[write] **6 October 2026; sources 34–39.** *Against the formal statement.* `lemma_15_5` (Sections14_15.lean, line 414, at HEAD 89c1cbc38) has the exact companion `lemma_15_5_holds` (Proofs15Restriction.lean, line 3116), with an existential threshold N_0 and retention $(\alpha\eta/4)^{2^{2^{k+4}+k+3}}\beta^{15}N^{17k+15}$. Its count normalization $\beta^{15}N^{17k+15}$ is this corollary's $\beta^{m-1}q^M$ at $m = 16$, $q = N$ prime. The intake observed that this corollary then gives the formal conclusion with an explicit N_0 and retention $\alpha^s\eta^{s-1}/(2(s+2)^s)$, provided the ordered and degenerate conventions of `respectedGeneralArrangementCount` match those used here; that matching was not checked at the intake or at the write, so the observation is recorded as a marked question (item II.50). The formal statement is already exact, so nothing formal depends on it.

II.146 Degree balances and the probability of a certificate

Source 35, delivered Section 3.

II.146.1 Product probability on a subspace

The following elementary fact replaces a count of all available Fourier coefficients by the mass that the selector assigns to them.

Lemma II.146.1 (Subspace mass under a product law). *Let $X_1, \dots, X_n$ be independent random variables in $\mathbb{F}_q$, each with largest atom at most μ . If $V \subseteq \mathbb{F}_q^n$ is an affine subspace of dimension D , then*

$$\Pr((X_1, \dots, X_n) \in V) \leq \mu^{n-D}. \quad (\text{II.146.1})$$

More generally, if the i th largest atom is at most μ_i and projection onto a coordinate set I , $|I| = D$, is injective on V , the right side can be replaced by $\prod_{i \notin I} \mu_i$.

Proof. Choose D coordinates for which the coordinate projection on the direction space has rank D . Every choice of their values has at most one completion in V . Conditional on those values, independence bounds the probability of that completion by the product of the largest atoms of the other coordinates. Averaging over the chosen coordinates proves both claims. $\square$

The exponent in this general lemma cannot be increased for arbitrary subspaces: a coordinate subspace fixing $n - D$ coordinates at their largest atoms attains it. This does not assert sharpness for the particular arrangement subspaces below.

II.146.2 The degree of a coefficient array

Consider a field coefficient array $b = (b_{j,e}) \in \mathbb{F}_q^s$. For each cube, interpolate the values $\pi(e)b_{j,e}$ by the unique multilinear polynomial

$$V_j(u) = \sum_{T \subseteq [k]} A_{j,T} u_T, \quad u_T = \prod_{i \in T} u_i. \quad (\text{II.146.2})$$

Here and below the empty product is one. For $b \neq 0$, its parity-removed degree is

$$t(b) = \max\{|T| : A_{j,T} \neq 0 \text{ for some } j\}.$$

This definition is valid over every field: evaluation of multilinear polynomials on the Boolean cube is invertible by triangular interpolation.

For $S \subseteq [k]$, define the Boolean moments

$$b_{j,S}^b = \sum_{e \in \{0,1\}^k} b_{j,e} e_S.$$

Summing each coordinate of the Boolean cube separately gives

$$b_{j,S}^b = (-1)^k \sum_{\substack{T \subseteq [k] \\ T \cup S = [k]}} A_{j,T}. \quad (\text{II.146.3})$$

In particular, for an array of degree t ,

$$b_{j,S}^b = 0 \quad (|S| < k - t), \quad (\text{II.146.4})$$

$$b_{j,S}^b = (-1)^k A_{j,[k] \setminus S} \quad (|S| = k - t). \quad (\text{II.146.5})$$

For each $A \subseteq [k+1]$, the associated feature relation is

$$\sum_{j,e} b_{j,e} (v_{j,e})_A = 0. \quad (\text{II.146.6})$$

There are 2^{k+1} such relations, including $A = \emptyset$. The universal line

$$\mathcal{U} = \{\lambda(\sigma_j \pi(e))_{j,e} : \lambda \in \mathbb{F}_q\} \quad (\text{II.146.7})$$

satisfies all of them for every arrangement. Indeed, the alternating sum on a cube vanishes unless a squarefree horizontal feature contains every horizontal coordinate. In that last case the two remaining sums are multiples of $\sum_j \sigma_j = 0$ and $\sum_j \sigma_j z_j = 0$.

In estimating nonuniversal certificates, restrict first to arrangements with every $h_i \neq 0$. This restriction is justified later because a zero side automatically makes (II.145.1) hold for every map.

Lemma II.146.2 (Necessary top-degree balances). *For $0 \leq t \leq k$, let $\mathcal{V}_t$ be the space of arrays whose polynomials in (II.146.2) have degree at most t , and which satisfy*

$$\sum_{j=1}^m A_{j,T} = 0 \quad (|T| = t). \quad (\text{II.146.8})$$

Then $\dim \mathcal{V}_t = D_t$. Every degree- t array satisfying all feature relations on an arrangement with nonzero sides belongs to $\mathcal{V}_t$.

Proof. There are mc_t independent interpolation coefficients of degree at most t . For each of the $\binom{k}{t}$ top monomials, (II.146.8) is one independent equation, giving exactly the asserted dimension.

For a horizontal coordinate set $A \subseteq [k]$, expansion at the anchor gives

$$\sum_e b_{j,e}(x_j + e \odot h)_A = \sum_{S \subseteq A} h_S b_{j,S}^b(x_j)_{A \setminus S}. \quad (\text{II.146.9})$$

Choose $|A| = k - t$. All terms except $S = A$ vanish by (II.146.4). The feature relation is therefore

$$0 = h_A \sum_j b_{j,A}^b = (-1)^k h_A \sum_j A_{j,[k] \setminus A}.$$

Because $h_A \neq 0$, this is (II.146.8). $\square$

The spaces $\mathcal{V}_t$ need not be nested. We never subtract their upper bounds to estimate a stratum. The coefficient arrays are first partitioned by their exact degree, and each resulting mass is bounded above by the mass of the appropriate $\mathcal{V}_t$.

II.146.3 A rank estimate valid for arbitrary field coefficients

The next estimate extends the degree-sensitive certificate argument of [161] from its small coefficient alphabet to arbitrary field coefficients. That extension is essential for a Fejér kernel of arbitrary bandwidth.

Lemma II.146.3 (Probability of a nonuniversal certificate). *Fix $b \in \mathbb{F}_q^s \setminus \mathcal{U}$ of parity-removed degree t . For every fixed $h \in (\mathbb{F}_q^\times)^k$, choose the anchors uniformly in $(\mathbb{F}_q^k)^m$ and the levels uniformly in W . The probability that all feature relations (II.146.6) hold is at most $Q_t(q)$. Consequently the number of successful arrangements with nonzero sides is at most $q^M Q_t(q)$.*

Proof. First let $t = 0$. Then $b_{j,e} = a_j \pi(e)$ for some nonzero vector a . The full horizontal feature requires $\sum_j a_j = 0$, and adjoining the level coordinate requires $a \cdot z = 0$. If the first condition fails there are no successful arrangements. Otherwise a is not a multiple of σ , since the universal line was excluded. The linear form $a \cdot z$ is therefore nonzero on $W = \sigma^\perp$ and vanishes on exactly a fraction q^{-1} of W . This proves the degree-zero bound.

Now suppose $t \geq 1$. Choose $S_0 \subseteq [k]$, of size $k - t$, for which

$$b^b = (b_{1,S_0}^b, \dots, b_{m,S_0}^b) \neq 0.$$

Such a set exists by (II.146.5). For brevity write $b_j^b = b_{j,S_0}^b$. The lowest horizontal and vertical feature relations give

$$\sum_j b_j^b = 0, \quad \sum_j b_j^b z_j = 0. \quad (\text{II.146.10})$$

For each $i \notin S_0$, the feature with horizontal set $S_0 \cup \{i\}$ gives an affine linear equation in the anchors. Its terms involving $x_{j,i}$ are

$$h_{S_0} \sum_j b_j^b x_{j,i}.$$

All remaining anchor terms use coordinates $x_{j,a}$ with $a \in S_0$; condition on those coordinates. In particular, choosing one j_0 with $b_{j_0}^b \neq 0$ gives a diagonal nonsingular minor in the t variables $x_{j_0,i}$,

$i \notin S_0$. For every choice of the other variables, at most a fraction q^{-t} of the anchors can pass these tests.

If $b^\flat$ is not proportional to σ , the second condition in (II.146.10) independently holds on a fraction q^{-1} of W . Thus the success probability is at most q^{-t-1} .

Suppose instead $b^\flat = c\sigma$, with $c \neq 0$. When the level vector z is nonconstant, choose a, b with $z_a \neq z_b$. For each $i \notin S_0$, use both the horizontal test just described and the same test multiplied by the level coordinate. On the variables $x_{a,i}, x_{b,i}$ their coefficient matrix is

$$ch_{S_0} \begin{pmatrix} \sigma_a & \sigma_b \\ z_a \sigma_a & z_b \sigma_b \end{pmatrix}.$$

Its determinant is nonzero. The t blocks use disjoint variables, so their combined rank is $2t$. For constant z , the rank- t argument still applies. The constant vectors form a one-dimensional subspace of W , which has dimension $m - 1$. The fraction of constant level vectors is consequently $q^{-(m-2)}$, and the total probability is at most

$$(1 - q^{-(m-2)})q^{-2t} + q^{-(m-2+t)}. \quad (\text{II.146.11})$$

At $t = 1$, this is exactly $q^{-2} + (q - 1)q^{-m} = Q_1(q)$. For $t \geq 2$, after division by q^{-t-1} it is at most $q^{1-t} + q^{3-m} \leq 2/q < 1$, since $p > 2$. This proves every stated probability. There are fewer than q^k choices of nonzero h , yielding the final counting bound. $\square$

The exception at degree one is thus geometrically explicit: all levels coincide, and the extra vertical rank disappears. Suppressing this event would incorrectly replace Q_1 by q^{-2} . The exhaustive small-field check in Section V.132 attains the stated Q_1 .

II.147 The random restriction and its collision correction

Source 35, delivered Section 4.

II.147.1 A finite positive Fourier selector

For $|z| = 1$, use the normalized Fejér kernel

$$K_L(z) = \left| \frac{1}{L} \sum_{a=0}^{L-1} z^a \right|^2 = \sum_{n=-(L-1)}^{L-1} c_n z^n, \quad c_n = \frac{L - |n|}{L^2}. \quad (\text{II.147.1})$$

Thus $0 \leq K_L \leq 1$, every $c_n \geq 0$, $\sum_n c_n = 1$, and

$$\mu := c_0 = L^{-1} = \max_n c_n.$$

Because $p > 2(L - 1)$, the support integers n embed injectively in $\mathbb{F}_p \subseteq \mathbb{F}_q$. We regard c_n as a probability law on that field subset.

Choose a nontrivial additive character $\chi : \mathbb{F}_q \rightarrow \mathbb{C}$. Let $v \in \mathbb{F}_q$ and $u_A \in \mathbb{F}_q$, for every $A \subseteq [k + 1]$, be independent uniform variables. Conditional on these seeds, include each *distinct physical point* $y \in B$ independently with probability

$$K_L \left(\chi \left(v\phi(y) + \sum_{A \subseteq [k+1]} u_A y_A \right) \right). \quad (\text{II.147.2})$$

Call the resulting set B' . The empty feature is included. By orthogonality, its random coefficient makes the unconditional inclusion probability of each physical point exactly μ . All random choices here have finite support; no continuous phase averaging is required.

For a fixed arrangement, first multiply the retention probabilities over its s labels, whether or not some labels coincide. Fourier expansion and averaging the seeds give

$$\begin{aligned} & \mathbb{E}_{\text{seeds}} \prod_{j,e} K_L \left(\chi \left(v\phi(v_{j,e}) + \sum_A u_A(v_{j,e})_A \right) \right) \\ &= \sum_{b \in \mathbb{F}_q^s} \left(\prod_{j,e} c_{b_{j,e}} \right) \mathbf{1}_{\{\text{all feature relations hold}\}} \mathbf{1}_{\{\sum_{j,e} b_{j,e} \phi(v_{j,e}) = 0\}}. \end{aligned} \quad (\text{II.147.3})$$

Coefficients outside the embedded support have weight zero. Every summand is nonnegative. This positivity allows us to retain a useful signal and bound each unwanted family separately.

Lemma II.147.1 (The universal Fourier signal). *On a respected arrangement, the contribution of $\mathcal{U}$ to (II.147.3) is*

$$S_s(L) = \sum_{n=-(L-1)}^{L-1} c_n^s = \mu^s R_s(L). \quad (\text{II.147.4})$$

On an unrespected arrangement its contribution is exactly μ^s .

Proof. Every array in $\mathcal{U}$ satisfies the feature relations. An array from this line with positive weight must have the form $b_{j,e} = n\sigma_j\pi(e)$ with one integer $|n| < L$: this follows from the injectivity of the support in the field and its symmetry. Its product weight is c_n^s . For a respected arrangement it satisfies the target relation for every such n . For an unrespected arrangement the target relation is n times a nonzero element of $\mathbb{F}_q$, so only $n = 0$ can contribute. This proves both statements. $\square$

II.147.2 Why physical coincidences require a separate term

If labels coincide, the survival probability of the arrangement is the product over its *distinct* points, whereas (II.147.3) used every label. Because each factor lies in $[0, 1]$, actual survival is at least the labelled product. This is favorable for the respected count. For the unrespected count it requires an upper correction.

Lemma II.147.2 (Coincident vertices of an unrespected arrangement). *An unrespected arrangement has all $h_i \neq 0$. The total number of arrangement parameters with nonzero sides and at least one coincident pair of vertex labels is at most*

$$C_{\text{coll}} q^{M-k-1}. \quad (\text{II.147.5})$$

For any such arrangement in B , its unconditional actual survival probability is at most μ .

Proof. If $h_i = 0$, pair the terms e and $e + \mathbf{e}_i$ in each cube of (II.145.1). Their physical vertices are equal and their signs are opposite, so the arrangement is respected by every map. This proves the first assertion.

With nonzero sides, distinct labels in the same cube are different points. A coincidence between cubes $j \neq \ell$ requires

$$z_j = z_\ell, \quad x_\ell - x_j = \delta \odot h \quad \text{for some } \delta \in \{-1, 0, 1\}^k. \quad (\text{II.147.6})$$

For a fixed unordered pair j, ℓ and δ , these are $k+1$ independent linear conditions on the arrangement parameter space. In particular the form $z_j - z_\ell$ is independent of $\sigma \cdot z$, because $m \geq 4$ and σ has nonzero coordinates outside j, ℓ . The locus has exactly q^{M-k-1} parameters before the nonzero-side restriction. There are $\binom{m}{2} 3^k$ loci, so the union bound proves (II.147.5).

Survival implies that any one specified vertex survives. That vertex has unconditional inclusion probability μ , which proves the last assertion. $\square$

Counting raw pairs of Boolean labels would introduce 4^k in this estimate. Grouping pairs that define the same δ produces 3^k . More importantly, the compensation is μ per possible collision, rather than one. The empty feature is what gives this exact marginal probability.

II.147.3 Completion of the selection proof

Proof of Theorem II.145.2. Let $X = G_\phi(B')$ and $Y = T(B') - G_\phi(B')$. For every respected arrangement, actual survival is at least its labelled product. By the nonnegative Fourier expansion and Lemma II.147.1,

$$\mathbb{E}X \geq S_s(L)G_\phi(B) \geq \alpha\mu^s R_s(L)T_0. \quad (\text{II.147.7})$$

For unrespected arrangements, first bound the expected labelled product. Their number is at most $T(B) - G_\phi(B) \leq (1 - \alpha)T_0$, and the universal line contributes μ^s to each. For a nonuniversal array of exact degree t , successful nonzero-side arrangements are possible only if the array is in $\mathcal{V}_t$, by Lemma II.146.2. The product-law mass of that space is at most μ^{s-D_t} , by Lemma II.146.1. Each fixed array succeeds on at most $q^M Q_t(q)$ arrangements by Lemma II.146.3. We may discard both membership in B and the target relation when taking an upper bound. The total expected labelled contribution of these arrays is therefore at most

$$q^M \sum_{t=0}^k \mu^{s-D_t} Q_t(q).$$

The universal line has already been removed, so the degree-zero probability bound is being used only on its valid domain.

For arrangements with distinct labels, actual survival is the labelled product. For the remaining unrespected arrangements, add their actual survival probabilities as a compensation. This may overcount their labelled products, which is harmless. Lemma II.147.2 bounds the compensation by $C_{\text{coll}}\mu q^{M-k-1}$. Thus

$$\begin{aligned} \mathbb{E}Y &\leq \mu^s(1 - \alpha)T_0 \\ &\quad + q^M \left(\sum_{t=0}^k \mu^{s-D_t} Q_t(q) + C_{\text{coll}}\mu q^{M-k-1} \right). \end{aligned} \quad (\text{II.147.8})$$

Subtracting (II.147.8) from η times (II.147.7), and using $q^M = \beta^{-(m-1)}T_0$, gives

$$\mathbb{E}(\eta X - Y) \geq \mu^s T_0 F_*.$$

Some outcome consequently satisfies $\eta X - Y \geq \mu^s T_0 F_* > 0$. For that outcome,

$$X \geq \frac{\mu^s T_0 F_*}{\eta}, \quad Y \leq \eta X,$$

proving the count and purity assertions. Finally the general bound $T(B') \leq (|B'|/q^{k+1})^{m-1} q^M$, together with the lower bound on X , proves the density assertion. $\square$

Remark II.147.3 (A larger class of target groups). The same theorem holds for a map into $\mathbb{F}_q^a$, for any positive integer a : use a random linear functional on the target in the selector. More generally, it holds for a finite abelian target H whenever multiplication by every integer $1 \leq n < L$ is injective on H . For example, it suffices that every prime divisor of $|H|$ exceed $L - 1$. Replace the phase in (II.147.2) by

$$\psi(\phi(y)) \chi \left(\sum_A u_A y_A \right),$$

where ψ is a uniform character of H , and apply K_L to this unit complex number. Orthogonality on H now enforces the target relation. The injectivity assumption ensures that no nonzero integer on the universal line annihilates the defect of an unrespected arrangement. Every other part of the proof is unchanged. The field characteristic condition is still required for the coefficient support used by the features.

II.148 The exponent, a fair comparison, and a downstream substitution

Source 35, delivered Section 5.

II.148.1 A weighted comparison without the full degree stratification

To isolate the contribution of the degree calculation, one should compare it with a weighted argument that uses the same feature family but remembers only whether an array is pure parity. This intermediate comparison is useful even though it is weaker than the main theorem.

Proposition II.148.1 (A weighted unstratified bound). *Theorem II.145.2 remains valid if its budget is replaced by*

$$\mathcal{K}_{\text{un}}(L, q) = L^{m-1} q^{-1} + 2L^{s-1} q^{-2} + C_{\text{coll}} L^{s-1} q^{-k-1}. \quad (\text{II.148.1})$$

For fixed k, m, β , this yields the sufficient bandwidth exponent $(s - 1)/2$.

Proof. The nonuniversal pure-parity arrays lie in the balanced $(m - 1)$ -dimensional space $\mathcal{V}_0$, of mass at most μ^{s-m+1} , and each has success probability at most q^{-1} . Every other successful array satisfies the empty-feature equation $\sum_{j,e} b_{j,e} = 0$. This is a nonzero linear equation on $\mathbb{F}_q^s$, so all these arrays together have mass at most μ . Their individual success probabilities are at most $2q^{-2}$, by Lemma II.146.3. The collision correction is unchanged. Normalizing these contributions by $\mu^s q^M$ gives (II.148.1).

