main binary factor on its complement. Concatenate the independent block enumerations and the selected terminal permutation. The first changed source factor gives the first changed target block, establishing the lower embedding.  $\square$

### 78.3 The exact capacity despite a possible coding gap

The only discrepancy between  $\text{wt}$  and  $\text{wt}_\kappa^+$  can occur at a singular non-strong-limit residual cardinal at most  $\kappa$ . The following inherited fusion mechanism determines its contribution to embedded cubes even when a short upper code is unavailable.

*Note 78.6* (Source 29, Lemma 5.6, “Small-range fusion”). *Let  $\chi$  be an infinite cardinal, let  $A$  be a linear order of cardinality less than  $2^\chi$ , and let  $K$  be nonempty. A nondecreasing map from a full binary cylinder with at least  $\chi$  initial free bits, followed by  $K$ , into  $A$  is constant on a full subcylinder obtained by fixing fewer than  $\chi$  of those bits.* This is source 19’s lemma 64.9, with the same proof: fixing the later bits and one point of  $K$  leaves  $2^\chi$  ordered test points, so some value has three preimages  $x_0 < x_1 < x_2$ ; a prefix of  $x_1$  of length below  $\chi$  beyond its first disagreements with  $x_0$  and  $x_2$  traps its whole cylinder between them.

*Note 78.7* (Source 29, Lemma 5.7, “A singular non-strong-limit layer”). *Suppose  $\lambda$  is singular and not strong limit, and  $0 < \eta < \lambda^+$ . In an order embedding, suppose the target enumerations share their earlier prefix and the remaining alphabet has cardinality  $\lambda$ . If the surviving source begins with  $\mathbb{B}_{\lambda \cdot \eta}$  followed by a nonempty factor  $K$ , one can fix that source binary block so that the next  $\lambda \cdot \eta$  target entries are constant on the surviving whole factor  $K$ .* This is source 19’s lemma 64.10, with the same proof: choose  $\rho < \lambda$  with  $2^{|\rho|} \geq \lambda$  and  $\chi = \max(|\rho|, \text{cf } \lambda) < \lambda$ , so that  $2^\chi > \lambda$  by König’s inequality; fix the target entries one at a time with note 78.6, each at a cost of fewer than  $\chi$  source bits. Source 29 makes the ordinal bookkeeping explicit: before coordinate  $j = \lambda \cdot \beta + \delta$  ( $\delta < \lambda$ ) the cost is at most  $\chi \cdot (j + 1) = \lambda \cdot \beta + \chi \cdot (\delta + 1) < \lambda \cdot \eta$ , and the total cost is at most  $\chi \cdot (\lambda \cdot \eta) = \lambda \cdot \eta$ .

**Theorem 78.8** (Exact cube and birthday capacity). *For every positive finite integer  $m$ ,*

$$\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} m \hookrightarrow \mathcal{W}_\alpha(X) \iff m \leq n!. \quad (\text{S29.11})$$

*Consequently, for every ordinal  $\beta$ ,*

$$\boxed{\mathbb{B}_\beta \hookrightarrow \mathcal{W}_\alpha(X) \iff \beta \leq \varrho_{\text{lo}} + \lfloor \log_2(n!) \rfloor.} \quad (\text{S29.12})$$

*For every ordinal  $\nu$ , the exact native-alphabet threshold is*

$$\boxed{\mathbf{No}_{<\nu} \hookrightarrow \mathcal{W}_\alpha(X) \iff \nu \leq \varrho_{\text{lo}} + \lfloor \log_2(n! + 1) \rfloor.} \quad (\text{S29.13})$$

*Proof.* The positive direction of (S29.11) follows from theorem 78.5. Conversely, suppose an embedding of  $\mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} m$  is given. Compose with the main-prefix projection and its binary code. Equal-length fusion fixes the main target prefix while retaining the whole later source factor, as in proposition 78.2.

At a regular residual layer fuse through its code of length  $\lambda_i \cdot \eta_i$ . At a singular strong-limit layer fuse through the padded code of length  $\lambda_i \cdot \lambda_i \cdot \eta_i$ . A layer with  $\lambda_i > \kappa$  has its short global code and cannot be singular strong limit, as shown in the sandwich proof. At a singular non-strong-limit layer at most  $\kappa$ , apply note 78.7; its cost is only  $\lambda_i \cdot \eta_i$ . These are exactly the successive summands defining  $\varrho_{\text{lo}}$ .

After the finitely many layers all target positions before the last  $n$  are fixed. The surviving  $m$  points must inject into the  $n!$  permutations of a single fixed residual  $n$ -element set. Hence  $m \leq n!$ , proving (S29.11).

Put  $a = \lfloor \log_2(n!) \rfloor$ . The allowed finite binary factor has  $2^a$  points, whereas the next one has  $2^{a+1} > n!$ . Thus  $\mathbb{B}_{\varrho_{\text{lo}}+a}$  embeds and  $\mathbb{B}_{\varrho_{\text{lo}}+a+1}$  does not. The cube hierarchy proves (S29.12) for every ordinal  $\beta$ .

For (S29.13), put  $b = \lfloor \log_2(n! + 1) \rfloor \geq 1$ . Since  $\varrho_{\text{lo}}$  is a nonzero limit, proposition 76.3 gives

$$\mathbf{No}_{<\varrho_{\text{lo}}+b} \simeq_e \mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} (2^b - 1), \quad \mathbf{No}_{<\varrho_{\text{lo}}+b+1} \simeq_e \mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} (2^{b+1} - 1).$$

The first finite factor has at most  $n!$  points, and the second has more. Equation (S29.11) permits the first alphabet and excludes the second. Inclusion between birthday alphabets supplies all smaller cutoffs and excludes all larger ones.  $\square$

**Corollary 78.9** (Coding bounds and exact equimorphisms). *One has*

$$\varrho_{\text{lo}} + \lceil \log_2(n!) \rceil \leq \ell_2(\mathcal{W}_\alpha(X)) \leq \varrho_{\text{up}} + \lceil \log_2(n!) \rceil.$$

If  $\varrho_{\text{lo}} = \varrho_{\text{up}}$ , then

$$\mathcal{W}_\alpha(X) \simeq_e \mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} n!, \quad \ell_2(\mathcal{W}_\alpha(X)) = \varrho_{\text{lo}} + \lceil \log_2(n!) \rceil.$$

In particular equality holds whenever every residual cardinal is regular, singular strong limit, or greater than  $\kappa$ .

*Proof.* Apply [note 76.2](#) to both sides of the sandwich. In the listed cases every lower and upper layer weight agrees. Ordinal absorption can also give  $\varrho_{\text{lo}} = \varrho_{\text{up}}$  in additional cases; equality of the computed ordinals is the precise criterion.  $\square$

The distinction in [theorem 78.8](#) and [corollary 78.9](#) is deliberate. The embedded cube spectrum and the embedded native birthday spectrum are exact even when  $\varrho_{\text{lo}} < \varrho_{\text{up}}$ . They do not, by themselves, supply an embedding of the whole order into the shorter upper cube. The remaining general-alphabet question is still whether

$$\mathcal{W}_\lambda(Y) \hookrightarrow \mathbb{B}_\lambda$$

holds for every ordered  $Y$  of singular non-strong-limit cardinality  $\lambda$ . Neither the present argument nor the earlier residual analysis settles that question (source 19, [section 64](#)).

[merge] At  $\alpha = \mu$  ( $\gamma = 1$ ,  $\zeta = 0$ ) the corollary gives  $\varrho_{\text{lo}} = \varrho_{\text{up}} = \mu$  and  $\ell_2(\mathcal{W}_\mu(\mathbf{No}_{<\theta})) = \mu$ , which is the coding rank of source 21's [theorem 77.4](#), there proved by the finite-alphabet obstruction ([lemma 77.3](#)) and here by fusion. The remaining question is source 19's "remaining coding gap" ([research question 113.94](#)) and source 29's [research question 113.212](#).

#### 78.4 A complete classification on the countable birthday band

**Corollary 78.10** (Every admissible length, without CH). *Let  $\omega < \theta < \omega_1$ , put  $\mu = 2^{\aleph_0}$ , and let  $\alpha$  be any ordinal of cardinality  $\mu$ . Write uniquely*

$$\alpha = \Lambda + n, \quad \Lambda \text{ a nonzero limit ordinal, } n < \omega.$$

Then

$$\begin{aligned} \mathcal{W}_\alpha(\mathbf{No}_{<\theta}) &\simeq_e \mathbb{B}_\Lambda \times_{\text{lex}} n!, \\ \ell_2(\mathcal{W}_\alpha(\mathbf{No}_{<\theta})) &= \Lambda + \lceil \log_2(n!) \rceil. \end{aligned}$$

Its embedded cubes have exactly the lengths

$$\beta \leq \Lambda + \lceil \log_2(n!) \rceil,$$

and its embedded birthday alphabets have exactly the bounds

$$\nu \leq \Lambda + \lceil \log_2(n! + 1) \rceil.$$

The same statements hold for any noninitial  $\theta$  with  $|\theta| < \aleph_\omega$ , using  $\mu = 2^{|\theta|}$ .

*Proof.* For a countable noninitial cutoff,  $\kappa = \omega$ . There is no singular cardinal at or below  $\kappa$ . A singular strong-limit cardinal  $\lambda > \kappa$  cannot lie below  $\mu$ , since strong limit would give  $2^\kappa < \lambda$ . Every residual weight is therefore just  $\lambda_i$ , so  $\varrho_{\text{lo}} = \varrho_{\text{up}} = \Lambda$ . Apply [theorem 78.8](#) and [corollary 78.9](#).

More generally, every infinite cardinal at or below a fixed  $\kappa < \aleph_\omega$  is one of the regular cardinals  $\aleph_j$  for finite  $j$ . Again there is no singular layer at or below  $\kappa$ , while no singular strong-limit residual can occur above it. The identical computation gives  $\varrho_{\text{lo}} = \varrho_{\text{up}} = \Lambda$ .  $\square$

For a limit  $\alpha$ , the corollary simply says  $\mathcal{W}_\alpha(\mathbf{No}_{<\theta}) \simeq_e \mathbb{B}_\alpha$ . A final single label adds no choice, so type  $\Lambda + 1$  still gives  $\mathbb{B}_\Lambda$ . A final pair gives two choices and hence  $\mathbb{B}_{\Lambda+1}$ . With three terminal labels one obtains  $\mathbb{B}_\Lambda \times_{\text{lex}} 6$ : the largest embedded cube has length  $\Lambda + 2$ , whereas the least binary coding length is  $\Lambda + 3$ .

At the minimum length  $\mu$ , the sharp birthday threshold is  $\mu + 1$ . Thus this stratum contains an ordered copy of  $\mathbf{No}_{\leq \mu} = \mathbf{No}_{< \mu+1}$  and contains no larger birthday alphabet. The  $+1$  here is ordinal successor, not the successor cardinal  $\mu^+$ .

Finally, [corollary 76.6](#) shows that the native alphabets at  $\omega + 1$ ,  $\omega + 2$ ,  $\omega \cdot 2$ ,  $\omega^2$ , and every other distinct countable noninitial cutoff are strictly ordered under order embeddability. Nevertheless, at each common admissible enumeration length their permutation orders have the same equimorphism type. No continuum hypothesis is used. Whether these corresponding permutation orders are actually isomorphic is a finer question about their cuts and local order structure, not one decided by the spectra proved here.

[merge] Two comparisons. (1) The initial-cutoff counterpart is source 30's [corollary 64.20](#) (Part X): at  $\kappa = \omega_1$ , and at every initial cutoff  $\kappa < \aleph_\omega$ , every admissible stratum is  $\simeq_e \mathbb{B}_\lambda \times_{\text{lex}} n!$  in ZFC, by the equality clause of source 19's [theorem 64.7](#) (source 19's own [corollary 64.8](#) states the classification under  $\mu \leq \aleph_\omega$ ). So the cutoffs  $\omega_1$  and every countable  $\theta > \omega$  give equimorphic strata of each common length, although their alphabets are strictly ordered by [corollary 76.6](#). (2) By [theorem 77.4](#) the minimal strata ( $\alpha = \mu$ ) at the countable noninitial cutoffs share coding rank, density, cellularity and point characters, and their global cofinality  $\text{cf } \lambda$  is  $\omega$  at each of them; so no invariant computed in this Part distinguishes the permutation orders of two countable noninitial cutoffs, while their alphabets are distinguished by [corollary 76.6](#). Source 29's [research question 113.213](#) asks whether they are isomorphic.

## 79 What this Part answers

[merge] Dated notes, 3 October 2026. Each item names the question, where it is asked, and the result that answers it. Where the question index of [section 113](#) (dated 2 October 2026) or an earlier Part's status section says otherwise, these notes supersede it. Questions of sources 13–18 are cited by their own numbers; those of sources 19–30 by their labels.

- (a) *Source 12's question on noncardinal birthday bounds* ([research question 113.12](#)): **answered in part**; the index row “Noncardinal cutoffs; away from inaccessible truncations” and Part VI's status ([section 33](#), items (b) and (g)) are superseded for the noncardinal half. The question asks which features of the ordinal tail of  $\theta$  survive “in its coding rank and local character”. Answer: the coding rank of the minimal slice is always  $\mu = 2^{|\theta|}$ , its point characters are  $\text{cf } \mu$ , its density and cellularity  $\mu^{<\mu}$ , and of the ordinal tail only  $\text{cf } \lambda$  ( $\theta = \lambda + n$ ) survives, as the global cofinality and coinitality; the minimal slice is not isomorphic to any interval or ray of itself ([theorem 77.4](#) and [corollary 77.5](#)). The alphabet itself remembers  $\theta$  exactly:  $\mathbb{B}_\beta \hookrightarrow \mathbf{No}_{<\theta}$  iff  $\beta < \theta$ , so the alphabets of one band are strictly ordered by embeddability ([theorem 76.5](#) and [corollary 76.6](#)). Every enumeration length at a noninitial cutoff has a coding

sandwich, an exact cube spectrum and an exact birthday threshold (theorems 78.5 and 78.8 and corollary 78.9), and on the bands  $|\theta| < \aleph_\omega$  every length is classified up to equimorphism in ZFC, which forgets  $\theta$  (corollary 78.10). Open: the order type and isomorphism classification, cut spectra and saturation (source 21’s own reservation, and its research question 113.122); whether two countable noninitial cutoffs give isomorphic strata (research question 113.213); the upper coding gap at singular non-strong-limit residual cardinals at most  $\kappa$  (research questions 113.94 and 113.212). The same question is asked by source 15 (its Question 13.2), source 17 (Question 15.2) and source 18 (Question 19.3), with the same status, and by source 19 (research question 113.97), which is answered in the same part. Source 20’s research question 113.116 asks for gap spectra and their arrangement at noninitial cutoffs: the results here bear on it only through embedding spectra, and it stays open.