For example, it is enough to impose

$$q \geq \max \left\{ 4\beta^{-(m-1)} L^{m-1}, 2\sqrt{(2 + C_{\text{coll}})\beta^{-(m-1)}} L^{(s-1)/2} \right\}. \quad (\text{II.148.2})$$

Then the first term of the budget is at most $\beta^{m-1}/4$; the other two together are at most the same amount, using $q^{-k-1} \leq q^{-2}$. Since $s = m2^k \geq 2m$, the governing power of L is $(s - 1)/2$. $\square$

Thus the advance is more than a substitution of a probability weight for an unweighted union bound. Degree stratification further reduces the exponent from $(s - 1)/2$ to $E_{k,m}$, strictly so when $k \geq 2$. The unstratified proposition above is itself a consequence of the full feature system and the certificate estimates; it is not attributed to the earlier one-monomial report.

II.148.2 The exponent profile

Proposition II.148.2 (Unimodality and asymptotic size). *Let*

$$E_{k,m} = \max_{0 \leq t \leq k} \frac{D_t}{t+1}.$$

The sequence $D_t/(t+1)$ is unimodal and has at most two adjacent maximizing indices. It increases strictly whenever $t < k/2$. Moreover,

$$E_{k,m} \leq \frac{s-1}{2}, \quad \text{strictly if } k \geq 2, \quad E_{k,m} \sim \frac{2s}{k} \quad (k \rightarrow \infty) \quad (\text{II.148.3})$$

for each fixed $m \geq 4$.

Proof. Put $b_t = \binom{k}{t}$, $g_t = D_t/(t+1)$. For $0 \leq t < k$, the binomial recurrence gives the exact identity

$$g_{t+1} - g_t = \frac{mb_t}{(t+1)(t+2)} \left(\frac{(m-1)k - (m-2)t + 2}{m} - \frac{c_t}{b_t} \right). \quad (\text{II.148.4})$$

The first expression in parentheses decreases strictly with t . The second increases strictly, as is seen from

$$\frac{c_t}{b_t} = \sum_{j=0}^t \prod_{i=0}^{j-1} \frac{t-i}{k-t+i+1}.$$

When t increases, each existing nonempty product increases and a positive summand is added. Hence the sign in (II.148.4) changes at most once, from positive to negative, and at most one difference can be zero. If $t < k/2$, then $c_t/b_t \leq t+1$, while

$$\frac{(m-1)k - (m-2)t + 2}{m} - (t+1) = \frac{(m-1)(k-2t) - (m-2)}{m} \geq \frac{1}{m}.$$

This proves the assertions about the profile.

For the elementary upper bound, the $t=0$ term is $m-1 < (s-1)/2$. For $t \geq 1$, use $D_t \leq s-1$ and $t+1 \geq 2$. If $k \geq 2$, the degree-one numerator is strictly below $s-1$, and the terms $t \geq 2$ have denominator at least three, proving strictness.

For the asymptotic, let X be binomial with parameters $k, 1/2$. Then

$$\frac{D_t}{s} = \Pr(X \leq t) - \frac{1}{m} \Pr(X = t).$$

Take $t = \lceil k/2 + k^{2/3} \rceil$. Chebyshev's inequality shows that both $1 - \Pr(X \leq t)$ and $\Pr(X = t)$ tend to zero, while $k/(t+1) \rightarrow 2$. Thus $\liminf kE_{k,m}/s \geq 2$.

For the reverse inequality fix $0 < \delta < 1/2$. If $t \geq (1/2 - \delta)k$, then

$$\frac{kD_t}{s(t+1)} \leq \frac{1}{1/2 - \delta}.$$

If $\sqrt{k} \leq t < (1/2 - \delta)k$, Chebyshev gives $\Pr(X \leq t) \leq 1/(4\delta^2 k)$, so this same ratio is at most $1/(4\delta^2(t+1))$, which tends uniformly to zero. For $t < \sqrt{k}$,

$$c_t \leq (\sqrt{k} + 1)k^{\sqrt{k}}, \quad \frac{kD_t}{s(t+1)} \leq \frac{kc_t}{2^k} \rightarrow 0.$$

Hence the limsup is at most $1/(1/2 - \delta)$. Letting δ decrease to zero proves the asymptotic. □

The maximizing index can be found without comparing large rational numbers: locate the first t for which the parenthesized expression in (II.148.4) is nonpositive. Equality gives exactly two adjacent maximizers. If no such index occurs before k , the maximum is attained at $t = k$.

II.148.3 Eight-arrangements: explicit numbers

In the interface of the original proof, $d = 8$, so $m = 16$, $s = 2^{k+4}$, and $M = 17k + 15$. The original Lemma 15.5 [158] uses

$$J = s2^{s-1} = 2^{2^{k+4}+k+3}$$

and a sufficient condition

$$(\alpha\eta/4)^J \beta^{15} q \geq k 3^s.$$

Its guaranteed retained count is $(\alpha\eta/4)^J \beta^{15} q^{17k+15}$. The recent one-stage Fejér report [160] already replaces this count loss by

$$\frac{\alpha^s \eta^{s-1}}{3^{s-1}(s+1)^s} \beta^{15} q^{17k+15},$$

under its explicit sufficient size condition

$$q \geq (k+1)\beta^{-15} \left(\frac{18(s+1)^2}{(\alpha\eta)^2} \right)^s$$

and its separate characteristic condition. We retain the same powers $\alpha^s \eta^{s-1}$ and replace the field-size exponent $2s$ in that convenient condition by the following smaller values.

k	s	Maximizing t	Earlier $2s$	Weighted $(s-1)/2$	Graded $E_{k,16}$
1	32	1	64	31/2	31/2
2	64	1	128	63/2	23
3	128	2	256	127/2	109/3
4	256	3	512	255/2	59
5	512	3	1024	511/2	203/2
6	1024	4	2048	1023/2	897/5
7	2048	5	4096	2047/2	633/2
8	4096	5	8192	4095/2	1724/3

Table II.148.1: Sufficient inverse- $\alpha\eta$ exponents for eight-arrangements, with k, m, β fixed. The weighted column is Proposition II.148.1, proved here. Constants and density powers are given separately in the theorems.

For $k = 2, m = 16$, the exact dimensions are

$$(D_0, D_1, D_2) = (15, 46, 63), \quad C_{\text{coll}} = 1080.$$

Thus one may take $L = \lceil 65/(\alpha\eta) \rceil$ and require

$$q \geq \max \left\{ 6\beta^{-15} L^{15}, (12\beta^{-15} L^{46})^{1/2}, (6486\beta^{-15} L^{63})^{1/3} \right\}. \quad (\text{II.148.5})$$

The corresponding respected count is at least

$$\frac{\alpha^{64} \eta^{63}}{2 \cdot 66^{64}} \beta^{15} q^{49},$$

with purity at least $1/(1+\eta)$. In particular, the largest bandwidth power in (II.148.5) is 23, not 128. When the density β also varies, the full maximum in (II.148.5) must be retained; the single exponent comparison does not discard those density dependences.

II.148.4 One explicit substitution into the original proof

The preceding improvements can be passed through one adjacent interface without redoing the entire inverse argument. The arrangement-count input supplied by the product-property lemma in the source transcription (Lemma 14.8) is

$$G_\phi(B) \geq \beta^{7 \cdot 4^{k+1}} \gamma^{21k4^{k+1}} q^{17k+15}. \quad (\text{II.148.6})$$

Here $0 < \beta, \gamma \leq 1$, and β is the density of the relevant domain B . We state the consequence conditionally on this numerical input, so that no unstated variant of the product-property definition is needed.

Corollary II.148.3 (A replacement at the Lemma 15.6 interface). *Suppose the eight-arrangement count (II.148.6) holds, and put*

$$A_k = 7 \cdot 4^{k+1} - 15, \quad B_k = 21k4^{k+1}, \quad s = 2^{k+4}.$$

Take

$$L = \left\lceil 2^{44}(s+1)\beta^{-A_k}\gamma^{-B_k} \right\rceil.$$

If (II.145.12) holds with $m = 16$ and this bandwidth, and $p > 2(L-1)$, there is a subset with purity at least $1 - 2^{-44}$ and at least

$$\frac{2^{-44(s-1)-1}}{(s+2)^s} \beta^{sA_k+15} \gamma^{sB_k} q^{17k+15} \quad (\text{II.148.7})$$

respected arrangements.

Proof. In Corollary II.145.3, substitute $\alpha = \beta^{A_k}\gamma^{B_k}$ and $\eta = 2^{-44}$. Equation (II.148.6) is precisely the required lower bound αT_0 . Expanding the parameter powers in (II.145.13) gives (II.148.7). $\square$

[write] **6 October 2026; sources 34–39.** The input (II.148.6) has exactly the corrected exponents of the formal `lemma_14_8` (Sections14_15.lean, line 292; companion `lemma_14_8_holds`, `Proofs14ProductToArrangements.lean`, line 18, at HEAD 89c1cbc38): $\beta^{7 \cdot 4^{k+1}} \gamma^{21k4^{k+1}} N^{17k+15}$, the exponent $21k4^{k+1}$ in place of the printed $7k4^{k+1}$, as the formal `lemma_15_6` records.

This is a proved local substitution with all exponents visible. Obtaining a global bound for $r_\ell(N)$ would additionally require propagating the new largeness hypotheses through every later restriction, modeling step, and density-increment iteration. That separate optimization has not been carried out here.

II.149 Source 38’s Part II: sharp odd-order stability at the Proposition 6.1 endpoint [write]

Added in the seventh write, 6 October 2026.

The next section is source 38’s Section 6, its delivered Part II. *Logically it continues source 31’s chapter on the Proposition 6.1 endpoint* (Section II.104), which gives the exact profile over all finite abelian groups and leaves the odd-order coefficients open; it is printed here because no number printed earlier may move. Source 38’s introduction is Section F.43.

What is proved. For unit vectors v on groups of odd order with $\|v\|_{U^3}^8 \geq 1 - \varepsilon$, the optimal distance $\mathfrak{S}_{\text{odd}}(\varepsilon)$ from quadratic coset phases is $\varepsilon/4 + 3\varepsilon^2/16 + (\sqrt{2}/64)\varepsilon^{5/2} + O(\varepsilon^3)$, uniformly

in the group; the fractional term comes from characters of order three and disappears when $\gcd(|G|, 6) = 1$ (Theorem II.150.11); through a uniform preliminary stability (Theorem II.150.1, credited to source 31), an explicit local envelope (Theorem II.150.5) and tangent rigidity at order-three characters. Over all groups source 31's profile has the second coefficient $5/16$, attained on $\mathbb{Z}/2\mathbb{Z}$ (note after the theorem). This answers source 31's odd-order question (item II.46).

Relation to the formal statements (checked at HEAD 89c1cbc38). `proposition_6_1` (Section 06_07.lean, line 37) has the exact companion `proposition_6_1_holds` (Proofs05_10.lean, line 505); no near-extremal stability statement is formal. Nothing in this chapter is formalized.

II.150 The sharp odd-order local stability coefficients

Source 38, delivered Section 6.

Delivered part heading of source 38: Sharp odd-order stability for the critical uniformity inequality

The preceding project report proves an odd-order envelope with coefficient 12 in front of $(1-t)^2 t^2$ and leaves its optimal local coefficient open [172]. We determine that coefficient and the next, fractional-power term. The latter distinguishes groups with three-torsion from groups whose order is coprime to six. The resulting statement is a sharp asymptotic modulus, with an explicit finite remainder.

The classification of critical-norm extremizers and qualitative near-extremizers is established by Eisner–Tao [7, Theorem 1.4]. We begin with the finite argument and the explicit preliminary estimate needed here, including their proofs. This makes the quantitative conclusions independent of any unproved assertion in a preceding report. The original Fourier-to-structure setting is Gowers' Proposition 6.1 [1]; the Weyl representation also connects the calculation to stabilizer-state testing [125].

II.150.1 Normalization and quadratic coset phases

Let G be a finite abelian group, $N = |G|$, and let $\langle u, v \rangle = \mathbb{E}_x u(x) \overline{v(x)}$ be the inner product, linear in its first argument. Write $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$. A phase $Q : K \rightarrow \mathbb{T}$ on a subgroup $K \leq G$ is *quadratic* if all its third multiplicative derivatives equal one. Equivalently, for every $h \in K$,

$$Q(x) \overline{Q(x-h)} = c_h \chi_h(x), \quad |c_h| = 1, \quad \chi_h \in \widehat{K}.$$

To see the equivalence, a unit phase with constant first differences is a constant times a character; apply this observation to the first derivatives of Q . A normalized quadratic coset phase is a function

$$\psi(x) = \sqrt{\frac{N}{|K|}} \mathbf{1}_{x_0+K}(x) Q(x-x_0). \quad (\text{II.150.1})$$

Let $\mathcal{Q}_{\text{cos}}(G)$ be this family, including arbitrary constant unit phases. For $\|v\|_2 = 1$, put

$$\kappa(v) = \|v\|_{U^3}^8, \quad \mathcal{F}(v) = \max_{\psi \in \mathcal{Q}_{\text{cos}}(G)} |\langle v, \psi \rangle|^2.$$

The maximum exists, as follows also from the finite eigenline classification below. For a nonzero unnormalized function f , take $v = f/\|f\|_2$; then $\kappa(v) = \|f\|_{U^3}^8 / \|f\|_2^8$.

The phase space $V = G \times \widehat{G}$ has size N^2 . For $z = (h, \chi)$ define

$$W_z = M_\chi T_h, \quad (M_\chi u)(x) = \chi(x)u(x), \quad T_h u(x) = u(x - h).$$

These unitary operators multiply according to addition of their labels, up to unit scalars. Their commutator is

$$W_z W_y = B(z, y) W_y W_z, \quad B((h, \chi), (k, \eta)) = \chi(k) \overline{\eta(h)}. \quad (\text{II.150.2})$$

The alternating bicharacter B is nondegenerate, by character separation on G and on $\widehat{G}$.

For $\|v\|_2 = 1$ set $q_v(z) = |\langle v, W_z v \rangle|^2$. Fourier Parseval and the derivative formula for the U^3 norm give

$$0 \leq q_v \leq 1, \quad \sum_{z \in V} q_v(z) = N, \quad \kappa(v) = \frac{1}{N} \sum_{z \in V} q_v(z)^2 \leq 1. \quad (\text{II.150.3})$$

Indeed $\langle v, W_{(h, \chi)} v \rangle$ is the normalized Fourier coefficient of $v(x) \overline{v(x - h)}$ at χ . Its squared sum in χ is $\mathbb{E}_x |v(x)|^2 |v(x - h)|^2$; summing in h gives N . Its fourth-power sum in χ is the fourth power of the derivative's U^2 norm, and averaging in h gives $\kappa(v)$. The inequality follows from $q_v^2 \leq q_v$ and proves the critical U^3 – L^2 bound with coefficient one.

II.150.2 An explicit preliminary stability theorem

We prove the following estimate on all finite abelian groups. The constant and high-coefficient argument are credited to [172]; they serve here as a self-contained prerequisite.

Theorem II.150.1 (Uniform preliminary stability). *If $\|v\|_2 = 1$ and $\varepsilon = 1 - \kappa(v) < 1/120$, then*

$$\mathcal{F}(v) \geq 1 - 20\varepsilon. \quad (\text{II.150.4})$$

The bound is independent of the order and exponent of G .

Lemma II.150.2 (Projective overlap and additive closure). *If $q_v(z), q_v(y) \geq 1 - a$ with $0 \leq a \leq 1/2$, then*

$$q_v(z - y) \geq (1 - 2a)^2.$$

If a nonempty finite subset S of an abelian group satisfies $|S - S| < 3|S|/2$, then $S - S$ is a subgroup.

Proof. Decompose the unit vectors $W_z v, W_y v$ along v and its orthogonal complement. After adjusting their constant phases, their inner product has absolute value at least $(1 - a) - a = 1 - 2a$. The projective Weyl multiplication law identifies its squared modulus with $q_v(z - y)$.

For the second assertion put $D = S - S$. If $d = b - c \in D$, the sets $S - b, S - c \subseteq D$ have intersection of size greater than $|S|/2$. Equivalently more than half of $x \in S$ satisfy $x + d \in S$. For any $d, e \in D$, the two corresponding subsets of S intersect; for an x in their intersection, both $x + d, x + e$ belong to S . Thus $d - e \in D$, so the nonempty set D is closed under subtraction and is a subgroup. $\square$

Call a subgroup $H \leq V$ *isotropic* if $B(h, k) = 1$ for all $h, k \in H$.

Lemma II.150.3 (A gap for noncommuting subgroups). *If $H \leq V$ is not isotropic, then every unit vector v satisfies*

$$\frac{1}{|H|} \sum_{h \in H} |\langle v, W_h v \rangle|^2 \leq \frac{1}{2}.$$

Proof. For an operator A , average its conjugates:

$$\mathcal{P}(A) = \frac{1}{|H|} \sum_{h \in H} W_h A W_h^*.$$

Conjugation removes the projective scalars, so $\mathcal{P}$ is the orthogonal projection, for the Hilbert–Schmidt inner product, onto the operators commuting with all W_h . Put $\rho = |v\rangle\langle v|$ and $\sigma = \mathcal{P}(\rho)$. This is a positive operator of trace one, and

$$\frac{1}{|H|} \sum_{h \in H} |\langle v, W_h v \rangle|^2 = \text{tr}(\rho\sigma) = \text{tr}(\sigma^2).$$

Every eigenspace of σ is invariant under all W_h . None can be one-dimensional: a common eigenline would force every scalar commutator in (II.150.2) to equal one, contrary to the hypothesis. Each positive eigenvalue therefore has multiplicity at least two, and is at most $1/2$. Hence $\text{tr}(\sigma^2) \leq \frac{1}{2} \text{tr} \sigma = 1/2$. $\square$

[write] **6 October 2026; sources 34–39.** This is source 31’s Lemma II.106.4, reproved for completeness; the preliminary stability around it is credited to source 31 by the source. Source 36’s Theorem IV.17.1 is its sharp rank-sensitive form over $\mathbb{F}_p^n$.

Lemma II.150.4 (Isotropic eigenspaces and quadratic coset phases). *If $H \leq V$ is isotropic, then $|H|$ divides N , and each common character eigenspace of its normalized representation has dimension $N/|H|$. In particular, if $|H| = N$, the common eigenvectors form an orthonormal basis indexed by $\hat{H}$, and each is a quadratic coset phase. Conversely, every quadratic coset phase arises this way for an isotropic subgroup of size N .*

Proof. The commuting unitary operators W_h are simultaneously diagonalizable. Choose a common eigenvector with eigenvalues λ_h and put $U_h = \lambda_h^{-1} W_h$. Evaluating the projective product on that eigenvector shows that $U_h U_k = U_{h+k}$. For each $\gamma \in \hat{H}$ its character projector is

$$P_\gamma = \frac{1}{|H|} \sum_{h \in H} \overline{\gamma(h)} U_h.$$

Every nonidentity Weyl operator has trace zero: a nonzero translation has no diagonal entries, while a nontrivial pure modulation has character sum zero. Thus $\text{tr} P_\gamma = N/|H|$. This positive number is an integer, proving the divisibility and dimension statements.

Assume now that $|H| = N$. Let K be its projection into G and let $D = \{\chi : (0, \chi) \in H\}$. Isotropy gives $D \subseteq K^\perp$; the equality $|H| = |K||D| = N$ forces $D = K^\perp$. The modulation eigenrelations restrict the support of a common eigenvector to one coset $x_0 + K$. The translation eigenrelations for $h \in K$ force that entire coset into the support, with constant modulus. Normalization fixes the modulus to $\sqrt{N/|K|}$. The same relations state that each derivative of its phase on K is a constant times a character, which is precisely quadraticity.

Conversely consider (II.150.1). For every $h \in K$ the derivative character on K has $|K^\perp|$ extensions to G . Each extension gives a Weyl operator preserving the line through ψ . The labels of all line-preserving Weyl operators form a subgroup, by the projective multiplication law, and its commutators must be one since they act on a nonzero common eigenvector. No label whose translation lies outside K can preserve that line. Consequently this isotropic subgroup has exactly $|K||K^\perp| = N$ elements. The finite-group character-extension fact used here follows, for example,

by extending a character one cyclic generator at a time and choosing a suitable root of its already specified value.

There are finitely many subgroups of V and exactly N eigenlines for each isotropic subgroup of size N . The classification therefore also proves that $\mathcal{Q}_{\text{cos}}(G)$ is finite modulo constant unit phases, and that the maximum defining $\mathcal{F}(v)$ is attained. $\square$

Proof of Theorem II.150.1. Write $q = q_v$ and put $S = \{z : q(z) \geq 19/20\}$. Equation (II.150.3) gives $\sum_z q(z)(1 - q(z)) = N\varepsilon$, so the q -mass outside S is at most $20N\varepsilon$. Hence

$$|S| \geq \sum_{z \in S} q(z) \geq (1 - 20\varepsilon)N.$$

The overlap lemma puts $S - S$ inside $\{q \geq 4/5\}$, so $|S - S| \leq 5N/4$. Since $\varepsilon < 1/120$,

$$|S - S| \leq 5N/4 < \frac{3}{2}(1 - 20\varepsilon)N \leq 3|S|/2.$$

Thus $H = S - S$ is a subgroup. Every coefficient there is at least $4/5$, so Lemma II.150.3 makes H isotropic. Also $|H| \geq |S| > 5N/6 > N/2$, and divisibility in Lemma II.150.4 implies $|H| = N$.

Since $q(0) = 1$, one has $0 \in S$ and $S \subseteq H$. Expand v in the common eigenbasis of H , with coefficient probabilities p_γ . Character orthogonality gives

$$\sum_\gamma p_\gamma^2 = \frac{1}{N} \sum_{h \in H} q(h) \geq 1 - 20\varepsilon.$$

The largest p_γ is at least their sum of squares because their sum is one. Its eigenvector is a quadratic coset phase, proving (II.150.4). $\square$

At $\varepsilon = 0$, the argument and the mass identity also recover the exact extremizers: they are precisely the normalized quadratic coset phases. The cutoff $1/120$ and preliminary coefficient 20 are sufficient constants; their optimality is not asserted.

II.150.3 The explicit odd-order local envelope

Theorem II.150.5 (Explicit odd-order local envelope). *Suppose $|G|$ is odd and $\|v\|_2 = 1$. Let ψ be any normalized quadratic coset phase with $|\langle v, \psi \rangle|^2 = 1 - t$, where $0 \leq t \leq 1/6$. Set $F = 1 - t$. Then*

$$\kappa(v) \leq F^4 + 6F^2t^2 + 2\sqrt{2}F^{3/2}t^{5/2} + 104Ft^3 + t^4. \quad (\text{II.150.5})$$

If $3 \nmid |G|$, the term $2\sqrt{2}F^{3/2}t^{5/2}$ may be omitted. The constants 6 and $2\sqrt{2}$, in that order of asymptotic comparison, are optimal uniformly over odd-order groups. No optimality is claimed for 104.

Here “in that order” means that the coefficient of F^2t^2 is first minimized; among envelopes with that coefficient equal to 6, the coefficient of $F^{3/2}t^{5/2}$ is then minimized. The theorem does not assert an exact finite- t optimum.

II.150.4 A Weyl-coset expansion

Choose the isotropic subgroup H of size N associated with ψ by Lemma II.150.4, and normalize its representation so that ψ has character label zero. Its common eigenbasis is indexed by $\Gamma = \widehat{H}$. Nondegeneracy of the commutator pairing gives $|H^\perp| = N^2/|H| = N$, hence $H^\perp = H$. The map sending a Weyl label to its commutator character on H therefore identifies V/H with Γ . A Weyl operator from a coset with label γ shifts eigenvector labels by γ , up to unit scalar factors. This follows by commuting that operator past each U_h . These facts hold for every maximal isotropic subgroup; no change to a coordinate subgroup is assumed.

Choose the global phase so that

$$v = \sqrt{F}\psi + \sqrt{t}w, \quad \langle w, \psi \rangle = 0, \quad \|w\|_2 = 1.$$

The case $t = 0$ is immediate and is henceforth suppressed. Let s_γ be the coefficient probabilities of w in the common eigenbasis. Then $s_0 = 0$, $\sum s_\gamma = 1$. Define

$$A = \sum_\gamma s_\gamma^2, \quad B = \sum_\gamma s_\gamma s_{-\gamma}, \quad C = \sum_{\alpha+\beta=\gamma} s_\alpha s_\beta s_\gamma.$$

Since $|\Gamma|$ is odd, its nonzero elements form disjoint pairs $\{\gamma, -\gamma\}$. If m_i are their total probabilities, then

$$A + B = \sum_i m_i^2 \leq 1, \quad B \leq \frac{1}{2}. \quad (\text{II.150.6})$$

In particular $2A + 4B \leq 3$.

For $z \notin H$ put

$$l_z = \langle \psi, W_z w \rangle + \langle w, W_z \psi \rangle, \quad d_z = \langle w, W_z w \rangle.$$

Write $\int_{V \setminus H} a = N^{-1} \sum_{z \notin H} a(z)$; this is a finite measure, not necessarily a probability measure.

Here is an explicit formula for the coset coordinates, including the phase factors. Write $w = \sum_\beta b_\beta \psi_\beta$, where $U_h \psi_\beta = \beta(h) \psi_\beta$ and $b_0 = 0$. Choose a representative z_γ for a Weyl coset. There are unit scalars $u_{\gamma, \beta}$ such that, after removing the same common unit factor from all coefficients at $z_\gamma + h$, the ambiguity coefficient of a vector with coordinates c_β is

$$\sum_{\beta \in \Gamma} c_{\beta+\gamma} \overline{c_\beta} u_{\gamma, \beta} \overline{\beta(h)}. \quad (\text{II.150.7})$$

This follows by first applying U_h and then the label-shifting operator W_{z_γ} . Thus, for $\gamma \neq 0$, the linear term is

$$l_\gamma(h) = b_\gamma u_{\gamma, 0} + \overline{b_{-\gamma}} u_{\gamma, -\gamma} \gamma(h).$$

The same common factor multiplies l and d , and cancels from every product $|l|^4$, $|l|^2 |d|^2$, and $l^2 \bar{l} \bar{d}$ used below. In particular the argument does not require the projective scalar factors to vanish separately.

Lemma II.150.6 (The exact fourth-order coefficient). *One has*

$$\int_{V \setminus H} |l|^4 = 2A + 4B. \quad (\text{II.150.8})$$

Furthermore, with

$$K(w) = 4 \operatorname{Re} \int_{V \setminus H} l^2 \bar{l} \bar{d},$$

there exist real numbers $J(w), M(w)$ such that

$$\begin{aligned} \kappa(v) &= F^4 + 6F^2t^2(A + B) + F^{3/2}t^{5/2}K(w) \\ &\quad + Ft^3J(w) + F^{1/2}t^{7/2}M(w) + t^4\kappa(w), \end{aligned} \quad (\text{II.150.9})$$

$$0 \leq J(w) \leq 4 + 6\sqrt{3}, \quad |M(w)| \leq 43^{1/4}, \quad \kappa(w) \leq 1. \quad (\text{II.150.10})$$

Proof. On H the coefficient of v is, up to a unit scalar, $F + t\hat{s}(h)$. Character orthogonality gives its fourth moment as

$$F^4 + F^2t^2(4A + 2B) + 4Ft^3C + t^4E(s),$$

where $E(s) = \sum_{a+b=c+d} s_a s_b s_c s_d$. The term with one nonzero label vanishes because $s_0 = 0$.

Consider a Weyl coset with nonzero shift label γ . Up to a common unit scalar, the two summands of l are two characters on H with coefficient magnitudes $\sqrt{s_\gamma}$ and $\sqrt{s_{-\gamma}}$. The ratio character has label γ . Both that character and its square are nontrivial since Γ has odd order. Therefore the fourth moment over this coset is

$$s_\gamma^2 + s_{-\gamma}^2 + 4s_\gamma s_{-\gamma}.$$

Summing over nonzero shift labels proves (II.150.8).

Outside H the Weyl coefficient is $\sqrt{Ft}l + td$. Expand its fourth power. Besides the fourth and fifth-order terms already displayed, the coefficients are

$$J = 4C + \int_{V \setminus H} (2|l|^2|d|^2 + 4(\text{Re}(l\bar{d}))^2), \quad M = 4 \text{Re} \int_{V \setminus H} |d|^2 l \bar{d}.$$

The t^4 terms on and off H add up to $t^4\kappa(w)$. The fourth-order coefficients add to $6(A + B)$, proving the exact identity. Since $C \leq 1$, $\|l\|_4 \leq 3^{1/4}$, and $\|d\|_4 \leq \kappa(w)^{1/4} \leq 1$, Hölder's inequality gives (II.150.10). $\square$

For clarity, the critical estimate for w in this proof does not require an inverse theorem. For any vectors u_1, u_2 , the mixed ambiguity coefficient satisfies

$$\left(\frac{1}{N} \sum_z |\langle u_1, W_z u_2 \rangle|^4 \right)^{1/4} \leq \|u_1\|_2 \|u_2\|_2. \quad (\text{II.150.11})$$

Indeed the maximum squared coefficient is at most $\|u_1\|_2^2 \|u_2\|_2^2$, and Weyl orthogonality gives total squared mass $N\|u_1\|_2^2 \|u_2\|_2^2$. Multiplying these two bounds proves (II.150.11). Taking $u_1 = u_2 = w$ gives $\kappa(w) \leq 1$.

II.150.5 The order-three resonance

Lemma II.150.7 (A single opposite pair). *Let w_0 be supported on the two eigenvector labels $\{\gamma, -\gamma\}$, with $\|w_0\|_2 \leq 1$. Then*

$$|K(w_0)| \leq 2\sqrt{2}.$$

If $3\gamma \neq 0$, then $K(w_0) = 0$.

Proof. The linear coefficient $l(w_0)$ is supported on Weyl cosets with shift labels $\pm\gamma$. The coefficient $d(w_0)$, away from H , is supported on shift labels $\pm 2\gamma$. These sets meet only if $3\gamma = 0$, proving the vanishing assertion.

In the remaining case choose the shift- γ coset. Its linear coefficient has the form $b + c\chi$, up to unit scalars, where $|b| = u$, $|c| = v$, and χ is an order-three character. Its quadratic coefficient has the form $d\chi^{-1}$, with $|d| = uv$. In the average of $l^2\bar{l}\bar{d}$, precisely the powers χ^{-1} and χ^2 can contribute after multiplication by χ . Their total absolute value is at most $u^3v^2 + u^2v^3$. The other shift coset has the same bound. Consequently

$$|K(w_0)| \leq 8u^2v^2(u+v) \leq 2\sqrt{2},$$

using $u^2 + v^2 \leq 1$. Equality in the scalar bound occurs at $u = v = 1/\sqrt{2}$. $\square$

Lemma II.150.8 (Stability of the fifth-order coefficient). *Put $D = 1 - A - B$. Then*

$$K(w) \leq K_* + 20 \cdot 3^{3/4} \sqrt{D}, \quad K_* = \begin{cases} 2\sqrt{2}, & 3 \mid N, \\ 0, & 3 \nmid N. \end{cases} \quad (\text{II.150.12})$$

Proof. Equation (II.150.6) implies that the greatest opposite-pair mass is at least $1 - D$. Let w_0 be the unnormalized orthogonal projection of w onto that pair. Then $\|w - w_0\|_2 \leq \sqrt{D}$. The fourth-moment formula for l , by homogeneity, gives

$$\|l(w) - l(w_0)\|_4 \leq 3^{1/4} \sqrt{D}, \quad \|l(w)\|_4, \|l(w_0)\|_4 \leq 3^{1/4}.$$

The mixed ambiguity estimate (II.150.11) gives

$$\|d(w) - d(w_0)\|_4 \leq (\|w\|_2 + \|w_0\|_2) \|w - w_0\|_2 \leq 2\sqrt{D}.$$

Expand the difference of $l^2\bar{l}\bar{d}$ at w and w_0 , using three terms for the cubic factor and one for d . Hölder gives

$$|K(w) - K(w_0)| \leq 4(3 \cdot 3^{3/4} + 2 \cdot 3^{3/4}) \sqrt{D} = 20 \cdot 3^{3/4} \sqrt{D}.$$

Lemma II.150.7 concludes the proof. If $3 \nmid N$, no label has order three because $|\Gamma| = N$. $\square$

Proof of Theorem II.150.5. Insert (II.150.12) into the exact expansion and set $L = 20 \cdot 3^{3/4}$. Completing the square gives

$$-6F^2t^2D + LF^{3/2}t^{5/2}\sqrt{D} \leq \frac{L^2}{24}Ft^3 = 50\sqrt{3}Ft^3.$$

The remaining terms are at most

$$F^4 + 6F^2t^2 + K_*F^{3/2}t^{5/2} + (4 + 56\sqrt{3})Ft^3 + 4 \cdot 3^{1/4}F^{1/2}t^{7/2} + t^4.$$

Since $t/F \leq 1/5$ for $t \leq 1/6$, the last two intermediate remainder coefficients satisfy

$$4 + 56\sqrt{3} + 4 \cdot 3^{1/4} \sqrt{t/F} \leq 4 + 56\sqrt{3} + \frac{4 \cdot 3^{1/4}}{\sqrt{5}} < 104.$$

This proves the explicit envelope. Sharpness of the two asymptotic coefficients follows from the examples below. $\square$

Corollary II.150.9 (Tangent rigidity at the optimal coefficients). *Consider any sequence of unit vectors on finite abelian groups of odd order, and choose a maximizing quadratic coset phase for each vector. After adjusting its constant phase, write*

$$v = \sqrt{F}\psi + \sqrt{t}w, \quad F = \mathcal{F}(v) = 1 - t, \quad t \downarrow 0.$$

If

$$\kappa(v) = F^4 + 6F^2t^2 + 2\sqrt{2}F^{3/2}t^{5/2} + o(t^{5/2}), \quad (\text{II.150.13})$$

then, in the common eigenbasis associated with ψ , the tangent w concentrates in a pair $\{\gamma, -\gamma\}$ with $3\gamma = 0$. More precisely, these labels have order three for all sufficiently late terms, the two coefficient moduli tend to $1/\sqrt{2}$, and the orthogonal projection w_0 to that pair satisfies

$$1 - A - B = o(\sqrt{t}), \quad \|w - w_0\|_2 = o(t^{1/4}).$$

No classification of the two coefficient phases is asserted.

Proof. Put $D = 1 - A - B \geq 0$ and $K_0 = 2\sqrt{2}$. Comparing (II.150.13) with the exact expansion (II.150.9), using its uniform remainder bounds, gives

$$6\sqrt{F} \frac{D}{\sqrt{t}} = K(w) - K_0 + o(1).$$

The bound (II.150.12) implies that $K(w)$ is bounded, so first $D = O(\sqrt{t})$ and hence $D \rightarrow 0$. It then gives $K(w) \leq K_0 + o(1)$. Since the left side of the displayed identity is nonnegative, both $D/\sqrt{t} \rightarrow 0$ and $K(w) \rightarrow K_0$ follow.

Choose a pair of greatest mass and project to it as in Lemma II.150.8. Then $\|w - w_0\|_2^2 \leq D = o(\sqrt{t})$, and the same Lipschitz estimate gives $K(w_0) \rightarrow 2\sqrt{2}$. Lemma II.150.7 forces the pair label to have order three eventually. If its coefficient moduli are a, b , then $a^2 + b^2 \rightarrow 1$ and

$$K(w_0) \leq 8a^2b^2(a + b) \leq 2\sqrt{2}.$$

The limiting upper bound can be attained only when $a^2b^2 \rightarrow 1/4$: use $a + b \leq \sqrt{2}$ and $a^2b^2 \leq 1/4$. Together with $a^2 + b^2 \rightarrow 1$, this implies $a, b \rightarrow 1/\sqrt{2}$, as required. $\square$

II.150.6 An exact three-element sharpness family

Let $e_j = \sqrt{3}\mathbf{1}_{\{j\}}$ be the normalized point-mass basis on $\mathbb{Z}/3\mathbb{Z}$. For $0 \leq t \leq 1/6$ put

$$v_t = \sqrt{1-t}e_0 + \sqrt{t/2}(e_1 + e_2).$$

Then its best quadratic-coset fidelity is $\mathcal{F}(v_t) = 1 - t$. To verify this, note that a quadratic coset phase is either a point mass or has full support and constant modulus one. The latter's squared overlap is at most $(\sqrt{1-t} + \sqrt{2t})^2/3$, which is smaller than $1 - t$ on this interval. (Squaring the equivalent positive inequality reduces the assertion to $6t(1-t) < 1$.)

The norm is exactly

$$\kappa(v_t) = (1-t)^4 + 6(1-t)^2t^2 + 2\sqrt{2}(1-t)^{3/2}t^{5/2} + 4(1-t)t^3 + \frac{1}{2}t^4. \quad (\text{II.150.14})$$

One direct verification expands the cube sum. Of the $3^4 = 81$ affine maps (x, h_1, h_2, h_3) , the numbers with exactly r zero cube vertices are

r	0	2	3	4	8
number	8	32	16	24	1.

The values at every nonzero vertex coincide and are real. Substituting $a = \sqrt{1-t}$ and $b = \sqrt{t/2}$ gives $a^8 + 24a^4b^4 + 16a^3b^5 + 32a^2b^6 + 8b^8$, which is (II.150.14). Here is an elementary derivation of the count. With no nonzero directions there are one map with $r = 8$ and two with $r = 0$. With one nonzero direction there are six direction tuples; each has two translates with $r = 4$ and one with $r = 0$. With two nonzero directions there are twelve direction tuples; each has residue multiplicities 4, 2, 2 on the cube, hence one translate with $r = 4$ and two with $r = 2$. With three nonzero directions there are eight tuples; their residue multiplicities are 3, 3, 2, hence two translates with $r = 3$ and one with $r = 2$. Adding these contributions gives the table. A short exhaustive verification script accompanies the article.

This proves that the coefficient 6 cannot decrease, and that after it is fixed the coefficient $2\sqrt{2}$ cannot decrease. It also disproves the putative remainder-free envelope $\kappa \leq (1-t)^4 + 6(1-t)^2t^2 + t^4$ on all odd-order groups.

For an example with $3 \nmid N$, use $G = \mathbb{Z}/5\mathbb{Z}$, now with normalized point masses $e_j = \sqrt{5} \mathbf{1}_{\{j\}}$, and put $v_t = \sqrt{1-t}e_0 + \sqrt{t}e_1$. Then

$$\mathcal{F}(v_t) = 1 - t, \quad \kappa(v_t) = (1-t)^4 + 6(1-t)^2t^2 + t^4. \quad (\text{II.150.15})$$

Indeed the zero-shift coset contributes $F^4 + 4F^2t^2 + t^4$, and the two nonzero shift cosets ± 1 each contribute F^2t^2 . Full-support phases have squared correlation at most $2/5$, so the point mass is the maximizer for $t \leq 1/6$.