- (b) *Source 12’s question on compatibility between birthday cutoffs* (research question 113.19): **answered in part**; the index row “Compatibility between birthday cutoffs” is superseded. Restriction is not the answer: it is monotone for the native orders only in three degenerate cases (theorem 73.1), although two labels decide every sufficiently large restriction, so that eventual local comparison is the native order on the inverse limit, which is exactly the class well-orders of **No** (theorems 74.1 and 74.3 and corollary 74.4). Two coherent forward systems exist: the append-tail maps along all ordinal cutoffs, on the full spaces  $\mathcal{W}(\mathbf{No}_{<\alpha})$ , composing exactly, with the bounded-support core as direct limit (theorem 74.8); and the fixed-slot maps of the minimal slices within one cardinality band, composing exactly, homeomorphisms onto closed (clopen or nowhere dense) images (theorem 75.1 and corollary 75.2). With relation-table orders, restriction itself becomes a monotone inverse system (proposition 74.10). Open: which choices preserve finite condensation, coding ranks or canonical cylinders, and coherent minimal-length systems across a change of cardinality (research questions 113.113 and 113.124). The same question is asked by source 14 (its Question 14.10), source 17 (Question 15.11), source 18 (Question 19.4) and source 19 (research question 113.105), with the same status.
- (c) *Source 15’s question “Coherent restricted filtrations”* (its Question 13.9): **answered in part**. Native restriction is classified exactly (theorem 73.1); it is eventually correct for each fixed pair (theorems 74.3 and 74.5, with finitely many sign changes and no uniform bound); and relation-table orders give a monotone inverse system with convex fibres (proposition 74.10).
- (d) *The reals report’s question “Other ground orders”* (lwo:sec:research; Part VI’s status, section 33, item (g), which left noncardinal cutoffs open): **answered further**. For  $X = \mathbf{No}_{<\theta}$  with  $\theta$  noninitial and  $|\theta| < \aleph_\omega$ , the display  $\mathcal{W}_{\lambda+n}(X) \simeq_e \mathbb{B}_\lambda \times_{\text{lex}} n!$  holds for every limit  $\lambda$  with  $|\lambda| = |X|$  and every  $n < \omega$  (corollary 78.10). For every noninitial  $\theta$ ,  $\mathcal{W}_{\lambda+n}(X) \simeq_e \mathbb{B}_{\varrho_{\text{lo}}} \times_{\text{lex}} n!$  whenever  $\varrho_{\text{lo}} = \varrho_{\text{up}}$  (corollary 78.9), which is the display when moreover  $\varrho_{\text{lo}} = \lambda$  (for instance when no residual layer is a singular strong limit).
- (e) *Set-likeness from bounded data*. No question of the report asks it, but theorems 74.6 and 74.7 give two exact criteria for set-likeness of a class well-order in terms of its restrictions to birthday cutoffs: eventual stabilization of every local rank (GB), and the minimum type  $\kappa$  on a stationary, equivalently club, class of strong-limit cutoffs (GBC); unboundedly many such cutoffs do not suffice. Source 20’s research question 113.114 (exact birthday profiles modulo the club filter) stays open. A full coherent birthday profile exists exactly under global choice, over GB (end of section 74).

Source 21 says of its noncardinal calculations that they “answer part of the repository’s proposed question, while leaving full cut spectra, saturation, and isomorphism classifications open”, and of its coherent system that “the restriction to one set-sized upper alphabet and one cardinality band is

substantive”; source 29 says that whether the countable-band permutation orders are isomorphic “is a finer question” not decided by its spectra; items (a) and (b) record the same.

## Part XII

# Words, termination markers and comparison codes

[merge] (3 October 2026.) This Part prints what four batch-83 sources prove about word orders, termination markers and the other comparison codes of Part VII: source 23 (its Sections 2–7), source 27 (its Sections 2, 4 and 5), source 29 (its Sections 2 and 6, its Subsection 3.3 and its Section 7) and source 30 (its Sections 2, 7 and 8). It continues Part VII ([part VII](#)) and answers, in part, two of the questions that Part VII left open ([section 85](#)). It is organized by theme, not by source.

- [Section 80](#) prints the four sources’ maps of interpretations, in the manner of [section 34](#).
- [Section 81](#) prints source 23’s termination-marker criterion and point characters for an abstract set-cut saturated alphabet. Both are [theorems 36.1](#) and [36.2](#) of Part VII (source 16) in a general alphabet; they are printed as notes with a second route.
- [Section 82](#) treats strictly increasing words: source 23’s theorem that no placement of a marker makes them set-cut saturated ([theorem 82.1](#), new), source 27’s factorization at the terminator, its product formula for the centered order, its zero conventions, interval richness and characters at an arbitrary gap ([theorems 82.4](#) and [82.7](#), [corollary 82.5](#), and [propositions 82.6](#) and [82.8](#)), and source 29’s Section 6, which proves the same product independently; its duplicates are notes with second routes, and its threshold reduction ([proposition 82.14](#)) is printed as a proposition.
- [Section 83](#) prints source 29’s Section 7 on numerically well-ordered proper-class carriers.
- [Section 84](#) treats relation-table lexicography: source 27’s scan-independent spectrum and the scan dependence of its topology ([theorems 84.2](#) to [84.4](#)), the density of the set-like orders under a set-like scan ([theorem 84.5](#), with source 30’s [theorem 84.11](#)), and source 30’s extension, approximation and canonical-scan theorems.
- [Section 85](#) records, with dates, the questions this Part answers.

The batch-83 notation addendum ([section 1.3.2](#)), which continues [section 1.3.1](#), fixes the symbols. The renamings that matter most here: source 23’s marker  $e$ , source 27’s terminator at a cut and source 29’s  $\dagger$  at a cut are all printed  $\varepsilon$ , as source 16’s marker in [section 36](#); the symbol  $\dagger$  is kept for the centered terminator in the place of zero, with  $\dagger_-$  and  $\dagger_+$  as in [section 37](#). Source 27’s  $\mathcal{B}$  and source 29’s  $\mathbf{T}$ , the shorter-first order of all set-length surreal words, are source 16’s  $\mathbf{T}_{\min}$  of [theorem 36.2](#) and are printed so; their nonempty part  $(\mathcal{B} \setminus \{\emptyset\}, \mathbf{P})$  is  $\mathbf{T}_{\min}^+$ . Source 27’s centered order  $J$  and source 29’s  $\mathcal{C}$  are Part VII’s  $\mathcal{T}_c^{\text{inc}}$ . Source 27’s scan  $q$  is printed  $s$  (this report’s  $q$  is cf  $\mu$ ), its table bits  $b_R$  are printed  $t_R$  (this report’s  $b$  is a baseline), and its  $\kappa = |X|$  is printed  $\mu$ .

## 80 The four sources’ maps of interpretations

[merge] Each of sources 23, 27, 29 and 30 opens, as the six batch-81 sources did ([section 34](#)), with a map of the readings of “all well-orders of surreal numbers”. The four maps are printed whole,

in source order. They agree with each other and with the batch-81 maps; their statements are inherited and none is claimed as new.

- Prefix-freeness of exhaustive enumerations of one set (source 23’s [note 80.1](#), and the corresponding paragraphs of sources 27, 29 and 30) is `lwo:lem:prefix-free` of the reals report, used in [section 6](#) and restated by source 15 ([note 32.3](#)).
- The fixed-set spectrum (source 27’s display (S27.1) and source 29’s [note 61.4](#), which is printed in its own Part with source 29’s Section 3) is [theorem 6.1](#).
- The three lexicographies of the six well-orders of a three-element carrier (source 30’s Subsection 2.4) are source 15’s table in [section 38](#), with the same pair scan and the same three orders.
- That the baseline is least for inverse-rank lexicography, and that this endpoint separates it from enumeration lexicography (source 30’s Subsection 2.5), is [theorem 38.1](#).
- The non-convexity of order-type classes and the collapse of the set-like global orders to the single type `Ord` are made in the batch-81 maps ([section 34](#)) and in [section 38](#).
- The example  $\{-1/(\alpha + 1) : \alpha \in \text{Ord}\} \cup \{0\}$  of a numerically increasing class of type `Ord + 1` (sources 27, 29 and 30) is printed after [proposition 38.6](#) and in [section 38.8](#).

Each source’s Kanovei–Shelah paragraph agrees with the qualification of [section 34](#): the index set of Kanovei and Shelah consists of maps  $a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters, it is not the order of all well-orders of  $\mathbb{R}$ , and it motivates the method only [16]. Source 27’s paragraph is printed below. Those of sources 29 and 30 are in their Sections 1 (scope and provenance), which this Part does not print. Source 30 places the index in “Section 2” of the paper; source 29 (“§1 of the preprint”), source 27 (“Section 1”) and this report’s bibliography entry place it in Section 1, page 2, of the preprint, and that location is kept.

### 80.1 Source 23: a taxonomy of what can be ordered

| Construction           | Objects                                                                                               | Logical size and main caution                                                                                                               |
|------------------------|-------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|
| Fixed carrier          | Well-orders on a fixed set $X \subseteq \mathbf{No}$ ; equivalently bijections $\alpha \rightarrow X$ | A set in ZFC. Complete enumerations of the same carrier cannot be proper prefixes of one another.                                           |
| Fixed order type       | Bijections $\alpha \rightarrow X$ for one ordinal $\alpha$                                            | A set; it is nonempty exactly when $ \alpha  =  X $ .                                                                                       |
| Variable set carrier   | Well-orders on arbitrary set subsets of $\mathbf{No}$                                                 | An ordinary class, represented by injective ordinal-length words. Termination affects the order.                                            |
| Words with repetition  | Arbitrary $p : \alpha \rightarrow \mathbf{No}$ , with $\alpha$ a set ordinal                          | An ordinary class of labelled sequences, but not literally well-orders on their ranges unless one keeps positions as distinct objects.      |
| Inherited well-orders  | Set subsets well-ordered by the numerical $<$                                                         | Strictly increasing words. The restriction on continuations is substantial.                                                                 |
| Set-like global orders | Well-orders of all $\mathbf{No}$ with set predecessor classes                                         | Equivalent to class bijections $\text{Ord} \rightarrow \mathbf{No}$ ; a predicate on classes, not an ordinary class of all such bijections. |
| Raw global orders      | All class well-orders of all $\mathbf{No}$ , with no set-likeness requirement                         | Can have proper-class predecessor segments. Comparison must not assume an ordinal-indexed first disagreement.                               |

| Construction             | Objects                                                                          | Logical size and main caution                                                                          |
|--------------------------|----------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Increasing class subsets | Class subsets well-ordered by numerical $<$                                      | May have non-set-like inherited order. A global increasing enumeration of all <b>No</b> is impossible. |
| Unlabelled types         | Well-orders modulo order isomorphism                                             | Numerical lexicography does not descend to this quotient.                                              |
| Relation codes           | Characteristic functions of ordering relations, after choosing an order of pairs | A different lexicographic order; its dependence on the pair enumeration must be retained.              |

### 80.1.1 Enumeration lexicography

For words  $p : \alpha \rightarrow A$  and  $q : \beta \rightarrow A$ , compare their first different letter if one occurs before either word ends. If one is a proper prefix of the other, compare  $\varepsilon$  with the next letter of the longer word. We write  $p <_\varepsilon q$  for this order. The termination marker is not an allowed letter, even if one reserves a numerical label to model it.

End-first dictionary order means  $\varepsilon < A$ . End-last order means  $A < \varepsilon$ . A marker at a genuine class gap need not correspond to any surreal number. A marker immediately before  $a \in A$  has right side with minimum  $a$ ; immediately after  $a$  has left side with maximum  $a$ .

For injective words the ordinal indexing and the labels determine a well-order on the range. Conversely, every well-order on a set of labels has a unique ordinal enumeration. Thus injective words are a representation of all labelled set well-orders, not an additional choice of enumerations for the same labelled ordering.

*Note 80.1* (Source 23, Lemma 2.1, “No prefix ambiguity for complete enumerations”). *If  $p : \alpha \rightarrow X$  and  $q : \beta \rightarrow X$  are bijections and  $p$  is a prefix of  $q$ , then  $p = q$ .* Source 23’s proof: if  $\alpha < \beta$ , the next value  $q(\alpha)$  already occurs in  $p$ , since  $p$  exhausts  $X$ ; this contradicts injectivity of  $q$ . This is `two:lem:prefix-free` (section 6; source 15’s `note 32.3`).

Consequently none of the termination issues of source 23’s Part I (its Sections 4–7, printed in sections 81 and 82) changes the lexicographic order of exhaustive well-orders of a *fixed* carrier. They arise when carriers, or word lengths without exhaustivity, vary.

### 80.1.2 Other comparisons really are different

Shortlex first compares lengths and only then letters. Reverse lexicography requires a greatest disagreement, which arbitrary infinite words need not have. It is meaningful on finite words or suitable finite-difference families, but is not automatically a total order on all ordinal words. End-last lexicography is also sometimes used in tree orders; changing that convention changes prefix comparisons, not the numerical order of labels.

For relation-code lexicography, choose a set-like enumeration of ordered pairs of labels and compare the characteristic functions of the two relations at the first differing pair. Global choice supplies such an enumeration for a class carrier. This works even when the relations are not set-like. It is not the direct enumeration comparison of source 23’s Section 9 (section 106.1). A change in the schedule of pairs can change which disagreement decides the answer.

Finally, singleton words  $(a)$  and  $(b)$  have the same unlabelled well-order type for all labels  $a, b$ , yet  $(a) < (b)$  whenever  $a < b$ . Lexicography cannot be a comparison on unlabelled types that respects these representatives. Choosing the ordinal itself as a canonical representative gives a different, well-defined type order, rather than repairing this failure of descent.

## 80.2 Source 27: a map of the principal interpretations

There are arbitrarily many artificial encodings of well-orders, so no finite survey can enumerate every possible convention. The following table covers the structural choices responsible for the main differences. Once these choices are fixed, a further encoding is a new construction to be analyzed on its own terms.

| Interpretation     | Objects                                                              | Comparison and size                                                                                                 |
|--------------------|----------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------|
| Fixed carrier      | All well-orders of a fixed set $X \subseteq \mathbf{No}$             | Compare their ordinal enumerations at the first unequal numerical label. A set-sized linear order.                  |
| Fixed type         | Bijections $\alpha \rightarrow X$ , for a specified ordinal $\alpha$ | A stratum of the preceding order; its type can matter beyond $ \alpha $ .                                           |
| Variable carrier   | Injective words of every set ordinal length in $\mathbf{No}$         | Prefix termination must be specified. An ordinary class of set objects.                                             |
| Increasing subsets | Words strictly increasing in the numerical order                     | Equivalent to set-sized numerically well-ordered subsets, with an explicit termination convention.                  |
| Global enumeration | Class bijections $E : \text{Ord} \rightarrow \mathbf{No}$            | Exactly the set-like class well-orders; comparison is on class variables.                                           |
| Raw global order   | Arbitrary class well-orders on $\mathbf{No}$                         | May have proper-class predecessor segments. Use a common labelled prefix, not an assumed ordinal enumeration.       |
| Relation table     | A well-order $R$ viewed as a binary function on pairs                | Requires an independently fixed well-ordered scan of pairs. Its order need not agree with enumeration lexicography. |
| Unlabelled type    | Well-orders modulo order isomorphism                                 | For set relations the quotient is ordinal type. Numerical-label lexicography does not descend to this quotient.     |
| Model-relative     | The preceding objects inside $(M, \mathcal{X})$                      | The admitted classes $\mathcal{X}$ , internal well-foundedness, and external size must all be specified.            |

### 80.2.1 Fixed carriers and the absence of a termination ambiguity

For a set  $X$ , let  $\mathcal{W}(X)$  be all strict well-orders of  $X$ . Each  $R \in \mathcal{W}(X)$  has a unique ordinal type  $\alpha_R$  and an enumeration  $e_R : \alpha_R \rightarrow X$ . If  $R \neq S$ , neither enumeration can be a proper prefix of the other: a proper prefix that is already onto  $X$  leaves no unused label for a longer injective word. Consequently the common domain contains a least disagreement  $\delta$ , and

$$R <_{\text{en}} S \iff e_R(\delta) <_X e_S(\delta).$$

This is a strict linear order. The familiar proof of transitivity compares the two first-disagreement positions for three words; the earlier position decides, and equal positions use transitivity in  $X$ .