Remark II.150.10 (Finite comparison and the meaning of the coefficient). The earlier envelope is $F^4 + 12F^2t^2 + t^4$ on odd-order groups [172]. Our explicit upper bound is strictly smaller for $0 < t \leq 1/25$, because

$$2\sqrt{2}\sqrt{t/F} + 104t/F \leq \frac{1}{\sqrt{3}} + \frac{13}{3} < 6.$$

More significantly, its two successive asymptotic coefficients are optimal. The exact three-element family shows why there is no remainder-free replacement by the polynomial with coefficient 6. The next contribution is larger than any constant multiple of t^3 as $t \downarrow 0$, and must be retained when three-torsion is allowed.

II.150.7 The optimal local modulus through its fractional term

Define

$$\mathfrak{S}_{\text{odd}}(\varepsilon) = \sup\{1 - \mathcal{F}(v) : |G| \text{ odd}, \|v\|_2 = 1, \kappa(v) \geq 1 - \varepsilon\},$$

where the supremum ranges over all finite abelian groups as well as all such functions. Define $\mathfrak{S}_{6'}$ by restricting to $\gcd(|G|, 6) = 1$.

Theorem II.150.11 (Sharp uniform asymptotic stability). *As $\varepsilon \downarrow 0$,*

$$\mathfrak{S}_{\text{odd}}(\varepsilon) = \frac{\varepsilon}{4} + \frac{3\varepsilon^2}{16} + \frac{\sqrt{2}}{64}\varepsilon^{5/2} + O(\varepsilon^3), \quad (\text{II.150.16})$$

$$\mathfrak{S}_{6'}(\varepsilon) = \frac{\varepsilon}{4} + \frac{3\varepsilon^2}{16} + O(\varepsilon^3). \quad (\text{II.150.17})$$

The implied constants are independent of group order and exponent. For optimal squared distance to a normalized coset phase, replace these right sides respectively by

$$\frac{\varepsilon}{4} + \frac{13\varepsilon^2}{64} + \frac{\sqrt{2}}{64}\varepsilon^{5/2} + O(\varepsilon^3), \quad \frac{\varepsilon}{4} + \frac{13\varepsilon^2}{64} + O(\varepsilon^3).$$

Proof. Theorem II.150.1 gives $1 - \mathcal{F}(v) \leq 20\varepsilon$ when $\varepsilon < 1/120$, on every finite abelian group. Thus $t = 1 - \mathcal{F}(v)$ is at most $1/6$ and is $O(\varepsilon)$ uniformly. Apply Theorem II.150.5 to a maximizing phase and expand:

$$\varepsilon \geq 4t - 12t^2 - K_*t^{5/2} - O(t^3).$$

First this gives $t \leq \varepsilon/4 + O(\varepsilon^2)$; inserting that estimate back into the quadratic and fractional terms gives

$$t \leq \frac{\varepsilon}{4} + \frac{3\varepsilon^2}{16} + \frac{K_*}{128}\varepsilon^{5/2} + O(\varepsilon^3).$$

All constants are uniform because the explicit envelope and preliminary bound are uniform. The exact family (II.150.14) gives the matching lower asymptotic expansion: its deficit is continuous and strictly increasing for all sufficiently small t , with derivative 4 at zero, so every sufficiently small ε is attained. Equation (II.150.15) gives the analogous lower bound when $3 \nmid N$.

Finally optimizing the constant phase of an extremizer gives

$$\min_{\psi \in \mathcal{Q}_{\cos}(G)} \|v - \psi\|_2^2 = 2(1 - \sqrt{\mathcal{F}(v)}) = t + \frac{1}{4}t^2 + O(t^3).$$

This changes $3/16$ to $3/16 + 1/64 = 13/64$ and preserves the $\varepsilon^{5/2}$ coefficient. □

[write] 6 October 2026; sources 34–39. *Answers source 31's odd-order question* (item II.46; checked at the write). Over all finite abelian groups source 31's exact profile $(1 - \sqrt{(1 + \sqrt{1 - 4\varepsilon})/2})/2$ expands as $\varepsilon/4 + 5\varepsilon^2/16 + O(\varepsilon^3)$, with equality on $\mathbb{Z}/2\mathbb{Z}$; on odd-order groups the second coefficient drops to $3/16$, and the term $(\sqrt{2}/64)\varepsilon^{5/2}$ comes from characters of order three, absent when $\gcd(|G|, 6) = 1$. The two profiles are compatible ($3/16 < 5/16$). The local envelope's constant 104 is not claimed optimal.

Scope and remaining questions. The critical-norm classification and the preliminary stability estimate are credited prerequisites, proved above for completeness. The new conclusion is the uniform sharp odd-order expansion through $\varepsilon^{5/2}$, together with an explicit finite- t estimate. It refines the local near-extremal regime of the derivative-Fourier framework; no new global inverse theorem is asserted.

Is the exact odd-order local optimum attained by the three-element family (II.150.14) throughout some nonzero interval? What is the sharp coefficient of ε^3 in $\mathfrak{S}_{\text{odd}}$ and $\mathfrak{S}_{6'}$? Does the latter coefficient depend on five-torsion? A sharper remainder retaining the opposite-pair deficit $1 - \sum_i m_i^2$ could help distinguish these possibilities.

II.151 Source 39's chapter: shared anchors at Lemma 16.10 [write]

Added in the seventh write, 6 October 2026.

The next ten sections are source 39's Sections 2–11, on the sampling and interpolation step inside Gowers's Lemma 16.10: one small set of columns serves as interpolation anchors for many fibres at

once. *Logically the chapter follows source 19's sampling sections* (Sections II.67–II.69), *which are its spine*, and source 23's geometric gluing (Section II.103); it is printed here because no number printed earlier may move. Source 39 re-derives much of source 19 without citing it (note in Section F.44). Its introduction is Section F.44; its repository interface, checks and questions are in Part V.

What is proved, and what is new in this report. Second routes (source 19's results, re-derived): the common r -subset sampler with an $O(q/\sigma)$ budget, the exact finite minimax as a maximum over class profiles attained by permutation orbits, the dynamic program, conditional-expectation selection, the sharp affine constant $\varphi^3 e^{-\varphi}$ (Theorems II.153.2, II.154.2, II.158.2, Corollary II.156.3). New: a certification rule that keeps sampled targets, with loss at most $tq(m-r)/(m(r+1))$; the closed balanced-and-capped solution of the finite profile problem for that rule, with an explicit quadratic-radical cap for affine classes (Theorems II.155.3, II.155.4; for source 19's rule the formula fails, note there); the two-regime limit $F_t(\min\{\lambda_t, r/q\})$ (Theorem II.157.3); unisolvent spaces and additive corruption (Corollary II.159.4, Theorem II.159.5); labelled slice covers and label-preserving refinement (Theorems II.160.1, II.161.2). The closing comparison of Lemma 16.10 is not addressed.

Relation to the formal statements (checked at HEAD 89c1cbc38). `lemma_16_10` (Section16.1e an, line 851) is open; source 39's Proposition V.145.1 matches the existing `Section16SampledOrAnchoredOn` interface (`Proofs16ShortColumns.lean`, line 27), a formalization candidate claimed by nobody. Nothing in this chapter is formalized.

II.152 A finite model of shared-anchor certification

Source 39, delivered Section 2.

Definition II.152.1 (Row families and ambient mass). Let J be a finite set with $|J| = m \geq 1$, and let H be a finite row set. Assign weights $w_h \geq 0$ with $W = \sum_h w_h > 0$. In each row choose pairwise disjoint sets

$$C_{h,1}, \dots, C_{h,q_h} \subseteq J, \quad B_h = \bigcup_{i=1}^{q_h} C_{h,i}.$$

Empty classes are permitted. The weighted mean class count and domain density are

$$\bar{q} = \frac{1}{W} \sum_h w_h q_h, \quad \delta_B = \frac{1}{mW} \sum_h w_h |B_h|.$$

All mass bounds in this article are normalized by the full ambient mass mW , not by $\sum_h w_h |B_h|$.

Allowing B_h to be a proper subset of J is essential. An intermediate partial graph in the inverse argument need not meet every vertical line in every column. It is also essential for the extremal profiles: in one of the asymptotic regimes it is best to use only part of the column set.

Definition II.152.2 (Certification). Fix an integer $t \geq 1$ and a sample $R \subseteq J$. Define

$$K_h(R) = (B_h \cap R) \cup \bigcup_{\substack{1 \leq i \leq q_h \\ |C_{h,i} \cap R| \geq t}} C_{h,i}. \quad (\text{II.152.1})$$

The normalized uncertified mass is

$$D_C(R) = \frac{1}{mW} \sum_h w_h |B_h \setminus K_h(R)|. \quad (\text{II.152.2})$$

The ambient good set $E_R \subseteq H \times J$ is obtained by deleting just these uncertified points. Thus all points outside the domain B remain in E_R , and all sampled domain points remain in E_R .

For a class C of size s with $a = |C \cap R|$, the discarded count is precisely

$$(s - a)\mathbf{1}_{\{a < t\}}. \quad (\text{II.152.3})$$

There are two contributions to the definition, and neither should be dropped: a class with enough anchors is retained entirely, while a class with too few anchors still retains its sampled points.

Remark II.152.3 (Monotonicity). If $R \subseteq R'$, then $K_h(R) \subseteq K_h(R')$ and $D_C(R') \leq D_C(R)$. Consequently, a result for at most r anchors can be padded to exactly $r \leq m$ distinct anchors without increasing the loss. The statements below use exact-size samples because their probability law and extremal problem are especially clean.

We use the convention $\binom{a}{b} = 0$ when $a \geq 0$ and $b \notin \{0, \dots, a\}$. A hypergeometric variable $\text{Hyp}(m, s, u)$ counts the members of a fixed s -element class in a uniformly chosen u -subset of an m -element set. The case $r = m$ is treated explicitly whenever an $(r + 1)$ -subset appears.

II.153 A cutoff-free shared sampling theorem

Source 39, delivered Section 3.

Lemma II.153.1 (Exact one-class loss). *Let R be a uniformly chosen r -subset of J , where $0 \leq r \leq m$. A class of size s contributes expected normalized loss $\ell_{m,r,t}(s)$ from (F.44.2). If $r < m$ and $Z \sim \text{Hyp}(m, s, r + 1)$, then*

$$\ell_{m,r,t}(s) = \frac{m - r}{m(r + 1)} \mathbb{E}[Z \mathbf{1}_{\{1 \leq Z \leq t\}}]. \quad (\text{II.153.1})$$

For $r = m$, this loss is zero.

Proof. The random variable $A = |C \cap R|$ has probability $\binom{s}{j} \binom{m-s}{r-j} / \binom{m}{r}$ of equalling j . Taking the expectation of (II.152.3) and dividing by m gives (F.44.2).

For the second formula, count ordered pairs (R, x) such that $|R| = r$, $x \in C \setminus R$, and $|C \cap R| < t$. The number of such pairs is

$$\sum_{|R|=r} |C \setminus R| \mathbf{1}_{\{|C \cap R| < t\}}.$$

Map a pair to $T = R \cup \{x\}$, an $(r + 1)$ -subset. Conversely, for fixed T , a choice $x \in T \cap C$ gives a valid pair exactly when $1 \leq |T \cap C| \leq t$. Hence the same count is

$$\sum_{|T|=r+1} |T \cap C| \mathbf{1}_{\{1 \leq |T \cap C| \leq t\}}.$$

Divide by $m \binom{m}{r}$ and use $\binom{m}{r+1} / \binom{m}{r} = (m - r) / (r + 1)$. When $r = m$, every domain point is sampled, so no point is discarded. $\square$

The shift from an r -sample to an $(r + 1)$ -sample is the central combinatorial identity. It converts the size-weighted error into the expectation of a variable bounded by t . No lower bound on s is required.

Theorem II.153.2 (Shared-anchor selection). *For every row family in Definition II.152.1, every $t \geq 1$, and every $0 \leq r \leq m$, there is one set $R \subseteq J$ with $|R| = r$ such that*

$$D_C(R) \leq \frac{1}{W} \sum_h w_h \sum_{i=1}^{q_h} \ell_{m,r,t}(|C_{h,i}|) \quad (\text{II.153.2})$$

$$\leq \min \left\{ \delta_B, \frac{t\bar{q}(m-r)}{m(r+1)} \right\}. \quad (\text{II.153.3})$$

In particular, if every row has at most q classes, then $D_C(R) \leq tq/(r+1)$.

Proof. For a uniform r -subset, linearity of expectation and disjointness of the classes give

$$\mathbb{E}_R D_C(R) = \frac{1}{W} \sum_h w_h \sum_i \ell_{m,r,t}(|C_{h,i}|).$$

At least one sample has loss no greater than this average. Formula (II.153.1) bounds each summand by $t(m-r)/(m(r+1))$ when $r < m$; the endpoint $r = m$ is immediate. Also, the loss is always at most δ_B , so its expectation has this bound as well. Finally, $\bar{q} \leq q$ and $(m-r)/m \leq 1$. $\square$

Corollary II.153.3 (An explicit anchor budget). *Let $0 < \sigma < 1$ and suppose every row has at most $q \geq 1$ classes. The choice*

$$r = \min \left\{ m, \left\lceil \frac{tq}{\sigma} \right\rceil \right\} \quad (\text{II.153.4})$$

permits $D_C(R) \leq \sigma$. A sufficient budget using the finite-population correction is

$$r \geq \left\lceil \frac{m(tq - \sigma)}{tq + \sigma m} \right\rceil, \quad 0 \leq r \leq m. \quad (\text{II.153.5})$$

The same formulas are valid with q replaced by any upper bound on $\bar{q}$, using a maximum with zero in (II.153.5) if its numerator is negative.

Proof. If (II.153.4) gives $r = m$, the loss is zero. Otherwise $tq/(r+1) < \sigma$. For (II.153.5), rearrange $tq(m-r) \leq \sigma m(r+1)$ to obtain $m(tq - \sigma) \leq r(tq + \sigma m)$, and apply Theorem II.153.2. $\square$

Example II.153.4 (Singletons are not an exception). If $t \geq 2$ and $C = \{x\}$, its class can never contain t distinct anchors. Nevertheless x is certified when $x \in R$, and its exact expected loss is

$$\ell_{m,r,t}(1) = \frac{m-r}{m^2}.$$

No false two-hit estimate is used. If every row consists of at most q singletons, the total expected loss is at most $q(m-r)/m^2$, which can be much smaller than the universal bound.

Remark II.153.5 (Why this improves the power of the error parameter). A truncation proof discards classes of density below σ/q and then requires each surviving class to fail with probability at most σ . That two-stage requirement can introduce an unnecessary second small parameter. Here the loss of a class is multiplied by its own mass before any estimate is made. The exact double count controls the *sum of discarded masses*, directly giving q/r rather than a per-class accuracy demand.

For affine interpolation, take $t = 2$. The repository's corrected long-column lemma requires $6q \leq r\sigma^2$, together with a size condition, and loses at most 2σ ambient mass [175]. Its short-column wrapper removes the separate long-column hypothesis by sampling all columns when needed [176]. Theorem II.153.2 instead uses the one uniform-subset procedure at all column lengths, gives loss σ with (II.153.4), and supplies the same sampled-or-anchored type of output. This comparison concerns the actual stated budgets, not a claim that all possible refinements of the older proof require a quadratic budget.

II.154 The exact finite minimax problem

Source 39, delivered Section 4.

Definition II.154.1 (Worst best-sample loss). For $m \geq 1$, $q \geq 1$, $0 \leq r \leq m$, and $t \geq 1$, let

$$\mathfrak{M}_{m,q,r,t} = \sup_{\mathcal{C}} \min_{\substack{R \subseteq J \\ |R|=r}} D_{\mathcal{C}}(R),$$

where $\mathcal{C}$ ranges over all finite weighted row families with at most q pairwise-disjoint classes in each row, on an m -element column set.

Theorem II.154.2 (Exact finite minimax formula). *The supremum in Definition II.154.1 is attained by a finite unweighted family. Its value is*

$$\mathfrak{M}_{m,q,r,t} = \max_{\substack{(s_1, \dots, s_q) \in \mathbb{N}_0^q \\ \sum_i s_i \leq m}} \sum_{i=1}^q \ell_{m,r,t}(s_i). \quad (\text{II.154.1})$$

An attaining family can be obtained by applying all permutations of J to any maximizing disjoint class profile.

Proof. Let the maximum on the right be A . There are finitely many profiles, so it is attained. Pad rows with empty classes to give exactly q labels. In each row, $\sum_i |C_{h,i}| \leq m$, hence $\sum_i \ell_{m,r,t}(|C_{h,i}|) \leq A$. Averaging over rows and applying (II.153.2) gives an r -set with loss at most A . Thus $\mathfrak{M}_{m,q,r,t} \leq A$.

For the reverse inequality, choose a maximizing profile (s_i) and disjoint sets $C_1, \dots, C_q \subseteq J$ of those sizes. Let the row set be the symmetric group $\text{Sym}(J)$, with equal weights. In row π , use classes $\pi(C_1), \dots, \pi(C_q)$. Fix any r -subset R . The loss in this row is the loss of the original profile against $\pi^{-1}(R)$, divided by m . As π runs uniformly through the symmetric group, $\pi^{-1}(R)$ is uniform among all r -subsets: each such subset occurs $r!(m-r)!$ times. Therefore the average row loss for this fixed R is $\sum_i \ell_{m,r,t}(s_i) = A$.

This holds for every R , so even the best sample has loss A . The family is finite and unweighted, proving both the lower bound and attainment. Equal copies of a row may be removed by passing to the orbit of the labelled partition, since orbit fibres have equal cardinality. $\square$

Corollary II.154.3 (A finite criterion for any proposed universal bound). *A number a bounds the best shared-sample loss for every row family with the parameters (m, q, r, t) if and only if*

$$\sum_{i=1}^q \ell_{m,r,t}(s_i) \leq a \quad \text{for every integer profile with } \sum_i s_i \leq m.$$

Thus any improvement in a universal finite sampling constant can be checked against a finite one-row profile optimization, even though the original minimax problem permits arbitrarily many rows.

II.154.1 Exact evaluation by dynamic programming

For $0 \leq a \leq q$ and $0 \leq b \leq m$, let $V_a(b)$ be the best sum of losses from a classes using at most b columns. Then

$$V_0(b) = 0, \quad V_a(b) = \max_{0 \leq s \leq b} (V_{a-1}(b-s) + \ell_{m,r,t}(s)). \quad (\text{II.154.2})$$

The minimax value is $V_q(m)$. Storing a maximizing s at each state recovers a profile. Once the $m+1$ rational values of ℓ are available, the dynamic program performs $O(qm^2)$ rational comparisons and additions. Memory is $O(qm)$ with parent pointers, or $O(m)$ when only the value is needed. These are arithmetic-operation counts; they do not bound the bit complexity of large binomial coefficients by a constant.

Example II.154.4 (Exact small extremizers). For $(m, q, r, t) = (6, 2, 2, 2)$, the profile $(3, 3)$ gives $\mathfrak{M} = 3/5$. The 20 labelled partitions of a six-element set into two three-element classes form a family for which all 15 two-element anchor sets have loss exactly $3/5$.

For $(7, 2, 3, 2)$, the maximizing profile $(3, 3)$ leaves one unused column and gives $\mathfrak{M} = 96/245$. Its 140 labelled placements have this average loss against every one of the 35 three-element samples. These identities are also checked by exhaustive rational enumeration in the supplied certificates.

Proposition II.154.5 (Boundary regimes). *For $q \geq 1$, one has $\mathfrak{M}_{m,q,m,t} = 0$. If $r < t$, then*

$$\mathfrak{M}_{m,q,r,t} = 1 - \frac{r}{m}. \quad (\text{II.154.3})$$

Proof. The first assertion follows because every point is sampled. If $r < t$, no class can have t sampled points, so only sampled targets are retained. For a class of size s , its expected discarded count is $s(1 - r/m)$; hence $\ell_{m,r,t}(s) = s(m - r)/m^2$. The profile maximum is obtained by using all m columns, for example in a single class. This gives (II.154.3). $\square$

Remark II.154.6 (The scope of the extremal family). The symmetrization theorem is valid with no field structure on J . If a field structure is subsequently added, the class family still need not exhibit the horizontal regularity required elsewhere in Gowers's proof. Moreover, even if a function is assigned to each class, a point left uncertified by this rule might be algebraically recoverable in some other way. The theorem proves minimax optimality of the rule in Definition II.152.2, and no stronger algorithmic lower bound.

II.155 A closed finite profile formula and the affine quadratic cap

Source 39, delivered Section 5.

The profile optimization in Theorem II.154.2 can in fact be solved without dynamic programming. The key extra fact is that the one-class loss is concave up to its first maximum and never increases afterwards. The hypergeometric expression makes this shape accessible through exact finite differences.

Write $\Delta u(s) = u(s+1) - u(s)$ and $\Delta^2 u(s) = u(s+2) - 2u(s+1) + u(s)$. These expressions are only used when their arguments lie between 0 and m .

Lemma II.155.1 (Finite differences of a hypergeometric average). *Let g be any function on $\{0, \dots, n\}$ and let $A_n(s) = \mathbb{E}[g(Z_s)]$ for $Z_s \sim \text{Hyp}(m, s, n)$, with $0 \leq n \leq m$. For $n \geq 1$,*

$$\Delta A_n(s) = \frac{n}{m} \mathbb{E}[\Delta g(Y)], \quad Y \sim \text{Hyp}(m-1, s, n-1). \quad (\text{II.155.1})$$

For $n \geq 2$ and $m \geq 2$,

$$\Delta^2 A_n(s) = \frac{n(n-1)}{m(m-1)} \mathbb{E}[\Delta^2 g(Y)], \quad Y \sim \text{Hyp}(m-2, s, n-2). \quad (\text{II.155.2})$$

Proof. Couple the class of size s with that of size $s+1$ by adding one distinguished column. A uniform n -subset contains that column with probability n/m . Conditional on containing it, its other $n-1$ columns are uniform in the remaining population of size $m-1$, with s successes. If the distinguished column is absent, the class count does not change; if it is present, the change in g is $\Delta g(Y)$. This proves (II.155.1). Apply the same argument to the hypergeometric average on its right, with population $m-1$, sample size $n-1$, and function Δg , to obtain (II.155.2). $\square$

Lemma II.155.2 (Exact curvature and the one-class shape). *Fix m, r, t . The sequence $s \mapsto \ell_{m,r,t}(s)$ is nondecreasing up to its first maximizing index $a = a_{m,r,t}$ and nonincreasing thereafter. It is discretely concave on $\{0, \dots, a\}$.*

More explicitly, when $1 \leq t \leq r < m$ and $0 \leq s \leq m-2$, put

$$K_{m,r} = \frac{r(m-r)}{m^2(m-1)\binom{m-2}{r-1}} > 0.$$

Then

$$\begin{aligned} \Delta^2 \ell_{m,r,t}(s) = K_{m,r} & \left[t \binom{s}{t} \binom{m-s-2}{r-t-1} \right. \\ & \left. - (t+1) \binom{s}{t-1} \binom{m-s-2}{r-t} \right]. \end{aligned} \quad (\text{II.155.3})$$

For $r > t$ this factors as

$$\Delta^2 \ell_{m,r,t}(s) = \frac{K_{m,r}}{r-t} \binom{s}{t-1} \binom{m-s-2}{r-t-1} [(r+1)(s+2) - (t+1)(m+1)]. \quad (\text{II.155.4})$$

For $r = t$ the second difference is nonpositive everywhere.

Proof. If $r = m$, the sequence is identically zero. If $r < t$, then $\ell(s) = s(m-r)/m^2$ by Proposition II.154.5, so it is linear and nondecreasing. These cases already give the claimed shape.

Suppose $1 \leq t \leq r < m$. In (II.153.1) set $g(z) = z \mathbf{1}_{\{z \leq t\}}$ for $z \geq 0$. Its second difference is zero except at $z = t-1$ and $z = t$, where it equals $-(t+1)$ and t , respectively. Apply Lemma II.155.1 with $n = r+1$, and multiply by the prefactor $(m-r)/(m(r+1))$. The remaining hypergeometric variable has population $m-2$, class size s , and sample size $r-1$. Writing its two relevant probabilities with binomial coefficients yields (II.155.3).

If $r = t$, its first term is zero, proving global concavity. If $r > t$, use

$$t \binom{s}{t} = (s-t+1) \binom{s}{t-1}, \quad \binom{m-s-2}{r-t} = \frac{m-s-r+t-1}{r-t} \binom{m-s-2}{r-t-1}.$$

These identities remain valid at the boundary with the zero convention. The bracket after factoring is

$$(s-t+1)(r-t) - (t+1)(m-s-r+t-1) = (r+1)(s+2) - (t+1)(m+1),$$

which proves (II.155.4).

Consequently the finite-difference sequence $d_s = \ell(s+1) - \ell(s)$ is first nonincreasing and then nondecreasing; in the case $r = t$ it is simply nonincreasing. Also $d_0 = (m-r)/m^2 > 0$, while $\ell(m) = 0$ and $\ell(m-1) \geq 0$, so $d_{m-1} \leq 0$. Every term on the final nondecreasing part is therefore nonpositive. On the initial nonincreasing part, the differences can cross from positive to nonpositive at most once. It follows that ℓ increases to its first maximum and never increases after it. The differences before that first maximum belong to the nonincreasing part, proving discrete concavity up to a . $\square$

Theorem II.155.3 (Balanced-and-capped finite extremizers). *Let $a = a_{m,r,t}$ be the least size maximizing $\ell_{m,r,t}$. Define*

$$B = \min\{m, qa\}, \quad v = \lfloor B/q \rfloor, \quad u = \lceil B/q \rceil, \quad \beta = B - qv. \quad (\text{II.155.5})$$

Then

$$\boxed{\mathfrak{M}_{m,q,r,t} = (q - \beta)\ell_{m,r,t}(v) + \beta\ell_{m,r,t}(u).} \quad (\text{II.155.6})$$

An extremizing profile has $q - \beta$ classes of size v and β classes of size u . In particular, an extremizer exists with at most two positive class sizes, and those sizes differ by at most one.

Proof. Start with any feasible profile. Replace every size greater than a by a . By Lemma II.155.2, this does not decrease its objective and does not increase its total size. All sizes now lie in $[0, a]$. Since ℓ is nondecreasing there, add columns to classes until their total is $B = \min\{m, qa\}$; this is feasible and does not decrease the objective.

If two sizes satisfy $y \geq x + 2$, move one column from the larger to the smaller. The objective changes by

$$\ell(x+1) - \ell(x) - (\ell(y) - \ell(y-1)) = \Delta\ell(x) - \Delta\ell(y-1) \geq 0,$$

using discrete concavity on $[0, a]$. Iterating this balancing operation terminates, for example because the sum of squared sizes strictly decreases at each nontrivial step. At termination the sizes differ by at most one and sum to B , hence have the multiplicities in (II.155.5). Their objective is (II.155.6). This profile is feasible, so Theorem II.154.2 proves equality. $\square$

[write] **6 October 2026; sources 34–39.** *Source 19's question, answered for this rule only* (checked at the write by exact rational arithmetic; the intake found the same counts). Source 19's Question 1 asks for the structure of the maximizers of its finite minimax (item II.39). For source 39's rule the formula (II.155.6) agrees with an exact maximization over all class profiles in all 2,835 cases $m \leq 18$, $0 \leq r \leq m$, $t \leq 3$, $q \leq 5$. For source 19's rule it does not: with source 19's one-class loss $W_{m,r,t}(s) = (s/m) \Pr\{X < \min(t, s)\}$ in place of $\ell_{m,r,t}$, the balanced-and-capped value differs from the exact maximum in 199 of the same 2,835 cases; the first is $m = 2$, $r = 1$, $t = 2$, $q = 2$, where the formula gives $1/2$ and the exact value is 1 (one class of size 2, lost with its one sampled point; under source 39's rule the same profile loses $1/2$). Source 19's one-class loss is not concave up to its first maximum, which is what the proof of Theorem II.155.3 uses. The rules also give different values, for example 0.3512 (source 39) against 0.3944 (source 19) at $m = 20$, $q = 2$, $r = 4$, $t = 2$. So the classification for source 19's rule stays open (item II.39).

When $\beta = 0$, one has $u = v$, so formula (II.155.6) never requires evaluating ℓ outside its domain. When $r = m$, the first mode is $a = 0$, giving zero. When $r < t$, it is $a = m$, and the formula reproduces $1 - r/m$. Empty classes cause no problem when $q > m$.

This theorem solves the finite optimization, rather than merely reducing it to a dynamic program. A scan of the $m + 1$ one-class values determines a ; the remaining computation is a single balancing

operation. The dynamic program in Section II.154 is retained as an independent exact verification method.

Theorem II.155.4 (An explicit quadratic cap for affine fibres). *Let $t = 2$. If $r = m$, then $a_{m,r,2} = 0$; if $r < 2$ and $r < m$, then $a_{m,r,2} = m$. For $2 \leq r < m$, define*

$$\zeta_{m,r} = \frac{B_{m,r} + \sqrt{B_{m,r}^2 + 4(r^2 - 1)(m - r)(m - r + 1)}}{2(r^2 - 1)}, \quad B_{m,r} = (r - 2)m + 2r - 1. \quad (\text{II.155.7})$$

Then the least maximizing class size is exactly

$$a_{m,r,2} = \lceil \zeta_{m,r} \rceil. \quad (\text{II.155.8})$$

Together with Theorem II.155.3, this is a closed finite formula for the affine minimax loss, requiring no search over profiles or class sizes.

Proof. The endpoint and $r < 2$ cases have already been established. For $2 \leq r < m$, apply (II.155.1) to (II.153.1). Since $\Delta g(z) = 1$ for $z = 0, 1$, $\Delta g(2) = -2$, and it is zero afterwards,

$$\Delta \ell_{m,r,2}(s) = \frac{m - r}{m^2} [\mathbb{P}(Z = 0) + \mathbb{P}(Z = 1) - 2\mathbb{P}(Z = 2)], \quad Z \sim \text{Hyp}(m - 1, s, r).$$

Apart from positive factors, the bracket has numerator

$$\binom{m - 1 - s}{r} + s \binom{m - 1 - s}{r - 1} - s(s - 1) \binom{m - 1 - s}{r - 2}.$$

For $0 \leq s \leq m - r + 1$, factor out the positive quantity $\binom{m - 1 - s}{r - 2} / (r(r - 1))$. The remaining quadratic is

$$-(r^2 - 1)s^2 + B_{m,r}s + (m - r)(m - r + 1). \quad (\text{II.155.9})$$

Its constant term is positive and its quadratic coefficient negative, so it has one positive root, namely (II.155.7). At $s = m - r + 1 \geq 2$, the unfactored numerator is strictly negative: only its last term is nonzero. Thus the positive root lies strictly between 0 and $m - r + 1$.

The first difference is positive at integer $s < \zeta_{m,r}$ and nonpositive at the first integer $s \geq \zeta_{m,r}$. By the unimodality already proved, this first change determines the least maximum, giving $a_{m,r,2} = \lceil \zeta_{m,r} \rceil$. If the root is an integer, the difference there is zero and the first of the two equal maximizing values is precisely that integer, so the ceiling formula still applies. $\square$

Remark II.155.5 (Exact implementation of the radical ceiling). Let $A = r^2 - 1$, $B = B_{m,r}$, $C = (m - r)(m - r + 1)$, and $D = B^2 + 4AC$. Set $k = \lfloor (B + \lfloor \sqrt{D} \rfloor) / (2A) \rfloor$. This is $\lfloor \zeta_{m,r} \rfloor$. The cap equals k when $Ak^2 - Bk - C = 0$, and otherwise equals $k + 1$. Integer square root and this exact equality test avoid floating-point decisions near an integer root. The supplied implementation uses this procedure.

Example II.155.6 (A genuinely finite improvement). For $(m, q, r, t) = (20, 2, 4, 2)$, the affine root formula gives $a = 7$. Since $qa = 14 \leq 20$, the exact worst-case profile is $(7, 7)$ and

$$\mathfrak{M}_{20,2,4,2} = \frac{1001}{2850} = 0.351228 \dots$$

The simple universal bound is $16/25 = 0.64$. The improved value is not an asymptotic estimate: every such row family has a four-anchor sample with loss at most $1001/2850$, and a finite permutation-orbit family attains equality.

II.156 The Poisson profile and its exact optimization

Source 39, delivered Section 6.

The expression F_t from (F.44.4) has a direct interpretation:

$$F_t(x) = x\mathbb{P}\{\text{Pois}(x) < t\}. \quad (\text{II.156.1})$$

It balances class mass against the probability that a class receives too few anchors. This section solves the associated continuous optimization exactly; Section II.157 justifies its use for the finite minimax problem.

Lemma II.156.1 (Unique maximum and the useful concavity interval). *For every $t \geq 1$, the function F_t has a unique positive maximizer λ_t . It is characterized by*

$$\sum_{j=0}^{t-1} \frac{\lambda_t^j}{j!} = \frac{\lambda_t^t}{(t-1)!}. \quad (\text{II.156.2})$$

One has $0 < \lambda_t \leq t$, with strict inequality when $t > 1$. The function is strictly increasing before λ_t , strictly decreasing after λ_t , and concave on $[0, \lambda_t]$.

Proof. Put $P_{t-1}(x) = \sum_{j=0}^{t-1} x^j/j!$. Direct differentiation gives

$$F'_t(x) = e^{-x} \left(P_{t-1}(x) - \frac{x^t}{(t-1)!} \right), \quad (\text{II.156.3})$$

$$F''_t(x) = \frac{e^{-x} x^{t-1}}{(t-1)!} (x - t - 1). \quad (\text{II.156.4})$$

For $x > 0$, the equation $F'_t(x) = 0$ becomes

$$\sum_{j=0}^{t-1} \frac{x^{j-t}}{j!} = \frac{1}{(t-1)!}.$$

The left side is strictly decreasing from infinity to zero. This proves a unique root and the claimed signs of the derivative.

At $x = t$, the terms $t^j/j!$ are nondecreasing for $0 \leq j \leq t-1$, and each is at most $t^{t-1}/(t-1)!$. Therefore $P_{t-1}(t) \leq t^t/(t-1)!$, strictly for $t > 1$. Hence $\lambda_t \leq t$, strictly for $t > 1$. Formula (II.156.4) now proves concavity on $[0, \lambda_t]$. $\square$

Theorem II.156.2 (Poissonized subprobability optimization). *For real $r > 0$, integer $q \geq 1$, and integer $t \geq 1$,*

$$\max_{\substack{p_1, \dots, p_q \geq 0 \\ \sum_i p_i \leq 1}} \sum_{i=1}^q p_i \mathbb{P}\{\text{Pois}(rp_i) < t\} = \frac{q}{r} F_t \left(\min \left\{ \lambda_t, \frac{r}{q} \right\} \right). \quad (\text{II.156.5})$$

An optimizer has all rp_i equal to $\min\{\lambda_t, r/q\}$.

Proof. Write $x_i = rp_i$. The optimization is $r^{-1} \max \sum_i F_t(x_i)$ subject to $x_i \geq 0$ and $\sum_i x_i \leq r$. Any coordinate larger than λ_t may be replaced by λ_t , decreasing the resource consumption and increasing the objective. We may therefore restrict to $x_i \in [0, \lambda_t]$.

By concavity and Jensen's inequality,

$$\sum_{i=1}^q F_t(x_i) \leq qF_t\left(\frac{1}{q} \sum_i x_i\right).$$

The average is at most both λ_t and r/q . Since F_t is increasing on $[0, \lambda_t]$, this is at most $qF_t(\min\{\lambda_t, r/q\})$. Equal coordinates at that value are feasible and attain the bound. $\square$

The inequality $\sum p_i \leq 1$, rather than equality, is part of the theorem. If $r/q > \lambda_t$, the optimizer leaves mass $1 - q\lambda_t/r$ unused. If the classes were forced to partition all columns with no leftover domain, the optimization would be different. The partial-graph application permits the subprobability formulation naturally.

Corollary II.156.3 (The affine constant). *For $t = 2$,*

$$\lambda_2 = \varphi, \quad \kappa_2 = \varphi^3 e^{-\varphi} = 0.839962094657 \dots$$

For $t = 1$, $\lambda_1 = 1$ and $\kappa_1 = e^{-1}$.

Proof. Equation (II.156.2) is $1 + x = x^2$ for $t = 2$. Its positive root is φ , and $F_2(\varphi) = \varphi(1 + \varphi)e^{-\varphi} = \varphi^3 e^{-\varphi}$. The $t = 1$ case is immediate. $\square$

[write] **6 October 2026; sources 34–39.** This is source 19's Corollary II.69.5 (the constant 0.839962094657; source 19's Lemma II.69.1 gives the maximizing mean). In the regime $q/r \rightarrow 0$ the two rules have the same limit, since the sampled points of a failed class carry vanishing mass.

Table II.156.1: Poisson thresholds and sharp sparse-sampling coefficients. Decimals are numerical approximations; (II.156.2) defines the exact values.

II.157 Uniform asymptotics and a sharp sample-complexity law

Source 39, delivered Section 7.

Pointwise Poisson convergence is not by itself enough to optimize over every class-size profile. The maximizing sizes vary with m , r , and q , and a profile may contain very large classes. We therefore prove a uniform marginal estimate, including a tail bound, before interchanging the limit with the profile maximum.

Lemma II.157.1 (An elementary product bound for sampling without replacement). *Let $z_1, \dots, z_m \geq 0$ and let R be a uniform r -subset of $\{1, \dots, m\}$. Then*

$$\mathbb{E} \prod_{i \in R} z_i \leq \left(\frac{1}{m} \sum_{i=1}^m z_i \right)^r. \quad (\text{II.157.1})$$

In particular, for $A \sim \text{Hyp}(m, s, r)$ and $c > 0$,

$$\mathbb{E} e^{-cA} \leq \left(1 - \frac{s}{m} (1 - e^{-c}) \right)^r \leq \exp \left(-\frac{rs}{m} (1 - e^{-c}) \right). \quad (\text{II.157.2})$$

Proof. The left side of (II.157.1) is the normalized elementary symmetric polynomial $e_r(z_1, \dots, z_m) / \binom{m}{r}$. Holding all but two coordinates u, v fixed, this polynomial before normalization has the form $A_0 + (u+v)B_0 + uvC_0$ with $A_0, B_0, C_0 \geq 0$. Replacing u, v by their average preserves their sum and increases their product, so does not decrease e_r .