For an infinite set  $X$  of cardinality  $\mu$ , the repository proves (theorem 6.1; the reals report)

$$|\mathcal{W}(X)| = 2^\mu, \quad \alpha \hookrightarrow \mathcal{W}(X) \iff \alpha < \mu^+, \quad (\text{S27.1})$$

and the same ordinal spectrum holds in the reverse order. Every linear order of size at most  $\mu$  embeds. These statements do not classify  $\mathcal{W}(X)$  up to isomorphism, do not imply separability, and do not identify its relation-table version. Its finite residual tails create adjacent points and finite

blocks: after an agreed prefix leaves  $n$  labels, the possible completions form the finite lexicographic order on  $n!$  permutations.

For a fixed type  $\alpha$ , write  $\mathcal{W}_\alpha(X)$  for the bijections  $\alpha \rightarrow X$ . Some strata have much greater binary coding length than others even though their cardinalities coincide. Birthday truncation of  $X$  is another independent parameter. At an infinite cardinal  $\kappa$ ,  $|\mathbf{No}_{<\kappa}| = 2^{<\kappa}$ , but neither a singular birthday bound nor a noninitial ordinal cutoff should be replaced by its cardinality without proof. The earlier corpus studies these distinctions extensively; the new scan results of [section 84.1](#) illustrate another reason why cardinality alone is insufficient.

### 80.2.2 Variable words and distinct terminators

If the carrier is allowed to vary, one word can be a proper prefix of another. Three standard conventions insert a distinct terminal symbol  $\varepsilon$  below every letter, above every letter, or at a cut  $X = L + R$ . The last convention means

$$x < \varepsilon \quad (x \in L), \quad \varepsilon < y \quad (y \in R).$$

Using the numerical value 0 as an ordinary letter *and* as an undistinguished padding symbol identifies different words: the empty word and (0) already have the same zero extension. One must either exclude 0 from the alphabet, place a distinct terminator immediately before or after it, or explicitly pass to the quotient defined by zero padding. These are different definitions.

Every set-length word is still a set. Hence the class of all such words does not create a class-of-classes problem. By contrast, a word of length Ord is itself a class, and treating all such words as members of one ordinary class would cross a type boundary.

### 80.2.3 Numerical well-ordering is much more restrictive

Every set-sized subset  $A \subseteq \mathbf{No}$  whose inherited numerical order is a well-order has a unique numerically increasing ordinal enumeration. This is the increasing-word interpretation studied in [section 82.2](#). It does not include arbitrary permutations of  $A$ . For example, the set  $\{0, 1\}$  supplies two labelled well-orders but only one numerically increasing enumeration.

There is no numerically increasing class bijection  $\text{Ord} \rightarrow \mathbf{No}$ , because its range would make the numerical surreal order a well-order. There are increasing proper-class subclasses, such as the ordinals. Such subclasses need not be set-like in their inherited order: take an increasing copy of Ord inside  $(0, 1)$  and append the point 1. The final point then has a proper class of predecessors. Thus even in the increasing interpretation, “ordinal sequence” and “arbitrary class well-ordered subset” must be distinguished.

### 80.2.4 Isomorphism types discard the lexicographic information

On a set carrier, every well-order is isomorphic to an ordinal. Two distinct enumerations of the same order type can compare either way after relabelling. For instance,  $(a, b)$  and  $(b, a)$  on  $a < b$  have the same ordinal type 2, while the first is lexicographically smaller. Numerical-label lexicography therefore does not descend to the quotient by abstract order isomorphism. Ordering the quotient by ordinal type is perfectly legitimate, but it is an additional, different order.

### 80.2.5 The Kanovei–Shelah connection

The historical connection should be stated precisely. Kanovei and Shelah use maps  $a : \mathfrak{c} \rightarrow \mathcal{P}(\mathbb{N})$  whose ranges are ultrafilters, ordered lexicographically using characteristic-function order on  $\mathcal{P}(\mathbb{N})$

[16]. Injectivity is not part of that definition. Their construction motivates the use of ordinal-indexed lexicographic codes without choosing a well-order of the underlying reals. It does not literally define the order of all well-order relations on  $\mathbb{R}$ , still less a collection of all class well-orders of **No**.

### 80.3 Source 29: interpretations and a disciplined choice of foundations

[merge] Source 29's Section 2, printed whole: its sign conventions, its interpretation table, its size ledger with the definition of uniform families (definition 80.2), used throughout its later sections, and its operations on orders. Its  $X_\theta$  is printed **No** $_{<\theta}$  (for an arbitrary set ordinal  $\theta$ , as in source 29) and its product  $\otimes_{\text{lex}}$  is printed  $\times_{\text{lex}}$ . Its Subsection 3.3, on relation scans and inverse ranks, follows at the end; the rest of its Section 3 is printed with its birthday spectra.

#### 80.3.1 Signs, birthdays, and numerical comparison

We represent a surreal number by a sign sequence

$$x : \text{bd}(x) \longrightarrow \{-, +\}, \quad \text{bd}(x) \in \text{Ord}.$$

At the first unequal coordinate, including the possibility that one sequence has ended, compare with

$$- < \text{termination} < +.$$

This is the numerical order. For each set ordinal  $\theta$ , write

$$\mathbf{No}_{<\theta} = \{x : \text{bd}(x) < \theta\}.$$

It is a set. The union over all set ordinals is the proper class **No**. Simplicity is a different relation: one sign sequence is simpler than another when it is a prefix. It is a tree order and is not a global well-order scan of the numerical line [12, 14].

The basic interpolation principle is the *set-cut property* (definition 5.1): if  $L, R$  are sets of surreals and  $L < R$ , then some  $z \in \mathbf{No}$  satisfies  $L < z < R$ . Empty sides are permitted. Deleting a set of forbidden labels does not destroy this property (lemma 5.2). One can choose a separator with birthday larger than the birthdays of all the constraints and forbidden labels; the inspected Lean foundation develops precisely this bounded-birthday route [8, 9]. It follows that **No** has no endpoints and every numerical interval between two distinct points is a proper class. The principle applies to sets of constraints. It does not fill an arbitrary cut between two proper classes.

#### 80.3.2 The interpretation table

The following choices cover the natural readings relevant to this problem. Altering the coding or comparison rule within one row can produce still further orders; the parameterized constructions below make those alterations explicit.

| Interpretation         | Object being compared                                                                                          | Logical size and decisive choice           |
|------------------------|----------------------------------------------------------------------------------------------------------------|--------------------------------------------|
| Fixed set of labels    | All auxiliary well-order relations on a set $X \subseteq \mathbf{No}$ , represented by exhaustive enumerations | A set; numerical first disagreement.       |
| Fixed enumeration type | Bijections $\alpha \rightarrow X$ for a specified ordinal $\alpha$                                             | A set; a stratum $\mathcal{W}_\alpha(X)$ . |

| Interpretation                 | Object being compared                                                                   | Logical size and decisive choice                                                         |
|--------------------------------|-----------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------|
| Variable set carrier           | Injective ordinal-length surreal words                                                  | A class of sets; termination placement matters.                                          |
| Inherited numerical well-order | Increasing words or their numerical carriers                                            | Set carriers form a class of sets; proper-class carriers require higher-order treatment. |
| Set-like global well-order     | Class bijections $\text{Ord} \rightarrow \mathbf{No}$                                   | Each is a class; the whole family is not an ordinary class of GB.                        |
| Arbitrary global well-order    | Class well-orders on $\mathbf{No}$ , possibly with proper-class predecessor segments    | Direct labelled-prefix comparison, without assigning set ordinal types.                  |
| Variable class carrier         | Class well-orders on arbitrary subclasses of $\mathbf{No}$                              | A higher-order collection; proper-class termination and prefixes must be specified.      |
| Relation-table encoding        | Characteristic bits of a relation under a fixed well-ordered scan of ordered pairs      | Scan-dependent; differs from enumeration comparison.                                     |
| Inverse-rank encoding          | Ranks of labels read in a fixed background scan                                         | Requires ranks to exist in the selected codomain; reverses some enumeration comparisons. |
| Abstract order types           | Well-orders modulo isomorphism, or ordinal notations encoding them                      | Labels have been forgotten; numerical lexicography does not descend to this quotient.    |
| Universe-relative version      | Any of the set constructions inside a specified set universe or type-theoretic universe | A legitimate bounded model; changing the universe changes the object.                    |

Free words with repeated labels are useful auxiliary objects, but are not themselves exhaustive well-orderings of their ranges. Likewise a surreal sign sequence has a well-ordered domain; this fact does not make it a well-ordering of the surreal class. These auxiliary encodings become legitimate only after their comparison and intended interpretation are stated.

### 80.3.3 Theories and the size ledger

Our set-sized arguments use ZFC unless a weaker basis is explicitly given. The native sign-spectrum argument uses only ZF. Our class arguments use GBC: Gödel–Bernays class theory with set choice and Global Choice. All classes have sets as their members. An expression such as “for every class well-order  $R$ ” is a quantification in the two-sorted language; it does not assert that there is a class whose members are the class relations  $R$ .

**Definition 80.2** (Uniform families). A family of class relations  $(R_i)_{i \in I}$  is *uniform* if one class relation  $F(i, x, y)$  codes all its members. Here the index  $i$  is always a set; its index carrier  $I$  may be a set or an ordinary class. A uniformly set-indexed family has a set index carrier. A class of set-coded words is an ordinary class because each word is a set.

This definition prevents a hidden appeal to a class choice principle. Choosing a class independently for each of a proper class of indices is stronger than exhibiting one elementary formula defining all rows. The local back-and-forth constructions used below are uniform in the latter sense: a tuple belongs to the output exactly when it appears in the unique deterministic set-length history with the indicated parameters.

A class well-order need not be set-like. We call  $R$  *set-like* when every predecessor segment  $\{y : yRx\}$  is a set. Under GBC, a proper-class set-like well-order has a class enumeration of type

Ord. A class well-order of type  $\text{Ord} + 1$  has a last point with a proper class of predecessors and admits no such exhaustive enumeration. Elementary comparison of two labelled orders remains possible; it is not the abstract comparability principle studied later.

### 80.3.4 Operations on orders

Write  $A \hookrightarrow B$  for an order embedding and  $A \simeq_e B$  for embeddings in both directions. These notions are strictly weaker than isomorphism in general. Define

$$A \times_{\text{lex}} B = \sum_{a \in A} B,$$

so the first coordinate is decisive. A natural number in such a product denotes its finite chain. The full binary cube is

$$\mathbb{B}_\beta = (\{0, 1\}^\beta, <_{\text{lex}}),$$

with the least unequal coordinate decisive. All products and sums of *lengths* are ordinal operations. For example,  $2 \cdot \omega = \omega$ , whereas  $\omega \cdot 2 > \omega$ . This distinction is essential to every coding-length calculation.

### 80.3.5 Relation scans and inverse ranks (source 29's Subsection 3.3)

A fixed well-ordered scan  $\mathbf{s}$  of  $X \times X$  permits another lexicographic order: compare the characteristic bits of two relations at the first scanned pair on which they differ. This is a legitimate order, but it uses the scan and the chosen orientation of zero and one. A first differing relation bit need not reveal the first differing enumerated label. The repository supplies finite counterexamples and scan-dependent endpoint classifications ([section 38](#), [theorem 38.2](#), and [corollary 38.3](#)).

Likewise one may scan the labels and compare their ordinal ranks in the two auxiliary well-orders. Already on  $0 < 1 < 2$ , the enumerations  $(1, 0, 2)$  and  $(2, 0, 1)$  compare in that order, whereas their rank vectors  $(1, 0, 2)$  and  $(1, 2, 0)$  show that the decisive scanned rank need not be attached to the first differing enumerated label. A reversal is given by  $(1, 2, 0)$  and  $(2, 0, 1)$ : enumeration comparison places the former first, while the rank of label 0 is respectively 2 and 1. On arbitrary non-set-like class well-orders, predecessor segments need not have set ordinal order types, so even the proposed rank codomain requires a further foundational choice.

These encodings are best treated as named additional structures. There is no canonical rule converting every such code order into the native numerical first-disagreement order.

## 80.4 Source 30: the interpretations and their foundational levels

There are indefinitely many artificial encodings. The following matrix organizes the natural independent choices rather than claiming to enumerate every possible coding.

| Version                | Objects and comparison                                         | Size and distinction                                                                 |
|------------------------|----------------------------------------------------------------|--------------------------------------------------------------------------------------|
| Fixed labelled set $X$ | Well-order relations on $X$ , compared by ordinal enumerations | A set in ZFC. Numerical order compares labels; it is not the order being enumerated. |
| Fixed type $\alpha$    | Bijections $\alpha \rightarrow X$ , by first unequal value     | A set; nonempty iff $ \alpha  =  X $ . Fixing type changes the topology.             |
| Variable set support   | Injective ordinal-length words in <b>No</b>                    | A class of set codes. Proper prefixes require a termination rule.                    |

| Version                 | Objects and comparison                                  | Size and distinction                                                                                    |
|-------------------------|---------------------------------------------------------|---------------------------------------------------------------------------------------------------------|
| Increasing support      | Words or subclasses well-ordered by native surreal $<$  | A restriction on the numerical order, not arbitrary labelled well-orders.                               |
| Set-like global orders  | Class bijections $\text{Ord} \rightarrow \mathbf{No}$   | A predicate on class variables in GBC. All have class type $\text{Ord}$ .                               |
| Arbitrary global orders | Class well-order relations on $\mathbf{No}$             | May have proper-class predecessors and common prefixes.                                                 |
| Relation-table scan     | Characteristic bits in a chosen well-order of pairs     | Depends on the scan; has a different topology and measurable structure.                                 |
| Inverse-rank scan       | Ranks of fixed labels in a baseline list                | Directly defined only for set-like class orders; the baseline is least.                                 |
| Type-first or quotient  | Compare types first, or identify isomorphic well-orders | Type-first changes the primary comparison; quotienting erases labels. Class types need not be ordinals. |
| Universe-relative       | Orders of $\mathbf{No}^u$ in a larger universe          | A higher-universe set/type; smallness remains relative to $u$ .                                         |

#### 80.4.1 Fixed sets and enumeration lexicography

For a linearly ordered set  $(X, <)$  define

$$\mathcal{W}_\alpha(X) = \{f : \alpha \rightarrow X : f \text{ is a bijection}\}.$$

For distinct  $f, g$  of the same length, compare  $f(\xi)$  and  $g(\xi)$  at their first unequal coordinate. Every well-order relation on  $X$  has a unique ordinal enumeration. For infinite  $|X| = \mu$  the union of these representations over  $\alpha < \mu^+$ ,  $|\alpha| = \mu$ , is a set, denoted  $\mathcal{W}(X)$ .