Repeatedly average a largest and a smallest coordinate. The sum remains fixed and the sum of squared deviations from the mean decreases by half the square of the current spread. Thus the spread tends to zero, and the coordinates converge to the common mean. By continuity, e_r at the original vector is at most $\binom{m}{r}$ times the r th power of the mean. The cases $r = 0, 1$ also follow directly.

For (II.157.2), set $z_i = e^{-c}$ on the class and $z_i = 1$ outside it. Apply (II.157.1) and $1 - u \leq e^{-u}$. $\square$

Theorem II.157.2 (Uniform one-class Poisson limit). *Fix $t \geq 1$. Along any sequence of integer pairs (m, r) with $r \rightarrow \infty$ and $r/m \rightarrow 0$,*

$$\sup_{0 \leq s \leq m} \left| r\ell_{m,r,t}(s) - F_t \left(\frac{rs}{m} \right) \right| \rightarrow 0. \quad (\text{II.157.3})$$

The supremum is over integer class sizes.

Proof. Write $x = rs/m$ and $A \sim \text{Hyp}(m, s, r)$. By the definition of ℓ ,

$$r\ell_{m,r,t}(s) = x \sum_{j=0}^{t-1} \left(1 - \frac{j}{s} \right) \mathbb{P}(A = j) \quad (\text{II.157.4})$$

when $s > 0$, with zero terms for impossible j . The $s = 0$ case is zero. The expression is nonnegative and at most $x\mathbb{P}(A < t)$.

First consider any sequence with $x \rightarrow x_0 \in (0, \infty)$. Then $s \rightarrow \infty$, $s/m \rightarrow 0$, and eventually $s + r < m$. The zero-count probability satisfies

$$\begin{aligned} \mathbb{P}(A = 0) &= \prod_{i=0}^{r-1} \left(1 - \frac{s}{m-i} \right), \\ \log \mathbb{P}(A = 0) &= -x + O \left(\frac{xr}{m} + \frac{x^2}{r} \right). \end{aligned}$$

Indeed, uniformly for $0 \leq i < r$, the quantity $s/(m-i)$ is $O(x/r)$; summing its first-order terms gives $x + O(xr/m)$, and summing its squares gives $O(x^2/r)$. For any fixed $j \geq 0$,

$$\frac{\mathbb{P}(A = j)}{\mathbb{P}(A = 0)} = \frac{(s)_j (r)_j}{j! \prod_{a=1}^j (m - s - r + a)} \rightarrow \frac{x_0^j}{j!}, \quad (\text{II.157.5})$$

where $(s)_j = s(s-1)\cdots(s-j+1)$. Consequently $\mathbb{P}(A = j) \rightarrow e^{-x_0} x_0^j / j!$, and (II.157.4) tends to $F_t(x_0)$. If $x \rightarrow 0$, both $r\ell$ and $F_t(x)$ lie between zero and x , so the same conclusion holds.

These sequential statements imply uniform convergence on every bounded interval of x . Otherwise one could choose a sequence of bounded x at which the error stays above a fixed positive number, pass to a convergent subsequence, and contradict the preceding argument.

It remains to control unbounded x . Since $A < t$ means $A \leq t-1$,

$$\mathbb{P}(A < t) \leq e^{t-1} \mathbb{E} e^{-A} \leq \exp(t-1 - (1-e^{-1})x)$$

by Lemma II.157.1. Thus, uniformly in m, r, s ,

$$0 \leq r\ell_{m,r,t}(s) \leq x \exp(t-1 - (1-e^{-1})x). \quad (\text{II.157.6})$$

The same bound holds for $F_t(x)$ by the Laplace transform of a Poisson variable, or it follows directly from (II.156.1). Both tails tend uniformly to zero as $x \rightarrow \infty$. Combining the compact interval convergence with these tail estimates proves (II.157.3). $\square$

Theorem II.157.3 (Asymptotic minimax profile). *Fix $t \geq 1$. Let m, r, q vary with $r \rightarrow \infty$, $r/m \rightarrow 0$, and $q \geq 1$. If q/r stays bounded, then*

$$\mathfrak{M}_{m,q,r,t} = \frac{q}{r} \left[F_t \left(\min \left\{ \lambda_t, \frac{r}{q} \right\} \right) + o(1) \right]. \quad (\text{II.157.7})$$

In particular, if $q/r \rightarrow 0$, then $\mathfrak{M}_{m,q,r,t} \sim \kappa_t q/r$.

Proof. Let $\varepsilon_{m,r}$ denote the supremum in (II.157.3). It tends to zero. For any feasible finite profile (s_i) , put $x_i = rs_i/m$. Then $\sum_i x_i \leq r$, so Theorems II.154.2, II.156.2, and II.157.2 give

$$\mathfrak{M}_{m,q,r,t} \leq \frac{q}{r} \left[F_t \left(\min \left\{ \lambda_t, \frac{r}{q} \right\} \right) + \varepsilon_{m,r} \right].$$

For a matching lower bound, set $x_* = \min\{\lambda_t, r/q\}$ and choose all q class sizes equal to $s_* = \lfloor mx_*/r \rfloor$. This is feasible since $qs_* \leq mqx_*/r \leq m$. Also $0 \leq x_* - rs_*/m < r/m \rightarrow 0$. The function F_t is uniformly continuous on $[0, \lambda_t]$, so

$$\mathfrak{M}_{m,q,r,t} \geq q\ell_{m,r,t}(s_*) \geq \frac{q}{r} (F_t(x_*) - o(1) - \varepsilon_{m,r}).$$

This proves (II.157.7). If $q/r \rightarrow 0$, then $x_* = \lambda_t$ eventually, and $\kappa_t > 0$, giving the relative asymptotic. $\square$

[write] **6 October 2026; sources 34–39.** Source 19's Theorem II.69.4 is the case $q/r \rightarrow 0$; the regime q/r bounded, where it is best to use only part of the column set, is new here and advances source 19's question on rates in the sharp law (item II.39).

Corollary II.157.4 (Two asymptotic regimes). *Under the hypotheses above, if $q/r \rightarrow \theta \in (0, \infty)$, then*

$$\mathfrak{M}_{m,q,r,t} \longrightarrow \Psi_t(\theta) := \begin{cases} \theta \kappa_t, & 0 < \theta \leq 1/\lambda_t, \\ e^{-1/\theta} \sum_{j=0}^{t-1} \frac{\theta^{-j}}{j!}, & \theta \geq 1/\lambda_t. \end{cases} \quad (\text{II.157.8})$$

In the first regime, asymptotically extremal class sizes are $s_i \sim \lambda_t m/r$ and need not exhaust the columns. In the second, they are $s_i \sim m/q$ and asymptotically exhaust the column budget.

Proof. Substitute $r/q \rightarrow 1/\theta$ in (II.157.7). The profiles in the lower bound proof have the stated sizes. At the transition the two expressions coincide because $\kappa_t = F_t(\lambda_t)$. $\square$

Proposition II.157.5 (Shape of the limiting loss curve). *Extend Ψ_t by $\Psi_t(0) = 0$. It is continuously differentiable, increasing, and concave on $[0, \infty)$. It is linear on $[0, 1/\lambda_t]$ and strictly concave thereafter. Moreover, $\Psi_t(\theta) \rightarrow 1$ as $\theta \rightarrow \infty$.*

Proof. On the nonlinear branch, differentiation gives

$$\Psi'_t(\theta) = \frac{e^{-1/\theta}}{(t-1)!\theta^{t+1}} > 0, \quad \frac{\Psi''_t(\theta)}{\Psi'_t(\theta)} = \frac{1 - (t+1)\theta}{\theta^2} < 0.$$

The last inequality holds because $\theta \geq 1/\lambda_t \geq 1/t$. At $\theta = 1/\lambda_t$, the right derivative is $e^{-\lambda_t} \lambda_t^{t+1}/(t-1)! = \kappa_t$ by (II.156.2); this equals the slope of the linear branch. The limit at infinity follows from (II.157.8). $\square$

The statement about $\theta \rightarrow \infty$ describes the explicitly defined curve Ψ_t , not an additional uniform finite-parameter limit outside the stated hypotheses of Theorem II.157.3.

Theorem II.157.6 (Sharp sparse-sampling anchor budget). *For $0 < \sigma < 1$, define the smallest worst-case sufficient sample size by*

$$r_*(m, q, t, \sigma) = \min\{0 \leq r \leq m : \mathfrak{M}_{m,q,r,t} \leq \sigma\}.$$

Fix t . Along sequences with $\sigma \rightarrow 0$, $q \geq 1$, and $q/(\sigma m) \rightarrow 0$, one has

$$r_*(m, q, t, \sigma) \sim \frac{\kappa_t q}{\sigma}. \quad (\text{II.157.9})$$

For affine certification the coefficient is $\kappa_2 = \varphi^3 e^{-\varphi}$.

Proof. The minimum exists since sampling all m columns gives zero loss. Fix $0 < \epsilon < \kappa_t$ and compare

$$r_- = \left\lfloor \frac{(\kappa_t - \epsilon)q}{\sigma} \right\rfloor, \quad r_+ = \left\lceil \frac{(\kappa_t + \epsilon)q}{\sigma} \right\rceil.$$

Both tend to infinity, both satisfy $r_{\pm}/m \rightarrow 0$, and $q/r_{\pm} \rightarrow 0$. Theorem II.157.3 therefore gives

$$\frac{\mathfrak{M}_{m,q,r_-,t}}{\sigma} \rightarrow \frac{\kappa_t}{\kappa_t - \epsilon} > 1, \quad \frac{\mathfrak{M}_{m,q,r_+,t}}{\sigma} \rightarrow \frac{\kappa_t}{\kappa_t + \epsilon} < 1.$$

The best-sample loss is nonincreasing in r , by Remark II.152.3, and the same is true of its supremum. Hence eventually $r_- < r_* \leq r_+$. Divide by q/σ and let $\epsilon \downarrow 0$. $\square$

Equation (II.157.9) is a genuine optimality statement for a sample-complexity problem. It does not say that the simple finite coefficient t in Corollary II.153.3 is sharp, nor that the asymptotic coefficient κ_t can be substituted into that finite corollary without an error term and additional scale assumptions.

II.158 Deterministic anchor selection by conditional expectation

Source 39, delivered Section 8.

The existence proof can be made constructive when the row classes are given explicitly. There is no need to enumerate all $\binom{m}{r}$ possible final samples.

Suppose $T \subseteq J$ is a partial sample of size $a \leq r$. Complete it by a uniform $(r - a)$ -subset of $J \setminus T$. For a class C , write

$$b = |C \cap T|, \quad c = |C \setminus T|, \quad n = m - a, \quad u = r - a.$$

If $b \geq t$, its conditional expected discarded count is zero. Otherwise it is

$$L_C(T) = \frac{1}{\binom{n}{u}} \sum_{j=0}^{t-b-1} (c-j) \binom{c}{j} \binom{n-c}{u-j}, \quad (\text{II.158.1})$$

with zero terms outside the feasible range. Indeed, the additional hits have law $\text{Hyp}(n, c, u)$, and after j such hits there are $c - j$ unsampled points in the class.

Define the conditional potential

$$\Phi(T) = \frac{1}{mW} \sum_h w_h \sum_i L_{C_{h,i}}(T). \quad (\text{II.158.2})$$

It is the expected final loss conditioned on T being contained in the final sample, with the remaining columns chosen uniformly.

Lemma II.158.1 (One-step potential identity). *If $|T| < r$, then*

$$\Phi(T) = \frac{1}{m - |T|} \sum_{x \in J \setminus T} \Phi(T \cup \{x\}). \quad (\text{II.158.3})$$

Proof. Choose the next column uniformly from $J \setminus T$, then choose the rest uniformly without replacement. This yields a uniform final r -subset containing T . More explicitly, each particular completion of size $r - |T|$ can have any of its $r - |T|$ points selected first, and these choices give the same total probability for every completion. The law of total expectation now gives (II.158.3). $\square$

Theorem II.158.2 (Exact derandomization). *Start with $T = \emptyset$. While $|T| < r$, add a column minimizing $\Phi(T \cup \{x\})$ over $x \notin T$. The final sample R satisfies*

$$D_C(R) = \Phi(R) \leq \Phi(\emptyset) = \frac{1}{W} \sum_h w_h \sum_i \ell_{m,r,t}(|C_{h,i}|). \quad (\text{II.158.4})$$

For rational row weights, every comparison can be performed exactly with rational arithmetic.

Proof. A minimum of finitely many real numbers is at most their average, so Lemma II.158.1 makes the potential nonincreasing at every step. When $|T| = r$, there is no remaining randomness; formula (II.158.1) is the actual discarded count. At the initial state it is the unconditional expectation from Lemma II.153.1. $\square$

The supplied implementation follows this algorithm with exact rational arithmetic. Its main module is `code/anchor_selection.py`; values have Python's `fractions.Fraction` type. It validates that classes within a row are disjoint and that columns and parameters are in range. A straightforward implementation evaluates at most rm candidate extensions, each using the supplied row classes. This is a finite algorithm for explicitly represented data; it is not asserted to be an efficient implementation of the entire inverse proof, where the class descriptions and the number of rows may be extremely large.

For a fixed row family the derandomized loss can be much smaller than the universal minimax value. The permutation-orbit construction is the limiting case: the final loss is the same for every sample, so no deterministic choice can improve on the average. This gives a useful exact test case for the implementation.

II.159 Polynomial reconstruction, general interpolation spaces, and errors

Source 39, delivered Section 9.

II.159.1 A polynomial graph-cover theorem

Let $\mathbb{F}$ be any field, and now regard J as an m -element subset of $\mathbb{F}$. The distinctness of the elements of J is the only hypothesis needed for the Vandermonde denominators. Let $B \subseteq H \times J$ and let $f : B \rightarrow \mathbb{F}$. Suppose each fibre B_h has a partition into at most q classes such that on each class $f(h, \cdot)$ agrees with a polynomial of degree at most $t - 1$. The polynomials may depend on both the row and the class.

For $a \in J$, define the partial horizontal section

$$B_a = \{h : (h, a) \in B\}, \quad \psi_a(h) = f(h, a) \quad (h \in B_a).$$

For a t -subset $S \subseteq J$ and $a \in S$, put

$$L_{S,a}(x) = \prod_{b \in S \setminus \{a\}} \frac{x - b}{a - b}. \quad (\text{II.159.1})$$

These polynomials satisfy $L_{S,a}(b) = \mathbf{1}_{\{a=b\}}$ for $b \in S$.

Theorem II.159.1 (Shared polynomial interpolants). *There is an r -subset $R \subseteq J$ and an ambient good set E_R with weighted complement at most*

$$\frac{1}{W} \sum_h w_h \sum_i \ell_{m,r,t}(|C_{h,i}|) \leq \frac{tq(m-r)}{m(r+1)}$$

(as a fraction of mW), such that every $(h, x) \in B \cap E_R$ lies on one of the following partial graphs:

$$(h, x) \longmapsto \psi_a(h) \quad (a \in R), \quad \text{defined when } h \in B_a; \quad (\text{II.159.2})$$

$$I_S(h, x) = \sum_{a \in S} L_{S,a}(x) \psi_a(h) \quad \left(S \in \binom{R}{t} \right), \quad \text{defined when } h \in \bigcap_{a \in S} B_a. \quad (\text{II.159.3})$$

There are at most $r + \binom{r}{t}$ candidate expressions. Every anchor actually used to certify a nonsampled target belongs to $B \cap E_R$ in the same row.

Proof. Choose the sample by Theorem II.153.2 and use the good set from Definition II.152.2. If $x \in R$, then the single expression with $a = x$ equals $f(h, x)$.

Otherwise, certification means that the class containing x contains at least t elements of R . Choose any t of them and call this set S . Let P be the polynomial of degree at most $t - 1$ agreeing with $f(h, \cdot)$ on the class. Lagrange interpolation gives

$$P(x) = \sum_{a \in S} L_{S,a}(x)P(a) = \sum_{a \in S} L_{S,a}(x)\psi_a(h) = I_S(h, x).$$

For completeness, the interpolation formula follows because its right side is a polynomial of degree at most $t - 1$ agreeing with P at the t distinct points of S ; their difference has t roots and degree at most $t - 1$, and hence is zero. The root bound follows by repeatedly factoring $X - a$ at each root over a field.

The domain conditions hold because S is contained in the same class. All its points are sampled, and the definition of E_R retains every sampled domain point. The number of expressions is the number of singletons plus the number of t -subsets of R . $\square$

For $t = 2$, the paired expression can be written without separating slope and intercept:

$$I_{\{a,b\}}(h, x) = \frac{x - b}{a - b}\psi_a(h) + \frac{a - x}{a - b}\psi_b(h). \quad (\text{II.159.4})$$

This is a linear combination of only two horizontal sections, with affine coefficients in x . If each section is multilinear in the base coordinates, the displayed function is multilinear in the base coordinates and x . There is no need to first place all pairwise slopes and intercepts into a larger common union and then refine that union.

Remark II.159.2 (Partial graphs and harmless spurious candidates). The theorem is a cover theorem, not a uniqueness theorem. Different candidate expressions may coincide, and many candidates need not agree with f at a given point. Only one correct expression is required for each retained point. Later list-cover bounds count all candidates because removing spurious ones is not needed for validity.

II.159.2 Unisolvent reconstruction spaces

Definition II.159.3 (A unisolvent space). A t -dimensional linear subspace $\mathcal{W} \subseteq \mathbb{F}^J$ is called t -point unisolvent if, for every $S \in \binom{J}{t}$, the evaluation map $\mathcal{W} \rightarrow \mathbb{F}^S$ is an isomorphism. We additionally require that the constant function 1 belong to $\mathcal{W}$.

The assumption about constants ensures that the direct single-anchor expressions in (II.159.2) remain in the same reconstruction space. If only the nonsampled targets were being considered, this extra assumption would not be needed.

Corollary II.159.4 (Interpolation-space extension). *Replace polynomial class functions in Theorem II.159.1 by members of a t -point unisolvent space $\mathcal{W}$ containing constants. Then the same sample, mass bounds, and candidate count hold, with the Lagrange functions $L_{S,a}$ replaced by the unique elements of $\mathcal{W}$ whose evaluations on S are the standard coordinate vectors.*

Proof. Invert the evaluation isomorphism on each S . If $P \in \mathcal{W}$, its vector of values on S determines it, so $P = \sum_{a \in S} P(a)L_{S,a}$ in $\mathcal{W}$. The rest of the proof is exactly the certification and domain argument of Theorem II.159.1. Constant functions handle sampled targets. $\square$

The polynomial theorem itself remains valid when $m < t$; in that case no t -subset of J exists, and only direct sampled targets can be certified. A t -dimensional subspace of $\mathbb{F}^J$ cannot exist when $m < t$, so the general space formulation is only applicable when its hypotheses can actually hold.

II.159.3 Additive robustness to corrupted domain points

Theorem II.159.5 (Robust shared interpolation). *Suppose $B^\circ \subseteq B \subseteq H \times J$ has weighted complement within B of normalized mass at most δ :*

$$\frac{1}{mW} \sum_h w_h |B_h \setminus B_h^\circ| \leq \delta.$$

Assume that f restricted to each B_h° can be partitioned into at most q polynomial classes of degree at most $t - 1$. Then there is a shared r -subset R and a family of the forms (II.159.2) and (II.159.3), using the actual sections of f on B , which covers all but at most

$$\delta + \frac{tq(m - r)}{m(r + 1)} \quad (\text{II.159.5})$$

of the ambient mass in B . The exact class-profile bound may replace the second term. No factor of r multiplies δ .