No proper-prefix tie occurs between distinct bijective enumerations of the same set: the shorter one would already have exhausted  $X$ . Thus the comparison extends across types without a termination rule. An order-isomorphism  $h : X \rightarrow Y$  induces  $f \mapsto h \circ f$  on enumerations. Arbitrary relabellings need not preserve the numerical comparison at the first disagreement.

#### 80.4.2 Variable support and termination

When the range varies,  $(x)$  can be a proper prefix of  $(x, y)$ . Putting the shorter word first, putting it last, comparing lengths first, or placing termination inside the alphabet produces inequivalent orders. The usual surreal sign order uses  $- < \text{termination} < +$ . A termination marker below every surreal entry is not that convention. Identifying a marker with the actual entry 0 also destroys injectivity unless an additional distinction is made.

All set-length words form a legitimate class: every individual word is a set. The prior reports embed these orders into  $\mathbf{No}$  and classify several termination families ([theorem 9.1](#) and [section 36](#)). Those embeddings do not authorize collecting all proper-class words into another ordinary class.

#### 80.4.3 Native order, birthday, and simplicity

The native surreal order is not a well-order, as witnessed by  $0, -1, -2, \dots$ . Simplicity is the initial-segment partial order on sign sequences; birthday is an ordinal rank with many ties. Neither supplies a well-ordered scan of all labels.

Ordering first by birthday and then by a selected well-order of each layer works under global choice. The existence of each individual layer order in ZFC does not provide that global selection.

Numerically increasing proper subclasses need not be set-like:

$$\{-1/(\alpha + 1) : \alpha \in \text{Ord}\} \cup \{0\}$$

has numerical order type  $\text{Ord} + 1$ . Its final point has a proper class of predecessors. This example separates increasing support from set-like global enumeration.

#### 80.4.4 Three scans of the same six objects

For labels  $0 < 1 < 2$ , enumeration order is 012, 021, 102, 120, 201, 210. Scanning inverse ranks of labels 0, 1, 2 gives 012, 021, 102, 201, 120, 210. Scanning relation bits in the pair order  $(0, 1), (0, 2), (1, 0), (1, 2), (2, 0), (2, 1)$  with  $0 < 1$  gives 210, 120, 102, 201, 021, 012. All three are abstract six-point chains, but they put the labelled objects in different positions. Infinite examples below distinguish their abstract topological and measurable structures as well. The accompanying script reproduces these finite comparisons. ([merge] The script is `code/30-tables-verify_finite.py`; the three orders are those of source 15's table in [section 38](#).)

#### 80.4.5 Inverse ranks, type-first comparison, and quotienting

The inverse-rank interpretation deserves a separate definition. Fix a baseline list  $b : \mu \rightarrow X$  of a set  $X$ . A well-order  $R$  of  $X$  assigns each label its ordinal rank  $r_R(x) = \text{otp}(\{y : yRx\}, R)$ . Scan the values

$$(r_R(b(\xi)))_{\xi < \mu}$$

and compare them as ordinals at the first unequal coordinate. This is a linear order on the same set of labelled well-orders, including comparisons between different order types. It generally differs from comparing the values in their increasing enumerations.

For the whole surreal class the same definition works for *set-like* well-orders, using a supplied  $b : \text{Ord} \rightarrow \mathbf{No}$ . It cannot assign ordinal ranks to a label whose predecessor class is proper. Its comparison is an elementary formula on two supplied class graphs; no collection of all rank functions is required.

The baseline order is the least point for inverse-rank lexicography. Indeed, if  $R$  first disagrees with the baseline at label index  $\delta$ , every earlier label has its unchanged rank. The rank of  $b(\delta)$  cannot be below  $\delta$ , because that rank is already occupied by an earlier baseline label. It must exceed  $\delta$ . In contrast, numerical enumeration lexicography on the full surreal class has no least point: any proposed first label can be replaced by a smaller one and the rest enumerated using the supplied global choice. The endpoint distinction alone prevents an order isomorphism between these two global interpretations. ([merge] This is [theorem 38.1](#), source 15's theorem, which also gives the characters of the inverse-rank order.)

Another convention compares order type first and uses enumeration lexicography only within a fixed type. For a set  $X$  of cardinality  $\mu$ , this is the ordinary lexicographic sum

$$\sum_{\substack{\alpha < \mu^+ \\ |\alpha| = \mu}} \mathcal{W}_\alpha(X).$$

Every fixed-type stratum is convex in this new order. Direct first-disagreement comparison across types has no such priority: with two different types, the first labels can be chosen in either numerical order. Thus these strata need not be convex in the original comparison.

Quotienting by isomorphism is a different operation. On a fixed set it leaves precisely the ordinal types  $\{\alpha < \mu^+ : |\alpha| = \mu\}$ . Ordering those types by their ordinal order is legitimate, but

is not induced by the labelled lexicographic comparison: changing representatives can reverse the comparison of two distinct type classes. On the whole class, all set-like global orders have type  $\text{Ord}$ , so their isomorphism quotient has just one member. Arbitrary global well-orders include such types as  $\text{Ord}+1$  and  $\text{Ord}+\text{Ord}$ ; they cannot all be replaced by set ordinals. A type-first construction there needs an explicitly specified class-type representation and comparison principle in an appropriate metatheory. The direct common-prefix formula ([theorem 14.2](#); source 30's Proposition 3.2) avoids that requirement.

#### 80.4.6 Why a reverse scan is not automatically defined

On finite words one can compare at the *last* unequal coordinate. On an infinite well-ordered domain a disagreement set need not have a greatest member. Two enumerations of a countable carrier which differ by switching every consecutive pair disagree unboundedly in  $\omega$ , so there is no last coordinate to inspect. A reverse-lexicographic rule therefore needs an additional restriction or completion convention. Even eventual agreement is insufficient by itself: a bounded set of disagreements can have limit order type and no maximum.

These examples are why the article fixes the scan, the label order, the allowed domains, and the treatment of termination before proving a lexicographic theorem. Allowing repetitions adds another independent choice: arbitrary ordinal-length words are legitimate set codes, but their multiplicities no longer represent a well-order of their range.

### 81 Termination markers over a saturated alphabet (source 23; second routes to Part VII)

[merge] Source 23's Sections 3–6, printed whole. Its alphabet is an arbitrary set-cut saturated class linear order  $A$  ([definition 5.1](#); source 23 says “set-cut saturated”) with a marker cut  $A = L \sqcup R$ , and its marker  $e$  is printed  $\varepsilon$ , as source 16's marker in [section 36](#); its word classes  $\mathcal{W}_e(A)$  (all set-length words) and  $\mathcal{I}_e(A)$  (injective ones) are printed  $\mathcal{T}_\varepsilon(A)$  and  $\mathcal{I}_\varepsilon(A)$ , and its prefix relation  $\sqsubseteq$  is kept. In a character pair source 23 writes **On**, printed **Ord**; in its words (its Subsection 1.2), the symbol “means ‘no set-sized cofinal family’ or its dual. It is not an additional cardinal.”

What is printed here is not new against the repository:

- Source 23's termination classification ([note 81.9](#)) and its surreal corollary ([note 81.10](#)) are source 16's [theorem 36.1](#) with an abstract saturated alphabet in place of **No**. In GBC every proper-class saturated alphabet is isomorphic to **No** ([proposition 5.13](#)), so the two statements say the same; source 23's version needs no such isomorphism, and its sufficiency proof, like source 16's, uses **GB** and the set-cut property only. The two proofs are the same common-prefix search with the same two-letter detour at an endpoint of a threshold side; source 23 organizes it by a set chain of straddling prefixes ([lemma 81.7](#)), as does the proof of Part II's [theorem 11.1](#).
- Source 23's uniform point characters ([note 81.12](#)) are the character part of [theorem 36.2](#) (source 16), and its regular-cardinal family of failures ([section 81.4.2](#)) is source 16's **T<sub>κ</sub>** there. The isomorphism classification of [theorem 36.2](#) (no repetitions; arbitrary and injective words isomorphic at every placement) is not in source 23, whose Question 16.1 asks for it.
- Its fresh-separator lemmas ([notes 81.2](#) and [81.3](#)) are [lemma 5.2](#) for an abstract alphabet; [lemma 81.4](#) and the three cylinder lemmas of [section 81.2](#) isolate steps of the proofs of [theorems 11.1](#) and [36.1](#).

*Pinned provenance.* Source 23 read this report at 109aaca15, before the batch-81 placement

(f0cd7032d) and Parts VI–VIII; its delivery calls the classification and the characters additions, and its Subsection 6.1 says that its adjacent placements “settle the additional case asked” in source 13’s question “A classification of termination cuts”. Both statements were true at its pin. At this report’s text that question is answered by source 16 (section 39, item (c)); source 23’s is an independent second proof. Its new result on words is the theorem on increasing words (theorem 82.1), printed in section 82.

### 81.1 Small cuts and fresh labels

*Note 81.1* (Source 23, Definition 3.1). *A class linear order  $A$  is set-cut saturated if for all sets  $B, C \subseteq A$  satisfying  $B < C$ , there is  $x \in A$  with  $B < x < C$ . Either set may be empty. A subset of a class order is cofinal if every point is at most some member of that subset; coinital is the dual notion. This is the set-cut property  $\eta_{\text{Ord}}$  of definition 5.1.*

The surreal order has this property: a separated set cut has a surreal separator. In sign-sequence language, bounding the option birthdays first supplies a separator at a suitably larger birthday. The repository proves a universe-relative form in `SignSequenceCut.lean` [8]. We use only the order property, not surreal arithmetic.

*Note 81.2* (Source 23, Lemma 3.2, “Two cuts give a fresh separator”). *Let  $A$  be set-cut saturated. Given sets  $B < C$  and a forbidden set  $D \subseteq A$ , there exists  $x \notin D$  with  $B < x < C$ . Consequently  $A \setminus D$  is set-cut saturated. This is lemma 5.2, with the same proof, for an arbitrary saturated alphabet.*

*Second route (source 23).* Choose  $z$  with  $B < z < C$ . Split  $D$  into  $D_- = \{d \in D : d \leq z\}$  and  $D_+ = \{d \in D : z < d\}$ . The sets  $B \cup D_-$  and  $C \cup D_+$  are strictly separated. Any separator  $x$  of this second cut is above every point of  $D_-$  and below every point of  $D_+$ , so it is outside  $D$  and still separates  $B, C$ .

*Note 81.3* (Source 23, Lemma 3.3, “No small bounds”). *A set-cut saturated class has no set-sized cofinal or coinital subset. Every nonempty initial or final segment of it is a proper class. For **No** this is in lemma 5.2 and the remarks after definition 5.1.*

*Second route (source 23).* A set cofinal subset would have a strict upper bound by the empty-right-side instance of saturation, a contradiction. The dual is identical. If an initial segment containing  $a$  were a set, its subset  $\{x : x < a\}$  would be a set. Saturating the cut consisting of that subset on the left and  $\{a\}$  on the right is impossible. The final-segment case is dual.

**Lemma 81.4** (Deletion preserves the relevant side conditions). *Let  $L$  be a nonempty initial segment of  $A$  and let  $D$  be a set. If  $L$  has no greatest element and has set cofinality  $\theta$ , then  $L \setminus D$  also has cofinality  $\theta$ . If  $L$  has no set cofinal subset, neither does  $L \setminus D$ . If  $L$  has a greatest element  $a$ , then either  $a \notin D$  remains greatest, or  $L \setminus D$  has no set cofinal subset. The dual assertions hold for final segments.*

*Proof.* When  $L$  has no maximum,  $L \setminus D$  is cofinal in  $L$ : above any  $x \in L$ , first choose  $y \in L$  with  $x < y$ , then choose a fresh point between  $x$  and  $y$ . A cofinal set in  $L \setminus D$  is therefore cofinal in  $L$ . Conversely, a set cofinal family in  $L$  can be moved point by point to larger fresh points of  $L$ , preserving its cardinal bound. This proves the first two assertions.

If  $a = \max L$  is removed and  $B \subseteq L \setminus D$  is a set, use note 81.2 on  $B < \{a\}$  to find a fresh point between them. It belongs to  $L \setminus D$  and is above  $B$ .  $\square$

We apply these lemmas both to  $A = \mathbf{No}$  and to a surreal alphabet with a set of reserved labels removed. This avoids a hidden injectivity problem in word extensions: all labels already used by a prefix form a set.

## 81.2 Cylinders and bounded straddling chains

[merge] Source 23 opens here its Part I, “Termination and the geometry of set-length words” (its Sections 4–7). It says that a prefix *crosses* a cut when its cylinder meets both sides, i.e. straddles it in the word of [section 1.3.1](#); its heading “Cylinders and bounded crossing chains” is printed with that word, and its proofs keep its own.

Fix a marker cut  $A = L \sqcup R$ . Let  $\mathcal{T}_\varepsilon(A)$  be all set-length words, and  $\mathcal{I}_\varepsilon(A)$  their injective suborder. For a word  $p$ , its cylinder is

$$C_p = \{w : p \sqsubseteq w\}.$$

It includes  $p$  itself. Concatenation always means ordinal concatenation; a suffix after a prefix of length  $\alpha$  is reindexed by the order type of the corresponding ordinal interval.

**Lemma 81.5** (Convex cylinders). *Every  $C_p$  is convex. Incompatible prefixes have disjoint, ordered cylinders. For arbitrary words,  $C_p$  is isomorphic to  $\mathcal{T}_\varepsilon(A)$ . For injective words it is isomorphic to  $\mathcal{I}_\varepsilon(A \setminus \text{ran } p)$ , with the induced marker cut.*

*Proof.* A word outside  $C_p$  either disagrees with  $p$  before  $p$  ends, or is a proper prefix of  $p$ . Its comparison with every member of  $C_p$  is decided by the same letter or the same marker comparison. It is therefore entirely on one side of the cylinder. Deleting the fixed prefix gives the claimed isomorphisms. For injective words the suffix must avoid exactly the labels already used by  $p$ .  $\square$

**Lemma 81.6** (Cylinders have no small end cofinalities). *Suppose  $L, R$  are nonempty. In either word order every cylinder has no set-sized cofinal or coinital subset, irrespective of whether the termination criterion of [section 81.3](#) holds.*

*Proof.* It suffices to work in a residual alphabet  $A \setminus D$ . Given a set of suffixes, collect their first letters into a set  $F$ . Choose a label  $r \in R \setminus D$  and a fresh label above  $F \cup \{r\}$ . Its singleton word is above all the suffixes, including the empty one. For a lower bound choose  $l \in L \setminus D$  and a fresh label below  $F \cup \{l\}$ . Nonemptiness of both residual sides follows from [note 81.3](#). Reattach the prefix.  $\square$

**Lemma 81.7** (Crossing-prefix reduction). *Let  $B < C$  be nonempty sets of words in either word order. Define*

$$T = \{p : B \cap C_p \neq \emptyset \text{ and } C \cap C_p \neq \emptyset\}.$$

*Then  $T$  is a set and a chain of prefixes. Its union  $p_*$  is a legitimate set word. Every constraint outside  $C_{p_*}$  lies on the correct side of that cylinder. Either  $p_* \notin T$ , and at most one constraint side meets  $C_{p_*}$ , or  $p_* \in T$  and no proper one-letter extension of  $p_*$  belongs to  $T$ .*

*Proof.* All members of  $T$  are prefixes of words in the set  $B \cup C$ , so they form a set. Two incompatible crossing prefixes would give a lower constraint in the higher cylinder and an upper constraint in the lower one, contradicting  $B < C$ . Thus  $T$  is a chain. Its lengths are bounded by

$$\Lambda = \sup\{\text{dom}(w) + 1 : w \in B \cup C\},$$

so its union is a set word. In the injective case two repeated entries in the union would already occur together in some member of the chain.

If a constraint  $w$  lies outside  $C_{p_*}$ , choose a crossing prefix long enough to decide the comparison between  $w$  and  $C_{p_*}$ . Such a prefix exists by the union definition, also when  $w$  is a proper prefix of  $p_*$ . A constraint of the opposite side extending that crossing prefix forces  $w$  to be on the required side of the entire cylinder. The last two alternatives follow directly from the definition of  $T$  and its union.  $\square$

This reduction is particularly useful for formalization. Its tree is a set of prefixes of the supplied data. It is not a recursion that successively constructs arbitrary classes, and it cannot run for Ord stages.

### 81.3 An exact termination-marker criterion

**Definition 81.8.** An interior marker cut  $(L, R)$  is *admissible* if

$$\begin{aligned} L &\text{ has a greatest element or has no set cofinal subset,} \\ R &\text{ has a least element or has no set coinital subset.} \end{aligned} \tag{32}$$

Here “interior” means both  $L$  and  $R$  are nonempty.

These are conditions (1)–(3) of [theorem 36.1](#).

*Note 81.9* (Source 23, Theorem 5.2, “Termination classification”). *Let  $A$  be a set-cut saturated class linear order. The following are equivalent:*

- (i) *the marker cut is interior and admissible;*
- (ii)  $\mathcal{T}_\varepsilon(A)$  *is set-cut saturated;*
- (iii)  $\mathcal{I}_\varepsilon(A)$  *is set-cut saturated.*

*The proof is uniform for the two word orders.* For  $A = \mathbf{No}$  this is [theorem 36.1](#) (source 16).

*Second route (source 23). Necessity.* If  $L$  is empty, the empty word is the least element; if  $R$  is empty, it is the greatest element. Either violates saturation with an empty constraint side.

Suppose  $L$  has no greatest element but has a set cofinal family  $S$ . The singleton words  $(s)$ , for  $s \in S$ , all lie below the empty word. No word lies strictly between all of them and the empty word: such a word must be nonempty, its first letter must belong to  $L$ , and that first letter is exceeded by a member of  $S$ . This is already a cut in the injective suborder. The argument for a set coinital family in  $R$ , with no minimum, is dual. Thus either (ii) or (iii) implies (i).

*Sufficiency.* Fix separated sets of constraints  $B < C$ . When a side is empty, [lemma 81.6](#) at the empty prefix supplies a separator. Otherwise apply [lemma 81.7](#) and write  $p = p_*$ . For injective words replace  $A$  by  $A' = A \setminus \text{ran } p$ ; for arbitrary words put  $A' = A$ . [Note 81.2](#) and [lemma 81.4](#) show that  $A'$  remains saturated and its induced marker cut is still admissible.

If  $p \notin T$ , at most one constraint side meets  $C_p$ . Choose a point in that cylinder strictly above, or strictly below, the active set of constraints, as appropriate. [Lemma 81.6](#) permits this, and all outside constraints were already correctly oriented.

It remains to consider  $p \in T$ . Project each active constraint to its next symbol after  $p$ , using  $\varepsilon$  for the constraint  $p$  itself. Call the resulting lower and upper symbol sets  $S$  and  $U$ . They are strictly separated: equality at an actual letter would make the corresponding child cylinder cross, contradicting maximality of  $p$ ; equality at  $\varepsilon$  would put the same word on both sides.

If neither symbol set contains  $\varepsilon$ , saturate the cut  $S < U$  in  $A'$ , choose a strict separating letter  $a$ , and take  $p \frown (a)$ .

Suppose next that  $\varepsilon \in S$ . Set  $S_0 = S \setminus \{\varepsilon\}$ ;  $U$  consists of actual letters in the right side  $R'$ . First choose  $a_0 \in A'$  with  $S_0 < a_0 < U$ . If  $a_0 \in R'$ , the word  $p \frown (a_0)$  works. Otherwise  $a_0 \in L'$ , so every lower actual symbol is below  $\varepsilon$ .

If  $R'$  has no set coinital subset, some  $a \in R'$  lies strictly below all of  $U$ ; then  $p \frown (a)$  works. If  $R'$  has minimum  $r$ , either  $r \notin U$  and  $r < U$ , or  $r \in U$ . In the first case choose any point of  $C_{p \frown (r)}$ . In the second case choose a point of this cylinder strictly below all upper constraints inside it, using

**lemma 81.6.** All lower constraints have next symbol at most  $\varepsilon$ , and all upper constraints outside this child have next symbol larger than  $r$ , so both choices separate the full cut.

The case  $\varepsilon \in U$  is the order-dual argument. The marker cannot belong to both symbol sets. This exhausts the possibilities and proves saturation in both word orders.

*Note 81.10* (Source 23, Corollary 5.3, “Surreal order type”). In GBC, when the marker is admissible, both  $\mathcal{T}_\varepsilon(A)$  and  $\mathcal{I}_\varepsilon(A)$  are order-isomorphic to **No**. This is the last sentence of [theorem 36.1](#), by class universality ([proposition 5.13](#)).

*Second route* (source 23). Each is an ordinary class of set codes and has a class enumeration by Ord. Back-and-forth along such enumerations constructs an isomorphism between any two set-cut saturated proper-class orders. At each stage the previous partial map is a set, the induced cut is a set cut, and a fresh separator extends it. Global choice selects the least available extension in fixed set-like well-orders. These are set-valued stages, so the resulting class map is obtained in GBC. Apply the construction to **No**.

*Remark 81.11* (What the endpoint exception does). If  $\varepsilon$  is immediately before  $a \in A$ , then the augmented alphabet has an adjacent pair  $\varepsilon < a$ . The words do not inherit that adjacency: there are entire cylinders with first letter  $a$ , and within them points below any prescribed set of constraints. This is exactly the minimum case in the proof. Removing  $a$  because it was already used in an injective prefix changes that side into one with no set coinitial family, by [lemma 81.4](#). It does not create a new obstruction.

[merge] This is the two-letter detour of source 16’s proof ([theorem 36.1](#)), and the reason why its adjacent placements  $0^-$  and  $0^+$  give **No** in (S16.6) ([equation \(S16.6\)](#)).

## 81.4 Exact point characters and examples

For an interior marker define

$$\begin{aligned} \chi_- &= \begin{cases} \text{cf}(L), & L \text{ has no maximum and has a set cofinal subset,} \\ \text{Ord}, & \text{otherwise,} \end{cases} \\ \chi_+ &= \begin{cases} \text{ci}(R), & R \text{ has no minimum and has a set coinitial subset,} \\ \text{Ord}, & \text{otherwise.} \end{cases} \end{aligned} \tag{33}$$

When a value is a set cardinal, it is necessarily infinite and regular.

*Note 81.12* (Source 23, Theorem 6.1, “Uniform point characters”). Every point of  $\mathcal{T}_\varepsilon(A)$  and every point of  $\mathcal{I}_\varepsilon(A)$  has left character  $\chi_-$  and right character  $\chi_+$ . The whole orders have no set-sized cofinal or coinitial subset. At most one of  $\chi_-, \chi_+$  can be a set cardinal. For  $A = \mathbf{No}$  the characters are those computed in the proof of [theorem 36.2](#) (source 16), and the last sentence is its observation that both threshold sides cannot fail.

*Second route* (source 23). Fix a word  $p$ . Every element below  $p$  that does not extend  $p$  lies below every extension of  $p$  whose next letter is in  $L$ . Thus the cylinders  $C_{p \smallfrown (a)}$ , for available  $a \in L$ , are cofinal below  $p$ . The available alphabet is  $A' = A$  or  $A \setminus \text{ran } p$ .

If  $L' = L \cap A'$  has no maximum and has set cofinality  $\theta$ , choose a strictly cofinal family of letters of size  $\theta$ . Their one-letter extensions of  $p$  are cofinal below  $p$ . Conversely, the first appended letters of any set cofinal family below  $p$  must be cofinal in  $L'$ : otherwise a child with a larger first appended letter dominates the family. Hence the left character is exactly  $\theta$ .

If  $L'$  has no set cofinal subset, the same projection argument rules out any set cofinal family below  $p$ . If it has maximum  $a$ , its last child cylinder  $C_{p \smallfrown (a)}$  is cofinal below  $p$ , and that cylinder

has no set cofinal subset. [Lemma 81.4](#) identifies these alternatives with the cases in (33), including removal of the original maximum. The right-hand proof is dual.

The assertions about the whole orders are [lemma 81.6](#). If both characters were small, there would be a set cofinal family  $S \subseteq L$  and a set cointial family  $U \subseteq R$ , with neither side having its endpoint. A separator of  $S < U$  in  $A$  could belong to neither side, contradicting  $A = L \sqcup R$ .

#### 81.4.1 Principal placements and reserved labels

A marker immediately before or after any surreal  $a$  is admissible. The side not having its endpoint has no small approach to  $a$ , by surreal set-cut saturation. Thus the corresponding arbitrary-word and injective-word orders are both isomorphic to **No**.

The reserved-central convention uses alphabet  $\mathbf{No} \setminus \{0\}$  and marker 0. Neither side has an endpoint or a small approaching family, so it is another admissible case. This recovers the successful special case in source 13 ([theorem 36.4](#)), while the adjacent placements settle the additional case asked there. ([merge] Pinned provenance: at this report's text the adjacent placements are source 16's (S16.6) ([equation \(S16.6\)](#)), and source 13's question is answered by [theorems 36.1](#) and [36.2](#); see the opening note of this section.)

#### 81.4.2 A regular-cardinal family of failures

For any infinite regular cardinal  $\theta$ , let

$$L_\theta = \{x \in \mathbf{No} : \exists \alpha < \theta (x < \alpha)\}, \quad R_\theta = \mathbf{No} \setminus L_\theta.$$

The ordinals below  $\theta$  are cofinal in  $L_\theta$ . A smaller cofinal set would give, by choosing ordinal upper witnesses for its members, a smaller cofinal set in  $\theta$ . Therefore  $\text{cf } L_\theta = \theta$ . Neither side has an endpoint. For example, an endpoint in  $R_\theta$  would contradict filling the set cut between all  $\alpha < \theta$  and that endpoint. The right side has no set cointial subset by the last argument of [note 81.12](#).

Putting the marker at this cut gives point character  $(\theta, \text{Ord})$  everywhere. Reversing the construction gives  $(\text{Ord}, \theta)$ . Distinct regular cardinals yield nonisomorphic word orders. They remain mutually embeddable with **No** under global choice, as discussed in source 23's Section 8 ([section 111.16](#)). Point characters distinguish isomorphism, not bi-embeddability.

[merge] This is source 16's threshold  $(L_\kappa, R_\kappa)$ , with  $\kappa$  for the regular cardinal, and the word orders are  $\mathbf{T}_\theta$  and  $\mathbf{T}_\theta^{\text{op}}$  of [theorem 36.2](#). Source 16 also shows that every termination order is equimorphic with **No** without global choice (the paragraph after [theorem 36.2](#)).

#### 81.4.3 Genuine two-large-sided gaps

The criterion also permits a marker at a nonprincipal cut with no set cofinal family on either side. Such a cut need not be realized by a surreal. For a concrete example, fix an  $\text{Ord}$ -long sign pattern in which both signs occur beyond every ordinal, such as alternation in consecutive two-position blocks. Compare each set-length sign sequence with this class pattern at its first disagreement or its end. The resulting cut has both sides nonempty and has no set cofinal or cointial family: any set of sequences has bounded lengths, and a sufficiently long prefix ending just before a suitable sign lies closer to the pattern. Its marker therefore produces surreal-isomorphic word orders.

This is not unrestricted cut filling inside **No**. It inserts a new symbol in the *alphabet presentation*, then studies an ordinary class of finite- or transfinite-length set codes built from that alphabet. The isomorphism in [note 81.10](#) is a new order map, not an extension fixing every original numerical label.

## 82 Increasing words: no saturating marker, a product at the terminator, and the zero conventions (sources 23, 27 and 29)

[merge] Part VII left two questions about strictly increasing words open (section 39, items (b) and (d)): the isomorphism type of the centered order  $\mathcal{T}_c^{\text{inc}}$  (source 18’s own question), and increasing words with an interior terminator at a threshold other than zero (source 16’s question “Centered increasing words”). Three batch-83 sources take them up independently. Source 23 shows that no placement of a marker, at zero or elsewhere, makes the increasing-word order set-cut saturated (theorem 82.1); for the threshold at zero this was known from source 16’s remark and source 18’s cut classification (theorem 37.2). Source 27 factors every increasing-word order at its terminator (theorem 82.4), which reduces the centered order to a lexicographic product of the shorter-first order of all words with its reverse (corollary 82.5), classifies the zero conventions up to isomorphism (proposition 82.6), shows that no interval is a surreal interval (theorem 82.7) and computes the point characters at an arbitrary class gap (proposition 82.8). Source 29 proves the factorization, the product and the zero conventions again, without knowledge of source 27; its statements are notes below. Its reduction of every actual threshold, under each zero convention, and of every gap with two large sides (proposition 82.14) is new as a proved statement; source 27 states its two simplest cases in a remark. The three results on thresholds other than zero complement one another; what remains open is recorded in section 85.

In this section, for an alphabet  $D$  (a set or a class, linearly ordered),  $\mathcal{T}^{\text{inc}}(D)$  is the class of strictly increasing set-length words over  $D$ , including the empty word;  $\mathcal{T}_{\text{sf}}^{\text{inc}}(D)$  and  $\mathcal{T}_{\text{lf}}^{\text{inc}}(D)$  compare proper prefixes first and last; and for a cut  $D = L + R$ ,  $\mathcal{T}_\varepsilon^{\text{inc}}(D)$  puts a distinct marker  $L < \varepsilon < R$ . Source 27 writes  $\text{Inc}_\perp$ ,  $\text{Inc}_\top$ ,  $\text{Inc}_C$ ; source 29 writes  $\text{Inc}_{\text{sf}}$ ,  $\text{Inc}_{\text{lf}}$ ,  $\text{Inc}_\dagger$ ; source 23 writes  $\mathcal{U}_e(A)$ .  $\mathbf{T}_{\min}$  is the shorter-first order of all set-length surreal words, repetitions allowed and the empty word included (theorem 36.2; source 27’s  $\mathcal{B}$ , source 29’s  $\mathbf{T}$ ), and  $\mathbf{T}_{\min}^+ = \mathbf{T}_{\min} \setminus \{\emptyset\}$  (source 27’s  $D$ , source 29’s  $\mathbf{P}$ ). The centered order with zero excluded is  $\mathcal{T}_c^{\text{inc}}$  (source 27’s  $J$ , source 29’s  $\mathcal{C}$ ); with zero retained and a distinct terminator immediately below or above it, as in proposition 37.5, the orders are  $\mathcal{T}_{\dagger-}^{\text{inc}}$  (source 27’s  $J_-$ , source 29’s  $\mathcal{C}_-$ ) and  $\mathcal{T}_{\dagger+}^{\text{inc}}$  ( $J_+$ ,  $\mathcal{C}_+$ ); the zero-padding quotient of proposition 37.4 is  $\mathcal{T}_{\text{pad}}^{\text{inc}}(Q_0, \mathcal{C}_{\text{pad}})$ . *False reading:*  $\mathbf{T}_{\min}$  is an order of *all* words; it is not  $\mathcal{T}$  with a central marker, and it is not the order of a binary cube.