Proof. Apply Theorem II.153.2 to the good classes inside B° . The points in B° that fail certification have at most the stated sampling mass. Every certified nonsampled good point has t anchors in its own good class, where the actual values of f agree with the class polynomial. Consequently the candidate built from those actual sections is correct. A good sampled point is covered directly.

Candidates using a corrupted anchor can be ignored for this correctness argument: their presence only adds possible graphs. Discarding the corrupt points themselves costs at most δ , and discarding uncertified good points costs at most the sampling term. The losses add. $\square$

The theorem does not claim that the unknown good set or its class partition can be discovered efficiently from corrupted data. It is an existence and list-cover result. The conditional-expectation algorithm applies directly when the good class descriptions are supplied.

II.160 Labelled slice covers and candidate counts

Source 39, delivered Section 10.

The sampling theorem controls how many horizontal sections are needed. A second, separate issue is how the candidate lists for those sections are carried through a common refinement. Replacing each individual slice list by one large union list is safe but can be very wasteful.

Let the base H have a partition into cells U . On each cell let $\mathcal{V}_U \subseteq \mathbb{F}^U$ be a linear space. Suppose that for each sampled anchor $a \in R$ there is a list

$$\mu_{U,a,1}, \dots, \mu_{U,a,L_a} \in \mathcal{V}_U$$

covering the partial section ψ_a at every good base point of its domain. The list sizes may depend on U ; uniform upper bounds are used below to avoid clutter. The phrase “covering” means that at least one member equals $\psi_a(h)$ at the point in question. No globally consistent branch is assumed.

Theorem II.160.1 (Labelled interpolation of slice lists). *Let $H_0 \subseteq H$ be a common good base set for the slice lists above. On $U \times J$, the points certified by Theorem II.159.1 whose base lies in H_0 are covered by at most*

$$\sum_{a \in R} L_a + \sum_{\substack{S \subseteq R \\ |S|=t}} \prod_{a \in S} L_a \quad (\text{II.160.1})$$

candidates in

$$\mathcal{V}_U \otimes \text{Poly}_{<t}(J) := \left\{ \sum_{j=0}^{t-1} v_j(h) x^j : v_j \in \mathcal{V}_U \right\}.$$

For a common bound $L_a \leq L$, the count is

$$rL + \binom{r}{t} L^t. \quad (\text{II.160.2})$$

If the base exceptional set has weighted mass at most ϵW , the total ambient exceptional mass is at most the sampling loss plus ϵ .

Proof. For each anchor a and each list member, include the direct lift $\mu_{U,a,j}(h)$, constant in x . For each t -subset $S \subseteq R$ and each choice of a list index j_a for every $a \in S$, include

$$\nu_{U,S,(j_a)}(h, x) = \sum_{a \in S} L_{S,a}(x) \mu_{U,a,j_a}(h). \quad (\text{II.160.3})$$

The direct lifts belong to the stated space because constants have degree less than t . Expanding the coefficients $L_{S,a}(x)$ in powers of x shows that every function in (II.160.3) also belongs to that space, using linearity of $\mathcal{V}_U$.

If a certified point is directly sampled, select a correct member of that anchor's list. Otherwise choose its t valid anchors from the same class. At its base point $h \in H_0$, each of those t anchor sections has at least one correct list member. Select these members individually. Formula (II.159.3) shows that the resulting candidate is correct at the target. A choice for other anchors is irrelevant.

The number of direct candidates is $\sum_a L_a$. For a fixed S , the number of possible assignments is $\prod_{a \in S} L_a$, giving (II.160.1). Removing a base set of weight ϵW deletes at most $m\epsilon W$ ambient mass, so the exceptional fractions add. $\square$

Corollary II.160.2 (Affine and multilinear specialization). *For affine fibres, the bound is*

$$rL + \binom{r}{2} L^2. \quad (\text{II.160.4})$$

If $\mathcal{V}_U$ consists of functions affine separately in every base coordinate, all the lifted candidates are affine separately in every base coordinate and in the final coordinate x .

Proof. Set $t = 2$ in Theorem II.160.1. Each coefficient in (II.159.4) is affine in x and independent of the base variables, while each list member is independent of x . The sum has degree at most one in each variable separately. $\square$

The mixed list count in (II.160.1) is the sum of the first and t th elementary symmetric polynomials in the list sizes. This formulation is useful when the horizontal sections have unequal complexity. The

uniform bound (II.160.2) is a convenient corollary, not the sharpest piece of information furnished by the construction.

There is no claim that all these expressions are different. The count is an upper bound on a concrete generated list, not a matching lower bound on the number of distinct necessary graphs. Algebraic coincidences, zero coefficients, repeated lists, or extra relations can reduce the number.

II.161 Hereditary refinement without loss of slice labels

Source 39, delivered Section 11.

A common refinement is only useful if it preserves the required geometric scale. The next theorem states an explicit abstract hypothesis that is sufficient. It does not assume that arbitrary intersections of progression partitions retain large scale.

Definition II.161.1 (Hereditary single-slice refinement). Let a finite base set H carry an additive nonnegative measure μ with $\mu(H) > 0$. Suppose there is a class of admissible nonempty cells, a scale $\text{sc}(U) \geq 1$ for each such cell, and linear candidate spaces $\mathcal{V}_U \subseteq \mathbb{F}^U$. Assume restrictions of members of $\mathcal{V}_U$ to an admissible subcell $U' \subseteq U$ belong to $\mathcal{V}_{U'}$.

Let $\psi_1, \dots, \psi_r$ be partial functions on H . Assume that for each i , every admissible U , and each error parameter τ under consideration, there is a finite partition of U into admissible cells U' such that

$$\text{sc}(U') \geq \text{sc}(U)^{a(\tau)}, \quad 0 < a(\tau) \leq 1, \quad (\text{II.161.1})$$

and an exceptional set in U of measure at most $\tau\mu(U)$, outside which ψ_i on each U' is covered by a list of at most $L(\tau)$ members of $\mathcal{V}_{U'}$. The same functions a, L are valid for every i and every cell encountered in the refinement.

If a concrete refinement lemma has additional lower-size hypotheses, those hypotheses must hold at every stage where it is invoked. They are not removed by Definition II.161.1. In an application, admissibility can encode properness, coordinate restrictions, or inheritance from a specified parent progression.

Theorem II.161.2 (Label-preserving common refinement). *Suppose H itself is admissible, with scale M . Under Definition II.161.1, choose errors $\tau_1, \dots, \tau_r > 0$. There is a common admissible partition of H and a common good base set such that the total exceptional measure is at most $\mu(H) \sum_i \tau_i$, every final cell has scale at least*

$$M \prod_{i=1}^r a(\tau_i), \quad (\text{II.161.2})$$

and on each final cell, slice i retains its own list of at most $L(\tau_i)$ candidates. It is not necessary to replace that list size by $\prod_i L(\tau_i)$.

Proof. Refine the initial cell using the single-slice property for ψ_1 at error τ_1 . Then refine every current cell using the property for ψ_2 at error τ_2 , and continue. At each stage retain, by restriction, the lists already attached to all earlier slices. Restriction closure ensures that these remain valid candidates and does not increase their sizes.

At stage i , the new exceptional sets in the parent cells have total measure at most $\tau_i \sum_U \mu(U) = \tau_i \mu(H)$ because the parent cells partition H . The union of all stage exceptions therefore has measure at most $\mu(H) \sum_i \tau_i$.

For scales, induction gives after stage i the lower bound $M^{\prod_{j=1}^i a(\tau_j)}$: if the parent scale is at least the previous bound, then raising it to the positive power $a(\tau_i)$ preserves the inequality. Once a slice acquires its list at its own stage, later stages only restrict it. Thus its final list has at most $L(\tau_i)$ elements, as claimed. $\square$

Corollary II.161.3 (Equal error allocation). *For $\tau_i = \epsilon/r$, the common good set loses at most ϵ of the base mass, the scale bound is*

$$M^{a(\epsilon/r)^r}, \quad (\text{II.161.3})$$

and each slice list has size at most $L(\epsilon/r)$. Combined with affine shared-anchor selection, the graph count per base cell is

$$rL(\epsilon/r) + \binom{r}{2} L(\epsilon/r)^2. \quad (\text{II.161.4})$$

The total ambient exceptional fraction is at most

$$\frac{2q(m-r)}{m(r+1)} + \epsilon. \quad (\text{II.161.5})$$

Proof. Apply Theorem II.161.2, then Theorem II.160.1 and Theorem II.153.2 with $t = 2$. All interpolation anchors lie in the same row as their target, so restricting to a common good base point preserves all the required anchor lists. $\square$

II.161.1 Unequal slice costs and a parameter frontier

If slice i has its own functions $a_i(\tau_i)$ and $L_i(\tau_i)$, the same proof gives scale $M^{\prod_i a_i(\tau_i)}$ and a labelled candidate bound

$$\sum_i L_i(\tau_i) + \sum_{|S|=t} \prod_{i \in S} L_i(\tau_i), \quad \sum_i \tau_i \leq \epsilon. \quad (\text{II.161.6})$$

This gives an explicit optimization problem for error allocation; equal errors need not be optimal for heterogeneous slices. The theorem asserts the whole feasible frontier (II.161.6). It does not solve an unspecified optimization without information about the cost functions.

The asymmetric version can also use the exact profile loss (II.153.2) in place of the universal sampling term. Thus the method retains three separate forms of information: the row class-size profile, the number of anchors actually chosen, and the list cost of each horizontal section. Collapsing all of them to a single worst-case parameter is optional rather than built into the proof.

II.162 Source 34's Appendix A: the sharp nonuniform transport threshold [write]

Added in the seventh write, 6 October 2026.

The next section is source 34's Appendix A. *Logically it belongs in source 07's chapter on transport rigidity* (Section II.11), after its Corollary II.15.3; it is printed here because no number printed earlier may move. In source 07's finite-fibre directional model the sufficient threshold $1/(2[1 + (k-1)\kappa]) = 1/(2 + (2k-2)\kappa)$ is optimal for every Freiman order $k \geq 2$ and every fibre ratio $\kappa \geq 1$, already with zero boundary loss, so a boundary bound alone gives no further improvement (Theorem II.163.1). This answers source 07's Question 1 (item II.9); source 07 had sharpness

at $\kappa = 1$ (Theorem II.16.1). The intake checked the sharpness family for four parameter triples, including the printed example on $\mathbb{Z}/8\mathbb{Z}$. The formal `lemma_10_9` (`Section10.lean`, line 335; companion `lemma_10_9_holds`, `Proofs10Shift.lean`, line 717, at HEAD 89c1cbc38) concerns the prime-order interface and is unaffected, as source 34 says. Source 34’s introduction is Section F.39.

II.163 The sharp nonuniform directional rigidity threshold

Source 34, delivered Appendix A.

This appendix supplies an independent local result for the inverse part of the argument. Source 07 of the merged report proves a sufficient nonuniform directional threshold and asks whether it is sharp [155]. The following construction settles that question in the same finite-fiber model. The sharpness examples have no boundary loss.

II.163.1 The precise sampling model

Let G, H be finite abelian groups, let $S \subseteq G$ be nonempty, and let X_g be a finite nonempty fiber for $g \in S$. Write

$$R_g = |X_g|, \quad \Omega = \sum_{g \in S} R_g, \quad \mu(g) = R_g/\Omega, \quad \frac{\max_g R_g}{\min_g R_g} \leq \kappa.$$

Let $\phi : \bigsqcup_{g \in S} X_g \rightarrow H$, let $D \subseteq G$, and let $\psi : D \rightarrow H$. For a direction $d \in D$, draw $g \sim \mu$ and x uniformly from X_g . If $g + d \notin S$, declare failure. Otherwise draw y independently and uniformly from X_{g+d} and test

$$\phi(y) - \phi(x) = \psi(d).$$

Let δ_d be its failure probability. The map ψ is a Freiman homomorphism of order k if every relation $d_1 + \cdots + d_k = e_1 + \cdots + e_k$ with directions in D , repetitions allowed, implies equality of the corresponding image sums.

Theorem II.163.1 (The exact universal strict threshold). *For every integer $k \geq 2$ and every real $\kappa \geq 1$, the optimal universal strict threshold is*

$$\delta_{\text{crit}}(k, \kappa) = \frac{1}{2 + (2k - 2)\kappa}. \quad (\text{II.163.1})$$

If every $\delta_d < \delta_{\text{crit}}(k, \kappa)$, then ψ is a Freiman homomorphism of order k . No larger universal strict threshold is valid. For rational κ , a counterexample attains equality in (II.163.1). Sharpness holds with $S = G$, hence with zero exit probability in every direction.

Proof. We first recall the sufficient bound with its sampling weights. Fix a relation $\sum_i d_i = \sum_i e_i$. Choose one common initial fiber with index $g \sim \mu$. Follow the two paths of partial sums. Where their indices are in S , choose uniform fiber samples, using the same initial and terminal samples for both paths and independent internal samples. Samples at distinct path positions are drawn separately even if their fiber indices coincide. Leaving S is a failure.

Each first edge has its prescribed defect at most $\delta := \max_{d \in D} \delta_d$. For a later edge, its starting index is $g + s$ for a fixed partial sum s . On indices for which both g and $g + s$ are in S ,

$$\mu(g) \leq \kappa \mu(g + s).$$

Therefore the probability of failure at that edge, restricted to paths that have not already left S , is at most $\kappa\delta$. This includes the first exit at that edge. A union bound over the two paths gives total failure probability at most

$$[2 + (2k - 2)\kappa]\delta < 1.$$

Some realization has every edge correct. Telescoping along its two paths, with their common endpoints, proves the required image relation. For an empty D the assertion is immediate; otherwise the maximum is attained because G is finite.

For sharpness, fix an integer $m \geq 2$ and positive integers $a \leq b$. Put $N = 2km$ and $G = H = \mathbb{Z}/N\mathbb{Z}$, with $S = G$. Partition the representatives $0 \leq r < N$ into $2k$ consecutive blocks of length m . Give every point-index in blocks 0 and $2k - 1$ a fiber of size a , and every other point-index a fiber of size b . On the fiber indexed by r , let ϕ be constant with value $\lfloor r/m \rfloor \in \mathbb{Z}/N\mathbb{Z}$. Take

$$D = \{m, -m\}, \quad \psi(m) = 1, \quad \psi(-m) = -1.$$

Only the final block fails in direction m , and only the first block fails in direction $-m$. Consequently

$$\delta_m = \delta_{-m} = \frac{a}{2a + (2k - 2)b}. \quad (\text{II.163.2})$$

There is no boundary failure. Yet the domain relation consisting of k copies of m and k copies of $-m$ is valid modulo $N = 2km$, whereas its image relation $k = -k$ fails because $N > 2k$. The map is not Freiman of order k .

For rational κ , take $b/a = \kappa$ to attain the stated threshold. For arbitrary real κ , choose rational ratios $b/a \leq \kappa$ tending to κ . The defects in (II.163.2) tend to (II.163.1) from above, so every larger proposed universal strict threshold admits a counterexample. $\square$

Example II.163.2. At $k = 2$, $\kappa = 3$, take $m = 2$, $a = 1$, and $b = 3$. The group is $\mathbb{Z}/8\mathbb{Z}$, the fiber sizes by block are $(1, 3, 3, 1)$, and each block has two indices. Both directional defects are $1/8$. The relation $2 + 2 = (-2) + (-2)$ holds modulo eight, but $1 + 1 \neq (-1) + (-1)$. This realizes equality at the threshold $1/(2 + 2 \cdot 3)$.

Corollary II.163.3 (A boundary bound alone gives no further improvement). *Within this model, adding an arbitrary upper bound on the exit probabilities, including the bound zero, does not increase the universal threshold in Theorem II.163.1.*

Proof. Every sharpness example in the theorem has $S = G$ and exit probability zero. $\square$

The sufficient threshold is credited to source 07; the matching nonuniform example resolves its sharpness question. The examples use composite cyclic groups. They do not determine the maximal Freiman order available under Gowers's original prime-order and nested-set hypotheses at Lemma 10.9. Those additional hypotheses can carry information absent from this general model.

II.164 Source 40's chapter: one-stage Fejér selection at Lemma 15.5 [write]

Added in the eighth write, 7 October 2026.

The next eight sections are source 40's Sections 2–9, on the arrangement-selection step of Gowers's Lemma 15.5. *Logically the chapter comes before source 35's degree-weighted selection* (Section II.144),

which builds on it and cites it ahead of its placement, and after source 17's Fejér restriction (its Section 9) and the Section 15 material of sources 25 and 27; it is printed here because no number printed earlier may move. Source 40's introduction, with its explicit theorem, is Section F.45; its checks and questions are in Part V.

What is proved. For ordered d -arrangements of k -cubes in a density- β set $B \subseteq \mathbb{F}_q^{k+1}$, a single normalized Fejér kernel of bandwidth $L = \lceil 2(s+1)/(\alpha\eta) \rceil$, $s = 2d2^k$, applied to the single feature $F(y, r) = r \prod_i y_i$, retains at least $\alpha^s \eta^{s-1} \beta^{2d-1} q^M / (3^{s-1} (s+1)^s)$ arrangements, a proportion $1/(1+\eta)$ of them respected, as soon as $p > 2(L-1)$ and $q \geq (k+1)\beta^{-(2d-1)}(18(s+1)^2/(\alpha\eta)^2)^s$ (Theorem F.45.1; the exact form is Theorem II.169.2). Gowers's repeated degree-one Riesz products lose the exponent $s2^{s-1}$; here the exponents are s and $s-1$, and the sufficient field size is also smaller (Corollary II.170.1 at $d=8$). The feature has exactly the intended universal relation space (Theorem II.166.2), and all other bounded-coefficient relations are counted by a zero-count with repeated vertices treated explicitly (Theorem II.167.3). Vector-valued targets cost nothing, target torsion is computed exactly (Corollary II.171.1, Proposition II.171.2), and within homogeneous positive-Fourier kernels a gain Q forces good survival at most $Q^{-(s-1)}$, attained by Fejér kernels (Theorem II.172.2, Proposition II.172.3). Source 35 improves the field-size exponent from $2s$ to $E_{k,m} \sim 2s/k$ and the retention constant to $\alpha^s \eta^{s-1} / (2(s+2)^s)$ (note after Theorem II.169.2).

Relation to the formal statements (checked at HEAD 6d4942222). `lemma_15_5` (Sections14_15.lean, line 414) has the exact companion `lemma_15_5_holds` (Proofs15Restriction.lean, line 3116), with an existential threshold. Whether Corollary II.170.1 gives it with an explicit threshold depends on matching the formal count conventions, as for source 35 (marked question, item II.50). Nothing in this chapter is formalized.

II.165 Arrangements, respect, and the counting normalization

Source 40, delivered Section 2.

Throughout, $\mathbb{F}_q$ denotes a finite field. Write $E_k = \{0, 1\}^k$, $\pi(\varepsilon) = (-1)^{|\varepsilon|}$, and

$$\sigma_j = \begin{cases} 1 & 1 \leq j \leq d, \\ -1 & d < j \leq 2d. \end{cases}$$

Products and sums occurring in coordinates are taken in $\mathbb{F}_q$. The symbols π and σ also denote their images in that field.