### 82.1 Source 23: naturally increasing words, a universal obstruction

Let  $\mathcal{T}_\varepsilon^{\text{inc}}(A)$  be the suborder of all strictly increasing set-length words, for a set-cut saturated class alphabet  $A$  and a marker cut  $A = L \sqcup R$ . It represents exactly the set subsets well-ordered by the inherited numerical order when  $A = \mathbf{No}$ .

**Theorem 82.1** (No fixed marker saturates increasing words). *For every placement of  $\varepsilon$  relative to a set-cut saturated class alphabet  $A$ , the order  $\mathcal{T}_\varepsilon^{\text{inc}}(A)$  is not set-cut saturated. The same conclusion holds after deleting the empty word.*

*Proof.* Suppose first that  $R$  is nonempty. Choose a strictly increasing sequence  $a_0 < a_1 < \dots$  in  $R$ , and let  $p = (a_n)_{n < \omega}$  and  $p_n = p \restriction n$  for  $n \geq 1$ . Then

$$p_1 < p_2 < \dots < p.$$

If a word  $q$  were above every  $p_n$  but below  $p$ , it could not disagree with  $p$  at any finite position: disagreement below would put it below a longer  $p_n$ , and disagreement above would put it above  $p$ . Nor could it end at a finite position. Thus it would properly extend  $p$ . But any new letter of

a strictly increasing extension is greater than  $a_0$ , hence lies in  $R$ . Such an extension lies *above*  $p$ , again a contradiction.

If  $R$  is empty, the marker is above every letter. Choose any strictly increasing sequence  $(a_n)$  in  $A$ . Now  $p < p_{n+1} < p_n$  for all  $n \geq 1$ . A point above  $p$  and below every  $p_n$  would have to properly extend  $p$ , but every proper extension is below  $p$  under the end-last convention. This is impossible. All displayed constraints are nonempty words.  $\square$

*Remark 82.2* (Why the arbitrary injective case escapes). For an admissible interior marker, an arbitrary injective extension can append a fresh letter on either side of the marker, independently of the numerical values of earlier letters. A strictly increasing extension cannot. The failure is therefore caused by the inherited-order condition, not by injectivity or by class size alone.

Every set ordinal is still realized by a strictly increasing surreal word: use its ordinal labels. Every set or class linear order embeds into  $\mathcal{T}_\varepsilon^{\text{inc}}(\mathbf{No})$  under global choice by first embedding it into  $\mathbf{No}$  ([proposition 5.13](#)) and then taking singleton words. Thus universality can coexist with the explicit countable failures of saturation just proved.

*Note 82.3* ([merge]; what is new in [theorem 82.1](#)). For the marker at zero (zero excluded,  $\mathcal{T}_c^{\text{inc}}$ ) the theorem is source 16’s remark at the end of its Subsection 8.1 (printed after (S16.7): “a positive increasing word of length  $\omega$  still has its finite prefixes cofinal below it”) and the obstruction of source 18’s [theorem 37.2](#), which classifies all unfilled set cuts there; the endpoint placements are (S16.5). The theorem is new for every other placement, in particular for the thresholds other than zero left open in [section 39](#), items (b) and (d): no such threshold gives a saturated order, hence (by the set-cut property of  $\mathbf{No}$ ) none gives an order isomorphic to  $\mathbf{No}$ . It does not classify the unfilled cuts at a general threshold; source 27’s [proposition 82.8](#) computes the point characters and source 29’s [proposition 82.14](#) the isomorphism type for gaps with two large sides. Source 23’s proof uses only an  $\omega$ -sequence in  $R$  (or in  $A$ ); it needs neither global choice nor a classification of the threshold.

## 82.2 Source 27: increasing words and an exact split at the terminator

[merge] Source 27’s Section 5, printed whole. Its notation is replaced as listed at the start of this section. Its reference to “the known local behavior” of the centered order is source 18’s [theorem 37.1](#), and its reference to the uniform residual isomorphisms of its Section 6 is [lemma 96.1](#).

The increasing-word interpretation remembers the numerical order much more directly than an arbitrary well-order enumeration. Its restriction also creates a useful factorization that arbitrary words do not possess.

### 82.2.1 A choice-free two-part factorization

For an ordered alphabet  $A$ , let  $\mathcal{T}_{\text{sf}}^{\text{inc}}(A)$  and  $\mathcal{T}_{\text{lf}}^{\text{inc}}(A)$  consist of the strictly increasing set-length words, including the empty word, with proper prefixes respectively smaller and larger. If  $A = L + R$ , write  $\mathcal{T}_\varepsilon^{\text{inc}}(A)$  for the version with a distinct terminator between  $L$  and  $R$ .

**Theorem 82.4** (Factorization at a terminal cut). *For every set or class alphabet  $A = L + R$ ,*

$$\mathcal{T}_\varepsilon^{\text{inc}}(A) \cong \mathcal{T}_{\text{lf}}^{\text{inc}}(L) \times_{\text{lex}} \mathcal{T}_{\text{sf}}^{\text{inc}}(R). \quad (34)$$

*The isomorphism is canonical and uses no choice principle.*

*Proof.* In an increasing word, the  $L$  entries form an initial segment of its ordinal domain, and all remaining entries lie in  $R$ . Thus it has a unique form  $l \frown r$ . Conversely, every such concatenation is increasing because all  $L$  letters precede all  $R$  letters numerically.

If  $l, l'$  differ at actual entries, that difference decides the full words. If  $l$  is a proper prefix of  $l'$ , the next token of  $l' \frown r'$  lies in  $L$ , whereas the corresponding token of  $l \frown r$  is the terminator or lies in  $R$ . Therefore the entire block indexed by  $l'$  precedes the entire block indexed by  $l$ , exactly as in  $\mathcal{T}_{\text{lf}}^{\text{inc}}(L)$ . At equal  $l$ , every possible tail letter is above the terminator, so the tails are compared by  $\mathcal{T}_{\text{sf}}^{\text{inc}}(R)$ . This proves both bijectivity and order preservation.  $\square$

The first coordinate in (34) is primary. The factorization would fail for unrestricted words, which may repeatedly return from  $R$  to  $L$ .

### 82.2.2 The centered surreal order

Let  $\mathbf{T}_{\min}$  be all set-length surreal words, with repetitions permitted and proper prefixes smaller. Let  $\mathcal{T}_c^{\text{inc}}$  be the increasing words over  $\mathbf{No} \setminus \{0\}$ , with negative letters below the terminator and positive letters above it.

The following standard construction, used in the repository (theorems 35.1 and 35.7), is worth making explicit. After any increasing positive prefix, its permissible next letters form the ray above a set of surreals. After any increasing negative prefix, its permissible negative letters form the interval above that set and below 0. Both fill every separated set cut and have no endpoints. With a fixed global enumeration, set-state back-and-forth identifies each such class order with  $\mathbf{No}$ , uniformly in the prefix. Recursively applying these child isomorphisms to a set-length word gives an isomorphism of the corresponding rooted word trees. Every individual recursion has set length; no class of chosen class isomorphisms is needed. This argument is justified in greater detail for residual alphabets in lemma 96.1.

**Corollary 82.5** (A product description of the centered order). *In GBC,*

$$\boxed{\mathcal{T}_c^{\text{inc}} \cong \mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}} \quad (35)$$

*Proof.* The tree construction identifies  $\mathcal{T}_{\text{sf}}^{\text{inc}}(\mathbf{No}_{>0})$  with  $\mathbf{T}_{\min}$ . It identifies  $\mathcal{T}_{\text{lf}}^{\text{inc}}(\mathbf{No}_{<0})$  with the proper-prefix-larger arbitrary-word order. Coordinatewise negation identifies the latter with  $\mathbf{T}_{\min}^{\text{op}}$ : it reverses actual letter comparisons, and taking the opposite reverses the prefix convention. Apply theorem 82.4.  $\square$

This is an explicit isomorphism type in terms of an already studied word order, not an identification with  $\mathbf{No}$ . It also applies to a genuine gap  $\mathbf{No} = L + R$  when  $L$  has no set cofinal subset and  $R$  has no set coinital subset: the same admissible-child orders fill all set cuts. A threshold at an actual surreal point, with that point excluded, is the simpler special case obtained by translation.

[merge] Corollary 82.5 answers the first open item of section 39 (b) in part: it reduces the isomorphism type of  $\mathcal{T}_c^{\text{inc}}$  to that of  $\mathbf{T}_{\min}$ , the endpoint type of source 16's classification (theorem 36.2). It is consistent with source 18's corollary 37.9: the fibre over an all-negative prefix is a copy of  $\mathbf{T}_{\min}$  and is the positive-tail part of that prefix's cone. It does not identify  $\mathcal{T}_c^{\text{inc}}$  with  $\mathbf{No}$  (corollary 37.3), and whether  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$  is isomorphic to  $\mathbf{T}_{\min}^+$  is source 27's Question 12.4.

### 82.2.3 What happens when zero is retained

Different ways of retaining zero need not give different abstract order types, even though they give different labelled words. Set  $\mathbf{T}_{\min}^+ = \mathbf{T}_{\min} \setminus \{\emptyset\}$ . Splitting at the first letter gives

$$\mathbf{T}_{\min}^+ \cong \mathbf{No} \times_{\text{lex}} \mathbf{T}_{\min}, \quad \mathbf{T}_{\min} \cong 1 + \mathbf{T}_{\min}^+.$$

Since  $\mathbf{No} + \mathbf{No}$  fills all set cuts and has no endpoints, class back-and-forth gives  $\mathbf{No} + \mathbf{No} \cong \mathbf{No}$ . Hence  $\mathbf{T}_{\min}^+ + \mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}^+$  and  $\mathbf{T}_{\min} + \mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}$ . Splitting  $\mathbf{No}$  at zero also gives  $\mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}^+ + \mathbf{T}_{\min} + \mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}^+ + \mathbf{T}_{\min}$ . In particular

$$\mathbf{T}_{\min}^+ + \mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}^+, \quad \mathbf{T}_{\min}^+ + \mathbf{T}_{\min} \cong \mathbf{T}_{\min}^+, \quad \mathbf{T}_{\min} + \mathbf{T}_{\min} \cong \mathbf{T}_{\min}. \quad (36)$$

Let  $\mathcal{T}_{\dagger+}^{\text{inc}}$  retain zero and place  $0 < \dagger_+$  below all positives. Let  $\mathcal{T}_{\dagger-}^{\text{inc}}$  instead place all negatives below  $\dagger_- < 0$ . Let  $\mathcal{T}_{\text{pad}}^{\text{inc}}$  be the quotient of increasing words by equality of their zero extensions. An equivalence class has a unique representative obtained by deleting a final zero if one is present; an internal zero before positive entries remains.

**Proposition 82.6** (Exact zero-convention types). *In GBC,*

$$\mathcal{T}_{\dagger+}^{\text{inc}} \cong \mathcal{T}_{\text{pad}}^{\text{inc}} \cong \mathcal{T}_c^{\text{inc}}, \quad \mathcal{T}_{\dagger-}^{\text{inc}} \cong \mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} (1 + \mathbf{T}_{\min}).$$

*The adjacent pairs in  $\mathcal{T}_{\dagger-}^{\text{inc}}$  are exactly  $p < p \frown (0)$  for all-negative prefixes  $p$ , including the empty one.*

*Proof.* For  $\mathcal{T}_{\dagger+}^{\text{inc}}$ , the negative-or-zero part is either an all-negative word  $p$  or  $p \frown (0)$ . In the upper-terminator comparison these form a consecutive pair  $p \frown (0) < p$ . Therefore the first factor has type  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} 2$  and the second has type  $\mathbf{T}_{\min}$ . Absorption of  $\mathbf{T}_{\min} + \mathbf{T}_{\min}$  gives the result.

For  $\mathcal{T}_{\text{pad}}^{\text{inc}}$ , fix an all-negative prefix. Its reduced tails occur in three successive forms: empty; zero followed by a nonempty positive word; a nonempty positive word. Their types are  $1, \mathbf{T}_{\min}^+, \mathbf{T}_{\min}^+$ , giving  $1 + \mathbf{T}_{\min}^+ + \mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}$  for each negative-prefix block.

For  $\mathcal{T}_{\dagger-}^{\text{inc}}$ , the nonnegative tail has three successive parts: the empty word, the cone beginning with 0, and the cones beginning positively. Their types are  $1, \mathbf{T}_{\min}, \mathbf{T}_{\min}^+$ , whose sum is  $1 + \mathbf{T}_{\min}$  by (36). The first two elements of this tail order are consecutive. All other comparisons admit interpolation by a fresh numerical letter, proving the exact adjacency assertion.  $\square$

These isomorphisms do not preserve the original labelled words or their prefix trees. In particular, a quotient that merges  $p$  with  $p \frown (0)$  can have the same abstract order type as a convention that keeps them distinct.

[merge] The adjacency clause is source 18's [corollary 37.7](#); the isomorphism types are new. They answer, up to isomorphism, the comparison of the zero conventions that [propositions 37.4](#) and [37.5](#) and [corollary 37.7](#) make at the level of cuts: three of the four conventions have one type, and the fourth differs from it exactly by the adjacent pairs.

### 82.2.4 Every interval is rich, but none is a surreal interval

For a point  $x$  of an order, its left character means the cofinality of the open initial segment below  $x$ ; its right character is the coinitality above it. “Proper” below means no set cofinal, or coinital, family exists. It is not a cardinal named Ord.

The known local behavior in  $\mathcal{T}_c^{\text{inc}}$  is simple: every right character is proper; the left character is  $\text{cf}(\alpha)$  when a word has positive entries and nonzero limit length  $\alpha$ , and is proper for the other words

(theorem 37.1). At a positive limit word, sufficiently long proper prefixes form a cofinal sequence. For a smaller family, disagreement coordinates are bounded, so it is not cofinal. At a successor word, the set-cut property supplies a fresh intermediate last letter above any specified set of lower competitors.

**Theorem 82.7** (Convex word cones in every interval). *Every nonempty open interval of  $\mathcal{T}_c^{\text{inc}}$  contains a convex cone isomorphic to  $\mathbf{T}_{\min}$ . Every such interval contains points of left character  $\lambda$  for every infinite regular set cardinal  $\lambda$ , and also points with proper left character. No nonempty open interval of  $\mathcal{T}_c^{\text{inc}}$  is isomorphic to  $\mathbf{No}$ , and  $\mathcal{T}_c^{\text{inc}}$  has no convex suborder isomorphic to  $\mathbf{No}$ .*

*Proof.* Given  $f < g$ , choose a prefix whose comparisons with  $f, g$  are already settled strictly. If their first difference is at actual entries, use an intermediate letter above the common prefix. If  $f$  is a proper prefix of  $g$ , the next letter of  $g$  is positive; use a smaller admissible positive letter. If  $g$  is a proper prefix of  $f$ , the next letter of  $f$  is negative; use a larger admissible negative letter. All these choices follow from the surreal set-cut property.

Append a positive letter if necessary, keeping the comparisons already settled. The resulting prefix  $p$  ends positively. Its entire extension cone is convex, lies inside  $(f, g)$ , and has only letters above the terminator available afterward. The rooted-tree construction identifies that cone with  $\mathbf{T}_{\min}$ .

Append to  $p$  a strictly increasing positive tail of length  $\lambda$ . The resulting length has cofinality  $\lambda$ , and the local-character calculation gives left character exactly  $\lambda$ . A successor-length extension gives proper left character. Taking  $\lambda = \omega$  gives a set cofinal below a point inside the interval; this is an unfilled strict set cut with that point as upper endpoint. Every surreal interval fills all separated set cuts, so no such interval is isomorphic to  $\mathbf{No}$ . Finally, a convex copy of  $\mathbf{No}$  would contain a nonempty ambient interval isomorphic to a surreal interval, which has just been excluded.  $\square$

Each convex cone above contains a copy of  $\mathbf{No}$  among its one-letter tails. Thus every interval contains surreal copies, but these copies are necessarily nonconvex. Universality and convex realization are different questions even at this very local level.

[merge] This strengthens source 18's remark after corollary 37.3 (every nonempty open interval contains a nonconvex copy of  $\mathbf{No}$ ); the convex cone of type  $\mathbf{T}_{\min}$  is the positive-prefix case of corollary 37.9.

### 82.2.5 Genuine gap thresholds produce additional behavior

The factorization in theorem 82.4 works for any class gap  $\mathbf{No} = L + R$ . A concise exact local classification records what changes. Assume both sides are nonempty. Let  $\lambda_L = \text{cf}(L)$  if  $L$  has no maximum and has a set cofinal subset, and put  $\lambda_L = \text{proper}$  otherwise. Let  $\lambda_R = \text{ci}(R)$ , allowing 1 for a minimum and proper when no set is coinital.

**Proposition 82.8** (Characters at a general terminal gap). *The order  $\mathcal{T}_\varepsilon^{\text{inc}}(\mathbf{No})$  has no endpoints, and its characters are as follows. In the last two rows the word has successor length.*

| Word                                                     | Left character      | Right character |
|----------------------------------------------------------|---------------------|-----------------|
| All letters in $L$ , including the empty word            | $\lambda_L$         | $\lambda_R$     |
| An $R$ letter occurs; length $\alpha$ is a nonzero limit | $\text{cf}(\alpha)$ | proper          |
| $p \frown (\min R)$ with $p$ entirely in $L$             | 1                   | proper          |
| Every other successor word with an $R$ letter            | proper              | proper          |

The only adjacent pairs are  $p < p \frown (\min R)$  when  $\min R$  exists.

*Proof.* Above an all- $L$  word, the first new letter must lie in  $R$ ; its coinital possibilities give exactly  $\lambda_R$ . A least such letter gives the stated immediate successor. After an  $R$  letter has occurred, a new letter can be chosen above the whole prefix and below every relevant letter of a given set of upper competitors. Thus the right character is proper.

Below an all- $L$  word, if  $L$  has no maximum and its range is not cofinal in  $L$ , the possible new  $L$  letters form a cofinal tail of  $L$ , giving character  $\lambda_L$ . If the range is cofinal, its length is a limit of cofinality  $\lambda_L$ . Increasing the common-prefix length and then replacing the next letter by a smaller admissible one gives a cofinal family of that size; bounded disagreement coordinates exclude a smaller one. If  $L$  has no set cofinal family, append an  $L$  letter above all relevant set constraints instead.

When  $L$  has a maximum  $m$ , a word not yet containing  $m$  can move closer from below through the cone beginning with  $m$  and then arbitrarily large  $R$  letters. No set is cofinal in that cone. For a word ending at  $m$ , replace its final letter by one below  $m$  but above all earlier and competing set constraints. Its left character is again proper, which explains why a maximum of  $L$  does not give character 1 in the first row.

After entering  $R$ , a limit-length word is approached by its long proper prefixes, giving  $\text{cf}(\alpha)$ . At a successor word the only obstruction to interpolation at its last letter is that this letter is  $\min R$  and the earlier prefix is all in  $L$ . This is exactly the adjacent pair already identified. Otherwise include an  $R$  letter below the last letter among the lower constraints and use the set-cut property. The same constructions give a point on each side of every word, proving the absence of endpoints.  $\square$

For a concrete gap let

$$L_0 = \{x : x < n \text{ for some } n < \omega\}, \quad R_0 = \{x : n \leq x \text{ for every } n < \omega\}.$$

Here  $\text{cf}(L_0) = \omega$  and  $R_0$  has no set coinital subset; a set of such elements would admit a smaller surreal still above all integers. Reversing and negating this gap gives a right side of coinitality  $\omega$ . The associated increasing-word order has points of right character  $\omega$ , and therefore cannot be isomorphic to the standard centered  $\mathcal{T}_c^{\text{inc}}$ , whose right characters are all proper. Changing only the character of the distinguished empty word would not by itself prove nonisomorphism of unmarked orders; the right-character argument uses the full point spectrum.

[merge] [Proposition 82.8](#) answers in part the second open item of [section 39](#) (b) and item (d): it gives the point characters, and with them the adjacent pairs, at every interior threshold; with [source 23's theorem 82.1](#) (no threshold saturates) and [source 29's proposition 82.14](#) (actual thresholds and gaps with two large sides give  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ ) it settles the isomorphism type except at gaps with a small cofinality or coinitality on one side. There, characters distinguish such an order from  $\mathcal{T}_c^{\text{inc}}$ , as just shown, but the general cut classification “was not proved” ([source 27's audit](#)), and [source 27's Question 12.5](#) asks for the isomorphism types. The threshold  $L_0$  is [source 16's](#) “natural numbers” threshold printed before [theorem 36.2](#), and its reverse is [source 23's](#)  $(L_\omega, R_\omega)$  of [section 81.4.2](#), there for all words.

### 82.3 Source 29: a canonical product and the zero conventions

[merge] [Source 29's Section 6](#), printed whole. It proves [source 27's](#) factorization, centered product and zero-convention types independently; those statements are notes quoting [source 29's](#) formulation, followed by its proofs as second routes. Its threshold reduction ([proposition 82.14](#)) and its explicit absorption identity  $\mathbf{T}_{\min}^+ + 1 + \mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}^+$  are new; the collapsing clause of [note 82.13](#), that identifying the adjacent pairs of  $\mathcal{T}_{+-}^{\text{inc}}$  gives  $\mathcal{T}_c^{\text{inc}}$ , is not stated by [source 27](#). The threshold reduction

is printed as a proposition, since source 27 only remarks on its two cases. Source 29's local isomorphisms  $\theta_p$  are printed  $h_p$ , as in the proof of [theorem 35.1](#); its product  $\otimes_{\text{lex}}$  is printed  $\times_{\text{lex}}$ .

All words in this section have *set ordinal length*. Their entries may range over the whole surreal class, but each individual word is a set graph. The resulting word spaces and their products are therefore ordinary classes of sets. They should be distinguished from collections whose individual points are proper-class well-orders.

The repository already identifies the shorter-first trees of free, injective, and numerically increasing surreal words, and determines the set-cut obstructions for centered increasing words ([theorems 35.1](#), [35.7](#) and [37.2](#)). We use those mechanisms to obtain an explicit product description and to compare the different treatments of the entry zero up to isomorphism.

### 82.3.1 Splitting an increasing word at its terminator

For a linearly ordered alphabet  $D$ , let  $\mathcal{T}^{\text{inc}}(D)$  be the set or class of all strictly increasing set-length  $D$ -words, including the empty word. The notations  $\mathcal{T}_{\text{sf}}^{\text{inc}}(D)$  and  $\mathcal{T}_{\text{lf}}^{\text{inc}}(D)$  mean that proper prefixes come first and last, respectively; first unequal entries always compare in the order of  $D$ . For orders  $A, B$ , write

$$A \times_{\text{lex}} B = \sum_{a \in A} B.$$

Thus the first coordinate is decisive. The notation records an *ordered* product and makes no commutativity assertion.

Suppose  $D = L + R$  is an initial/final partition, and put a distinct formal terminator  $\varepsilon$  between its parts:

$$L < \varepsilon < R.$$

The word order  $\mathcal{T}_{\varepsilon}^{\text{inc}}(D)$  compares the terminator against the next entry when one word is a proper prefix of another. Either side of the partition is allowed to be empty.

*Note 82.9* (Source 29, Theorem 6.1, “Canonical factorization”). *For any such ordered alphabet and terminator,*

$$\mathcal{T}_{\varepsilon}^{\text{inc}}(D) \cong \mathcal{T}_{\text{lf}}^{\text{inc}}(L) \times_{\text{lex}} \mathcal{T}_{\text{sf}}^{\text{inc}}(R).$$

*The isomorphism is the canonical decomposition into the maximal initial  $L$ -word and the remaining  $R$ -word. For a class alphabet, the statement uses only elementary class definitions and set operations; Global Choice is not required.* This is source 27's [theorem 82.4](#).

*Second route* (source 29). If  $f : \alpha \rightarrow D$  is increasing, the indices at which its entries belong to  $L$  form an initial segment of  $\alpha$ , say  $\beta$ . The remaining interval of indices has a unique ordinal order type  $\gamma$ . Thus  $f$  splits uniquely as

$$f = u \frown v, \quad u \in \mathcal{T}^{\text{inc}}(L), \quad v \in \mathcal{T}^{\text{inc}}(R).$$

Conversely, every such concatenation is increasing because  $L < R$ . The domains, restrictions, ordinal tail, and concatenation are sets. This proves the claimed bijection of carriers.

Consider two pairs  $(u, v)$  and  $(u', v')$ . If  $u, u'$  disagree at a common coordinate, their first unequal  $L$ -entries decide the comparison of both concatenated words, independently of their  $R$ -tails. If  $u$  is a proper prefix of  $u'$ , the next entry of  $u'$  belongs to  $L$ . At that position  $u \frown v$  either terminates or has an entry in  $R$ . In either case it is larger. Hence the entire  $u'$ -fiber lies below the entire  $u$ -fiber, exactly as required by longer-first comparison on the first factor. The reverse prefix case is symmetric.

Finally, when  $u = u'$ , the tails use only entries above  $\varepsilon$ . Their comparison is therefore shorter-first lexicography on  $R$ . These cases prove the order identity.

This factorization does not require a numerical bound for the entire alphabet. In particular, it remains valid when the two sides of the terminator are proper classes. The theorem applies to set-length words even when the partition itself cannot be specified by an actual surreal number.

### 82.3.2 The two surreal factors

Let  $\mathbf{T}_{\min}$  be the shorter-first order of all set-length surreal words, with repetitions allowed and the empty word included. Put

$$\mathbf{T}_{\min}^+ = \mathbf{T}_{\min} \setminus \{\emptyset\}.$$

The empty word is the minimum of  $\mathbf{T}_{\min}$ . We will use the following form of the repository's prefix-tree construction, including its uniformity requirement ([theorem 35.7](#)).

*Note 82.10* (Source 29, Lemma 6.2, “Uniform isomorphisms of admissible alphabets”). *Work in GBC with a fixed set-like global well-order. Suppose a class of permitted set words contains the empty word and is closed under restrictions and unions of coherent set-length prefix chains. Suppose it has, after each permitted prefix  $p$ , a proper class  $D_p$  of admissible next letters, giving exactly its permitted one-letter extensions. Assume these classes are uniformly defined from  $p$  and fixed class parameters, and each fills every separated set cut, including cuts with an empty side. Then its ordered prefix tree is isomorphic to the free surreal-word tree, preserving word lengths, prefixes, and comparison of first unequal entries. The same tree isomorphism preserves either shorter-first or longer-first comparison. This is the construction of [theorem 35.1](#) (source 16) and [theorem 35.7](#) (source 18), stated for an arbitrary uniformly given family of admissible alphabets; source 27 uses it in the proof of [corollary 82.5](#) and states the residual case as [lemma 96.1](#).*

*Second route (source 29).* For each prefix  $p$ , construct an increasing bijection  $h_p : \mathbf{No} \rightarrow D_p$  by deterministic back-and-forth. Restrict the fixed global well-order to the two alphabets. At each ordinal stage, map the least unused point on the source side to the least unused point in the cut required by the current partial map, and then do the reverse insertion. The partial map and all cut constraints at a set ordinal stage are sets. Set-cut filling supplies each insertion.

This construction is uniform: membership in  $h_p$  is expressed by existence of a set-length initial history of the deterministic construction. The parameters of that assertion are  $p$ , the fixed class definitions, and the global well-order. One elementary class relation therefore gives all  $h_p$  simultaneously. There is no independent choice of a class isomorphism for each prefix.

Given a free source word  $f$ , construct a permitted target word  $g$  by ordinary set recursion,

$$g(\xi) = h_{g \upharpoonright \xi}(f(\xi)).$$

The inverse uses  $h_{g \upharpoonright \xi}^{-1}$  at each coordinate. Thus this is a length-preserving bijection of the two word trees. A shared source prefix gives a shared target prefix, and the same increasing letter map acts at the first unequal coordinate. This preserves first-entry comparisons. Prefix comparisons are preserved for either of the two specified conventions.

The lemma applies to increasing words over each half of the surreal line. After a negative prefix  $p$ , the admissible negative alphabet is

$$D_p^- = \{x : \text{ran}(p) < x < 0\}.$$

For separated sets  $A < B$  in this alphabet, add  $\text{ran}(p)$  to the lower constraints and 0 to the upper constraints. The surreal set-cut property supplies another point of  $D_p^-$ . The same argument handles

an empty side. For positive prefixes the admissible alphabet is

$$D_p^+ = \{x : \{0\} \cup \text{ran}(p) < x\};$$

add  $\{0\} \cup \text{ran}(p)$  to the lower constraints. These classes are proper: if one were a set, its own elements could be placed on one side of a cut that would require a point beyond all of them in that same class.

*Note 82.11* (Source 29, Corollary 6.3, “The centered increasing-word product”). Let  $\mathcal{T}_c^{\text{inc}}$  be the order of strictly increasing set-length words over  $\mathbf{No} \setminus \{0\}$ , with

$$\mathbf{No}_{<0} < \dagger < \mathbf{No}_{>0}.$$

In GBC,  $\mathcal{T}_c^{\text{inc}} \cong \mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ . This is source 27’s [corollary 82.5](#).

*Second route (source 29).* By [note 82.10](#),  $\mathcal{T}_{\text{sf}}^{\text{inc}}(\mathbf{No}_{>0}) \cong \mathbf{T}_{\min}$ . The same lemma identifies longer-first increasing negative words with longer-first *free* surreal words. On free words, entrywise negation reverses comparison of unequal entries and converts a longer-first comparison into the reverse of a shorter-first comparison. Consequently

$$\mathcal{T}_{\text{lf}}^{\text{inc}}(\mathbf{No}_{<0}) \cong \mathbf{T}_{\min}^{\text{op}}.$$

Apply [note 82.9](#). Passing first to free words is essential: negating an increasing word directly gives a decreasing word.

The factorization explains the two kinds of cones already isolated in the repository ([corollary 37.9](#)). An all-negative prefix still allows both a negative part and a positive part. Once a positive entry has occurred, only the shorter-first positive-tail factor remains. The product is an explicit description in previously studied orders. It does not by itself assert that its displayed factors or fibers can be recovered from the pure linear order.

### 82.3.3 Absorption in the dictionary order

Some useful ordered-sum identities make the zero conventions much closer up to isomorphism than their definitions suggest.

*Note 82.12* (Source 29, Lemma 6.4, “Dictionary absorption”). In GBC,

$$\begin{aligned} \mathbf{T}_{\min}^+ &\cong \mathbf{No} \times_{\text{lex}} \mathbf{T}_{\min}, & \mathbf{T}_{\min}^+ + \mathbf{T}_{\min}^+ &\cong \mathbf{T}_{\min}^+, \\ \mathbf{T}_{\min}^+ + 1 + \mathbf{T}_{\min}^+ &\cong \mathbf{T}_{\min}^+, & \mathbf{T}_{\min} + \mathbf{T}_{\min} &\cong \mathbf{T}_{\min}. \end{aligned}$$

Three of the four identities are source 27’s ([equation \(36\)](#) and the display before it); the third is equivalent to source 27’s  $\mathbf{T}_{\min}^+ + \mathbf{T}_{\min} \cong \mathbf{T}_{\min}^+$ , since  $\mathbf{T}_{\min} = 1 + \mathbf{T}_{\min}^+$ .

*Second route (source 29).* Every nonempty free word splits into its first letter and its tail, so  $\mathbf{T}_{\min}^+ \cong \mathbf{No} \times_{\text{lex}} \mathbf{T}_{\min}$ . The two-copy sum  $\mathbf{No} + \mathbf{No}$  fills every set cut and has no endpoints. For example, if lower constraints enter the second copy, interpolate there; if upper constraints enter the first, interpolate there. In the remaining case all lower constraints are in the first copy and all upper constraints in the second, and one can choose in the second copy below its set of upper constraints. Empty sides cause no problem. Class back-and-forth in GBC therefore gives  $\mathbf{No} + \mathbf{No} \cong \mathbf{No}$ , and hence

$$\mathbf{T}_{\min}^+ + \mathbf{T}_{\min}^+ \cong (\mathbf{No} + \mathbf{No}) \times_{\text{lex}} \mathbf{T}_{\min} \cong \mathbf{T}_{\min}^+.$$

Now split  $\mathbf{T}_{\min}^+$  at the one-letter word  $q = \langle 0 \rangle$ . The part below  $q$  consists exactly of the words with negative first letter, and has type  $\mathbf{No}_{<0} \times_{\text{lex}} \mathbf{T}_{\min} \cong \mathbf{T}_{\min}^+$ . The part above  $q$  consists of

the nonempty tails in the zero cone, followed by the words with positive first letter. Each part has type  $\mathbf{T}_{\min}^+$ , so their sum has type  $\mathbf{T}_{\min}^+$  by the identity just proved. Splitting at  $q$  thus gives  $\mathbf{T}_{\min}^+ \cong \mathbf{T}_{\min}^+ + 1 + \mathbf{T}_{\min}^+$ . Finally  $\mathbf{T}_{\min} = 1 + \mathbf{T}_{\min}^+$ , whence

$$\mathbf{T}_{\min} + \mathbf{T}_{\min} = 1 + \mathbf{T}_{\min}^+ + 1 + \mathbf{T}_{\min}^+ \cong 1 + \mathbf{T}_{\min}^+ = \mathbf{T}_{\min}.$$

All products and ordered sums here have set-coded points.

In particular, the proper-class boundary between two copies of **No** does not contradict set-cut saturation: no set is cofinal in the first copy or cinitial in the second. The proof never treats those entire copies as set-sized cut constraints.

### 82.3.4 An exact comparison of the zero conventions

Retaining zero as an actual entry requires a choice in addition to saying that termination is centered. We compare the following four orders, always using strictly increasing set-length words:

$$\begin{aligned} \mathcal{T}_c^{\text{inc}} &: \text{zero excluded, with termination in its place;} \\ \mathcal{T}_{\dagger+}^{\text{inc}} &: \mathbf{No}_{<0} < 0 < \dagger_+ < \mathbf{No}_{>0}; \\ \mathcal{T}_{\dagger-}^{\text{inc}} &: \mathbf{No}_{<0} < \dagger_- < 0 < \mathbf{No}_{>0}; \\ \mathcal{T}_{\text{pad}}^{\text{inc}} &: \text{zero padding, with equal padded words identified.} \end{aligned}$$

The distinct terminators in the middle two cases are formal symbols, not additional numerical entries. In the last case every word is extended by zero at all later ordinal coordinates and comparison is at the first unequal coordinate. On the original words this is a preorder; taking the indicated quotient is necessary.

For increasing words, a canonical padded representative is obtained by removing a terminal zero when one is present. Such a zero can only follow negative entries. No other terminal zero tail is possible in a strictly increasing word. Equality after padding is exactly equality of these reduced representatives, so the quotient has an ordinary class of set representatives.

*Note 82.13* (Source 29, Theorem 6.5, “The zero-convention isomorphism types”). *In GBC*,

$$\mathcal{T}_c^{\text{inc}} \cong \mathcal{T}_{\dagger+}^{\text{inc}} \cong \mathcal{T}_{\text{pad}}^{\text{inc}} \cong \mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}, \quad \mathcal{T}_{\dagger-}^{\text{inc}} \cong \mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} (2 + \mathbf{T}_{\min}^+).$$

*The first three orders are dense without endpoints. The adjacent pairs of  $\mathcal{T}_{\dagger-}^{\text{inc}}$  are exactly*

$$u < u \frown \langle 0 \rangle, \quad \text{ran}(u) < 0.$$

*The empty word is allowed for  $u$ . Collapsing these two-point intervals and leaving every other point alone gives an order isomorphic to  $\mathcal{T}_c^{\text{inc}}$ .* The isomorphism types and the adjacent pairs are source 27’s [proposition 82.6](#) (with  $1 + \mathbf{T}_{\min} = 2 + \mathbf{T}_{\min}^+$ ); the adjacent pairs are also source 18’s [corollary 37.7](#). Density without endpoints and the collapsing clause are proved only here.

*Second route (source 29).* Put  $A = \mathcal{T}_{\text{lf}}^{\text{inc}}(\mathbf{No}_{<0}) \cong \mathbf{T}_{\min}^{\text{op}}$ . Nonempty increasing positive words have type  $\mathbf{T}_{\min}^+$ , because the prefix-tree isomorphism used in [note 82.11](#) fixes the empty root. We examine the fibers over a negative word  $u$ .

For  $\mathcal{T}_{\dagger+}^{\text{inc}}$ , the initial nonpositive word is uniquely either  $u \frown \langle 0 \rangle$  or  $u$ . Under longer-first comparison they occur in exactly that order. Each has an arbitrary increasing positive tail, including an empty tail, so each contributes a copy of  $\mathbf{T}_{\min}$ . The fiber over  $u$  consequently has type  $\mathbf{T}_{\min} + \mathbf{T}_{\min} \cong \mathbf{T}_{\min}$ . The order of different negative prefixes is  $A$ , by the same comparison as in [note 82.9](#). Thus  $\mathcal{T}_{\dagger+}^{\text{inc}} \cong A \times_{\text{lex}} \mathbf{T}_{\min}$ .

For  $\mathcal{T}_{\text{pad}}^{\text{inc}}$ , a reduced representative with negative prefix  $u$  either stops there, has zero followed by a nonempty positive word, or has a nonempty positive word immediately. These three parts occur in the displayed order: after  $u$ , zero agrees with padded termination, and the next positive entry makes the zero-containing word larger than the reduced root; an immediate positive entry is larger still at the earlier coordinate. The fiber therefore has type

$$1 + \mathbf{T}_{\min}^+ + \mathbf{T}_{\min}^+ \cong 1 + \mathbf{T}_{\min}^+ = \mathbf{T}_{\min}.$$

This proves the padded-quotient assertion.

For  $\mathcal{T}_{\text{t-}}^{\text{inc}}$ , the fiber over  $u$  consists, in order, of the root  $u$  itself; the entire cone beginning with  $u \frown \langle 0 \rangle$ ; and the nonempty tails whose first new entry is positive. The middle cone has type  $\mathbf{T}_{\min}$ , including its root. Thus the fiber is

$$1 + \mathbf{T}_{\min} + \mathbf{T}_{\min}^+ = 2 + \mathbf{T}_{\min}^+ + \mathbf{T}_{\min}^+ \cong 2 + \mathbf{T}_{\min}^+.$$

This proves the second product formula.

The order  $\mathbf{T}_{\min}$  is dense: between different first entries choose an intermediate entry, and between a proper prefix and an extension choose a first new entry smaller than that of the extension. It has no greatest point because every word has a proper extension. Its reverse has no least point. Hence  $A \times_{\text{lex}} \mathbf{T}_{\min}$  is dense without endpoints, including at comparisons involving different fibers.

In a  $\mathcal{T}_{\text{t-}}^{\text{inc}}$  fiber, the first two points are adjacent. There is no point between  $u$  and  $u \frown \langle 0 \rangle$ : an extension of  $u$  whose next entry is positive exceeds the latter, and an extension whose next entry is negative is below  $u$ . Any continuation after the zero also exceeds the latter. The remaining parts of the fiber are dense, and the second point is followed by a copy of  $\mathbf{T}_{\min}^+$  with no least point. Different fibers have infinitely many points between them, since their index order  $A$  is dense. There are consequently no other adjacent pairs and no larger finite-interval blocks.

Collapsing the initial two points of each fiber replaces  $2 + \mathbf{T}_{\min}^+$  by  $1 + \mathbf{T}_{\min}^+ = \mathbf{T}_{\min}$  and keeps the index  $A$ . The quotient is therefore  $A \times_{\text{lex}} \mathbf{T}_{\min} \cong \mathcal{T}_c^{\text{inc}}$ . One can implement it by retaining the smaller representative of each adjacent pair; no class of proper-class equivalence classes is introduced.

The original presentations thus give two types among these four conventions. The distinction caused by a terminator immediately below zero survives in the pure order through adjacency. In the other three cases, the different presentations can be absorbed by the ordered-sum identities of [note 82.12](#). The isomorphisms are not assertions that the original words, their entries, or their negative-prefix fibers are identified pointwise.

### 82.3.5 Numerical thresholds and genuine remaining parameters

**Proposition 82.14** (Threshold reductions). *For every actual surreal  $c$ , the conventions centered at  $c$  transfer to the corresponding conventions at zero by entrywise translation  $x \mapsto x - c$ . This includes deletion of the entry  $c$ , either adjacent distinct terminator, and padding by  $c$  with its quotient.*

*More generally, suppose  $\mathbf{No} = L + R$  is a partition into nonempty classes,  $L$  has neither a greatest member nor a set cofinal subset, and  $R$  has neither a least member nor a set coinital subset. The increasing-word order with terminator at this cut is, in GBC, isomorphic to  $\mathbf{T}_{\min}^{\text{op}} \times_{\text{lex}} \mathbf{T}_{\min}$ .*

*Proof.* Translation preserves and reflects numerical inequalities, preserves strict increase, and sends  $c$  to zero. It also sends padding by  $c$  to zero padding. All first-disagreement and termination comparisons are therefore preserved.

For the second assertion, each of  $L, R$  fills every separated set cut relative to itself. For instance, a cut in  $L$  with a nonempty upper side can be filled in  $\mathbf{No}$  and its filler lies in  $L$ ; when the upper side is empty, the absence of a set cofinal subset provides a point above the lower constraints. The

argument for  $R$  is dual. After a set increasing prefix in  $L$ , its remaining upper part is still proper and set-cut saturated, by adding that prefix to the lower constraints. The same holds in  $R$ . Apply [notes 82.9](#) and [82.10](#).  $\square$

An actual numerical threshold is therefore not an additional isomorphism parameter. Nor are the two large sides of a nonprincipal class gap, under the stated hypotheses. A nonprincipal cut with a one-sided *set* cofinality or cointinality is different: a set increasing prefix can then exhaust the available room on one side. The canonical factorization still holds, but the saturated-alphabet identifications used above need not apply. This is the remaining threshold issue; the proof does not transfer the repository's complete free-word termination classification to increasing words.

Finally,  $\mathcal{T}_c^{\text{inc}}$  is not isomorphic to **No**. The positive word  $\langle 1, 2, 3, \dots \rangle$  is the supremum of its finite prefixes in  $\mathcal{T}_c^{\text{inc}}$ : any smaller word disagrees earlier in the smaller direction or is one of its proper prefixes. Such a nontrivial set supremum cannot occur in **No**, since a surreal set cut inserts a point above the given set and below its proposed supremum. The product formula retains this obstruction rather than removing it.

[merge] The last paragraph is the proof of [corollary 37.3](#) (source 18). The second assertion of [proposition 82.14](#) is the case of [corollary 82.5](#) that source 27 states in the paragraph after it (“It also applies to a genuine gap . . .”); source 29 proves it, and extends the translation remark there to all four zero conventions.

## 83 Numerically well-ordered proper-class carriers (source 29)

[merge] Source 29's Section 7, printed whole; no other source proves its results. Its comparison of carriers by the least point of the symmetric difference ([note 83.1](#) and the display after it) is source 15's characteristic comparison  $<_\chi$ , printed before [proposition 38.6](#), where it is stated for sets and classes alike; source 29's longer-first order  $\prec_{\text{lf}}$  is  $<_\chi$ . The example of a numerically increasing class of type  $\text{Ord} + 1$  printed after [proposition 38.6](#) is the case  $b = 0$  of [example 83.3](#). New are the adjacency theorem, the two-point blocks, longer-first density, the cofinal representatives and the tree non-isomorphism ([theorems 83.2](#) and [83.5](#) to [83.7](#) and [corollary 83.4](#)). Source 29 cites source 19 (its “EarlierResidual”) for the mention of this interpretation; the batch-81 maps make it as well ([section 34](#)).

The preceding word constructions use set ordinal lengths. We now admit all available subclasses of **No** that are well-ordered by their inherited numerical order. Such a carrier need not be set-like, and no set ordinal enumeration is assumed. This interpretation is mentioned in the earlier project reports, but its proper-class adjacency behavior is different from the set-word case.

All assertions in this section are made in GBC about individual class parameters, uniformly coded families, or the external collection belonging to a specified class model. We do not form a GB class whose members are these proper-class carriers.

### 83.1 Comparison without an abstract class ordinal

*Note 83.1* (Source 29, Lemma 7.1). *The union of finitely many numerically well-ordered class carriers is numerically well-ordered. Distinct such carriers  $A, B$  have a least point  $d$  of  $A \triangle B$ , and*

$$C = A \cap (-\infty, d) = B \cap (-\infty, d)$$

*is their common initial segment.* The first two assertions are source 15's paragraph before [proposition 38.6](#).