Definition II.165.1 (Ordered d -arrangement). An ordered d -arrangement is a choice of

$$h \in \mathbb{F}_q^k, \quad x^{(1)}, \dots, x^{(2d)} \in \mathbb{F}_q^k, \quad r_1, \dots, r_{2d} \in \mathbb{F}_q, \quad \sum_{j=1}^{2d} \sigma_j r_j = 0.$$

Its labeled vertices are

$$v_{j,\varepsilon} = (x^{(j)} + \varepsilon \odot h, r_j), \quad 1 \leq j \leq 2d, \quad \varepsilon \in E_k, \quad (\text{II.165.1})$$

where $\odot$ denotes coordinatewise multiplication. It is an arrangement in B when every vertex belongs to B . Set

$$s = 2d2^k, \quad M = k + 2dk + (2d-1) = (2d+1)k + 2d-1, \quad (\eta_0)_{j,\varepsilon} = \sigma_j \pi(\varepsilon).$$

For $\phi : B \rightarrow \mathbb{F}_q$, its defect on the arrangement is

$$\Delta_\phi(\boldsymbol{\rho}) = \sum_{j,\varepsilon} \sigma_j \pi(\varepsilon) \phi(v_{j,\varepsilon}). \quad (\text{II.165.2})$$

The arrangement is *respected* when this defect is zero. Let $T(B)$ be the number of all arrangements in B and $G_\phi(B)$ the number of respected ones.

There are exactly q^M arrangements in the ambient space: the last r coordinate is uniquely determined by the first $2d-1$. Labeling is important. We never divide by a cube symmetry group, and we do not remove coincident configurations before forming $T(B)$.

Lemma II.165.2 (Density-sensitive total count). *For $B \subseteq \mathbb{F}_q^{k+1}$ of density β ,*

$$T(B) \leq T_0 := \beta^{2d-1} q^M. \quad (\text{II.165.3})$$

Proof. For fixed h and r , let $C_h(r)$ be the number of anchors $x \in \mathbb{F}_q^k$ for which the whole cube $(x + \varepsilon \odot h, r)$ lies in B . Necessarily

$$0 \leq C_h(r) \leq q^k, \quad \sum_{r \in \mathbb{F}_q} C_h(r) \leq |B|,$$

since the anchor itself is a vertex. Once $r_1, \dots, r_{2d-1}$ are fixed, r_{2d} is determined. Hence the arrangement count at this h is at most

$$q^k \sum_{r_1, \dots, r_{2d-1}} \prod_{j < 2d} C_h(r_j) = q^k \left(\sum_r C_h(r) \right)^{2d-1} \leq q^k |B|^{2d-1}.$$

Summing over the q^k possible h gives $q^{2k} |B|^{2d-1} = \beta^{2d-1} q^M$, as claimed. $\square$

Remark II.165.3 (Why this normalization is natural). For $B = \mathbb{F}_q^{k+1}$ there is equality. More generally, if $B = \mathbb{F}_q^k \times R$ for an additive subgroup $R \leq (\mathbb{F}_q, +)$, then all the final r coordinates determined by the constraint remain in R , and there is again equality in (II.165.3). Thus the factor β^{2d-1} cannot be universally reduced for finite fields. This observation concerns the total-count normalization, not optimality of the later selection theorem.

II.166 A single monomial isolates the universal relation

Source 40, delivered Section 3.

Define

$$P(y) = \prod_{i=1}^k y_i, \quad F(y, r) = rP(y). \quad (\text{II.166.1})$$

The next lemma strengthens the hypothesis in the cube-moment step underlying Gowers' Corollary 15.2: constancy of the top monomial alone is enough. No separate hypotheses for every squarefree submonomial are needed.

Lemma II.166.1 (Top-monomial cube rigidity). *Let K be any field, let each $h_i \in K$ be nonzero, and let $\eta : E_k \rightarrow K$. The formal polynomial*

$$U_\eta(x) = \sum_{\varepsilon \in E_k} \eta_\varepsilon \prod_{i=1}^k (x_i + \varepsilon_i h_i)$$

is constant in $x_1, \dots, x_k$ if and only if $\eta_\varepsilon = c\pi(\varepsilon)$ for some $c \in K$. In that case

$$U_\eta(x) = c(-1)^k \prod_i h_i. \quad (\text{II.166.2})$$

The assertion is valid in every characteristic.

Proof. For $A \subseteq [k]$, set $M_A = \sum_\varepsilon \eta_\varepsilon \prod_{i \in A} \varepsilon_i$. Expansion gives

$$U_\eta(x) = \sum_{A \subseteq [k]} M_A \prod_{i \in A} h_i \prod_{i \notin A} x_i.$$

The distinct x monomials are linearly independent. Since the h_i are nonzero, constancy is equivalent to $M_A = 0$ for every proper A . Writing $S = \text{supp}(\varepsilon)$, the moments are upper subset sums $M_A = \sum_{S \supseteq A} \eta_S$. Finite inclusion-exclusion gives

$$\eta_S = \sum_{A \supseteq S} (-1)^{|A|-|S|} M_A.$$

Indeed, after substituting for M_A , the coefficient of η_T is $\sum_{S \subseteq A \subseteq T} (-1)^{|A|-|S|}$, which is one for $T = S$ and zero otherwise. Thus $\eta_S = (-1)^{k-|S|} M_{[k]} = c(-1)^{|S|}$ with $c = (-1)^k M_{[k]}$. The constant term is $M_{[k]} \prod_i h_i$, giving (II.166.2). The reverse implication follows from the same expansion, or from $\prod_i (x_i - (x_i + h_i)) = (-1)^k \prod_i h_i$. $\square$

Eliminate r_{2d} using the arrangement equation:

$$r_{2d} = \sum_{j < 2d} \sigma_j r_j. \quad (\text{II.166.3})$$

The free parameters then form K^M .

Theorem II.166.2 (Universal relation space for one feature). *For coefficients $\eta = (\eta_{j,\varepsilon}) \in K^s$, the formal polynomial*

$$\mathcal{P}_\eta(h, x, r) = \sum_{j,\varepsilon} \eta_{j,\varepsilon} F(v_{j,\varepsilon}), \quad (\text{II.166.4})$$

with (II.166.3) substituted, is identically zero if and only if $\eta \in K\eta_0$. If it is not zero, its total degree is at most $k+1$.

Proof. Put

$$U_j(x^{(j)}, h) = \sum_\varepsilon \eta_{j,\varepsilon} P(x^{(j)} + \varepsilon \odot h).$$

After substitution, the polynomial in (II.166.4) is

$$\sum_{j < 2d} r_j (U_j + \sigma_j U_{2d}). \quad (\text{II.166.5})$$

Suppose it is identically zero. Specialize all h_i to one. Each coefficient $U_j + \sigma_j U_{2d}$ of the independent variable r_j is zero. The two summands depend on disjoint anchor variables. Consequently both are constant in their own anchor variables: this follows, for example, by fixing the other anchor at zero and comparing polynomial coefficients. As j ranges over $1, \dots, 2d - 1$, every block is covered. Lemma II.166.1 now gives $\eta_{j,\varepsilon} = c_j \pi(\varepsilon)$ for each j .

For general h the coefficient of r_j is therefore $(-1)^k (\prod_i h_i) (c_j + \sigma_j c_{2d})$. Its vanishing gives $c_j = -\sigma_j c_{2d}$, so with $c = -c_{2d}$ we have $c_j = c \sigma_j$ for all j , including $j = 2d$. Thus $\eta = c \eta_0$.

Conversely, if $\eta = c \eta_0$, the parity identity gives

$$\sum_{j,\varepsilon} \eta_{j,\varepsilon} F(v_{j,\varepsilon}) = c(-1)^k \left(\prod_i h_i \right) \sum_j \sigma_j r_j = 0.$$

Finally, each term is a product of $k + 1$ linear coordinate expressions in the free parameters, so its total degree is at most $k + 1$. $\square$

Remark II.166.3 (Formal polynomial versus finite-field function). The theorem is a polynomial identity statement over any field. It does not identify every pointwise relation in a small finite field with a formal identity. The passage to a large finite field is made through a zero-count in the next section. This distinction avoids a hidden small-characteristic assumption in the algebraic argument.

II.167 Bounded-coefficient exceptional arrangements

Source 40, delivered Section 4.

Let $H \geq 1$ and suppose $p > 2H$. Thus distinct integers in $[-H, H]$ have distinct images in $\mathbb{F}_q$.

Definition II.167.1 (H -regularity). An arrangement is H -regular if every vector $\eta \in \{-H, \dots, H\}^s$ satisfying

$$\sum_{j,\varepsilon} \eta_{j,\varepsilon} F(v_{j,\varepsilon}) = 0$$

is $a \eta_0$ for some integer $a \in [-H, H]$. All other arrangements are H -exceptional. Write D_H for the number of exceptional arrangements in the full ambient space.

This definition uses one feature, not the larger feature family in the source paper. Therefore it is a stronger regularity requirement. All signed multiples $a \eta_0$ really are relations by Theorem II.166.2.

Lemma II.167.2 (Polynomial zero-count). *A nonzero polynomial of total degree at most D in $m \geq 1$ variables over $\mathbb{F}_q$ has at most Dq^{m-1} zeros in $\mathbb{F}_q^m$.*

Proof. The one-variable case is the usual root bound. Induct on m . Write the polynomial as a polynomial of degree t in the last variable, with nonzero leading coefficient A of degree at most $D - t$ in the other variables. There are at most $(D - t)q^{m-2}$ choices where A vanishes, and at most t last-coordinate roots for every other choice. Bounding the first group by q roots each and the second by tq^{m-1} in total yields at most Dq^{m-1} roots. The case of a nonzero constant leading coefficient is included, and the bound is harmless when it exceeds q^m . $\square$

Theorem II.167.3 (Single-feature exceptional count). *Set*

$$C_{k,s,H} = \frac{k+1}{2} ((2H+1)^s - (2H+1)). \quad (\text{II.167.1})$$

Then

$$D_H \leq C_{k,s,H} q^{M-1} \leq (k+1)(2H+1)^s q^{M-1}. \quad (\text{II.167.2})$$

Every H -regular arrangement has s distinct physical vertices and, in particular, has all sidelengths nonzero.

Proof. The bounded coefficient box contains $(2H+1)^s$ integer vectors. Its intersection with the field line $\mathbb{F}_q \eta_0$ consists of exactly $2H+1$ vectors: one coordinate with sign $+1$ determines the scalar, and injectivity of reduction modulo p on $[-H, H]$ determines every other coordinate as the corresponding signed integer. These are just the intended multiples.

For each remaining coefficient vector, Theorem II.166.2 gives a nonzero polynomial of degree at most $k+1$ in the M free parameters. Its zero set has size at most $(k+1)q^{M-1}$ by Lemma II.167.2. The vectors η and $-\eta$ have the same zero set. None of the remaining vectors is zero, and their sign pairs have size two, giving exactly $((2H+1)^s - (2H+1))/2$ pairs. A union bound proves the first inequality in (II.167.2); the second only simplifies it.

If two labeled vertices v_a, v_b coincide, the vector with entries 1 at a , -1 at b , and zero elsewhere is a bounded relation. It is not a multiple of η_0 : it is nonzero, while $s \geq 4$ and a nonzero multiple of η_0 has no zero coordinate. Such an arrangement is exceptional. A zero sidelength forces precisely such a repeated vertex, proving the final assertion. $\square$

Remark II.167.4 (What the exceptional bound pays for). The bound includes zero sidelengths, repeated vertices, and all other bounded relations. No additional diagonal error is left to be inserted later. It is deliberately a union bound, not a claim that the corresponding algebraic hypersurfaces are disjoint or independent. The price of increasing H is explicit: roughly $(2H+1)^s/q$ of the ambient parameter space may have to be discarded from the exact survival calculation.

II.168 Fejér kernels and exact survival probabilities

Source 40, delivered Section 5.

II.168.1 The normalized kernel

For $L \geq 2$ define a function on the unit circle by

$$K_L(z) = \left| \frac{1}{L} \sum_{n=0}^{L-1} z^n \right|^2 = \sum_{a=-(L-1)}^{L-1} c_a z^a, \quad c_a = \frac{L - |a|}{L^2}. \quad (\text{II.168.1})$$

The coefficient formula follows by counting pairs (n, m) with $n - m = a$. All coefficients are nonnegative, $c_{-a} = c_a$, and $0 \leq K_L(z) \leq 1$ by the triangle inequality. Also $c_0 = 1/L$ and $\sum_a c_a = K_L(1) = 1$.

For an arrangement with s vertices set

$$b_{s,L} = c_0^s = L^{-s}, \quad (\text{II.168.2})$$

$$a_{s,L} = \sum_{a=-(L-1)}^{L-1} c_a^s = L^{-s} R_s(L), \quad (\text{II.168.3})$$

$$R_s(L) = 1 + 2 \sum_{a=1}^{L-1} \left(1 - \frac{a}{L}\right)^s = 1 + 2L^{-s} \sum_{a=1}^{L-1} a^s. \quad (\text{II.168.4})$$

Lemma II.168.1 (Finite gain bounds). *For integers $s \geq 1$ and $L \geq 2$,*

$$\frac{2L}{s+1} \leq R_s(L) \leq L. \quad (\text{II.168.5})$$

For fixed s , as $L \rightarrow \infty$,

$$\frac{R_s(L)}{L} \rightarrow \frac{2}{s+1}, \quad a_{s,L} \sim \frac{2}{s+1} L^{1-s}. \quad (\text{II.168.6})$$

Proof. The trapezoidal sum for the convex function $f(x) = (1-x)^s$ on $[0, 1]$ lies above its integral. That sum is $R_s(L)/(2L)$, whereas the integral is $1/(s+1)$. For the upper bound, use $(1-a/L)^s \leq 1-a/L$ in (II.168.4), giving $R_s(L) \leq 1 + (L-1) = L$. Finally, the trapezoidal sums converge to the integral by continuity; multiplying by the powers of L in (II.168.3) gives (II.168.6). $\square$

II.168.2 The correlated random subset

Choose a nontrivial additive character $\chi : \mathbb{F}_q \rightarrow \mathbb{C}$ with $|\chi(x)| = 1$. For example, if $q = p^m$, take $\chi(x) = \exp(2\pi i \operatorname{Tr}_{\mathbb{F}_q/\mathbb{F}_p}(x)/p)$, interpreting the trace as an integer modulo p . The elementary orthogonality relation is

$$\mathbb{E}_{u \in \mathbb{F}_q} \chi(uz) = \mathbf{1}_{z=0}. \quad (\text{II.168.7})$$

For $z \neq 0$, multiplication by z permutes the field and the sum of a nontrivial character is zero: translating that sum by an element where the character is not one multiplies it by a scalar factor different from one while leaving it unchanged.

Choose $t, u \in \mathbb{F}_q$ uniformly and independently. Conditional on these two seeds, select each physical point $v \in B$ independently with probability

$$w_{t,u}(v) = K_L(\chi(t\phi(v) + uF(v))). \quad (\text{II.168.8})$$

Let B' be the resulting random subset. Only two field-valued seeds are used for the correlated part of the selection; the pointwise Bernoulli choices are additional randomness.

Lemma II.168.2 (Exact labeled moment). *For any labeled arrangement in B ,*

$$\begin{aligned} \mathbb{E}_{t,u} \prod_{j,\varepsilon} w_{t,u}(v_{j,\varepsilon}) \\ = \sum_{\eta \in [-(L-1), L-1]^s \cap \mathbb{Z}^s} \left(\prod_{j,\varepsilon} c_{\eta_{j,\varepsilon}} \right) \mathbf{1}_{\sum \eta_{j,\varepsilon} F(v_{j,\varepsilon}) = 0} \mathbf{1}_{\sum \eta_{j,\varepsilon} \phi(v_{j,\varepsilon}) = 0}. \end{aligned} \quad (\text{II.168.9})$$

In particular, every summand is nonnegative.

Proof. Expand each factor using (II.168.1). Character multiplicativity turns the product into $\chi(u \sum \eta F + t \sum \eta \phi)$ times its coefficient. Averaging independently over u and t applies (II.168.7) twice. All sums are finite, so their interchange needs no limiting argument. $\square$

Proposition II.168.3 (Good and bad survival). *Assume $p > 2(L - 1)$ and write $H = L - 1$. Every respected arrangement, whether regular or exceptional, survives in B' with probability at least $a_{s,L}$. Every H -regular nonrespected arrangement survives with probability exactly $b_{s,L}$. Every H -regular respected arrangement survives with probability exactly $a_{s,L}$.*

Proof. First consider the labeled moment in (II.168.9). For a respected arrangement, all intended coefficient vectors $\eta = a\eta_0$ contribute. They satisfy the feature equation by Theorem II.166.2, and their ϕ sum is $a\Delta_\phi = 0$. Since $c_{-a} = c_a$, their total contribution is $\sum_a c_a^s = a_{s,L}$. All other contributions are nonnegative.

There is a distinction between the labeled moment and actual subset survival when vertices repeat. Conditional on the seeds, actual survival is the product of $w_{t,u}(v)$ over *distinct* physical vertices. As each weight lies in $[0, 1]$, this product is at least the product over all labeled occurrences. Averaging therefore preserves the lower bound $a_{s,L}$, even for exceptional respected arrangements.

For an H -regular arrangement the vertices are distinct by Theorem II.167.3, so the labeled moment is exactly its survival probability. Regularity allows only $\eta = a\eta_0$ in that moment. If $\Delta_\phi \neq 0$, the remaining equation is $a\Delta_\phi = 0$ in $\mathbb{F}_q$. The only $a \in [-H, H]$ satisfying it is $a = 0$, since $p > 2H$. The sole contribution is then $c_0^s = b_{s,L}$. If the defect is zero, all intended multiples contribute and the sum is exactly $a_{s,L}$. $\square$

Remark II.168.4 (Two easily missed issues). Nonnegativity of the Fourier coefficients is what permits us to retain only the intended terms for a lower bound; it is not merely a convenient normalization. Separately, conditional independence applies to physical points, not to vertex labels. The repeated-vertex inequality above is necessary before any first-moment estimate for the good arrangements is justified.

II.169 The one-stage selection theorem

Source 40, delivered Section 6.

II.169.1 An abstract first-moment step

The following elementary observation separates the probabilistic selection argument from the specific choice of kernel.

Lemma II.169.1 (Score selection). *Suppose a family of configurations has at most T_0 members, at least αT_0 of them good. A random subset retains each good configuration with probability at least $a > 0$. Each nonexceptional bad configuration is retained with probability at most b , and there are at most D exceptional bad configurations. If*

$$\alpha a - \frac{b + D/T_0}{\eta} > 0, \quad (\text{II.169.1})$$

there is an outcome with at least

$$\left(\alpha a - \frac{b + D/T_0}{\eta} \right) T_0 \quad (\text{II.169.2})$$

good configurations, in which the proportion of good configurations is at least $1/(1+\eta)$. In particular, if $D \leq bT_0$ and $a/b \geq 4/(\alpha\eta)$, this lower bound is at least $\alpha aT_0/2$.

Proof. Let X and Y count the retained good and bad configurations. By linearity of expectation, without any independence assumption between configurations,

$$\mathbb{E}X \geq \alpha aT_0, \quad \mathbb{E}Y \leq bT_0 + D.$$

Thus the real score $Z = X - Y/\eta$ has expectation at least (II.169.2). There is an outcome with $Z \geq \mathbb{E}Z$. For it, $X \geq Z$ and $Y \leq \eta X$, so $X/(X+Y) \geq 1/(1+\eta)$. The denominator is positive by (II.169.1). Under the final hypotheses, $(b + D/T_0)/\eta \leq 2b/\eta \leq \alpha a/2$. $\square$

II.169.2 The exact finite-bandwidth form

Theorem II.169.2 (Exact one-stage Fejér selection). *Let $k, d \geq 1$, $s = 2d2^k$, and $M = (2d + 1)k + 2d - 1$. Let $B \subseteq \mathbb{F}_q^{k+1}$ have density $\beta > 0$, and suppose $\phi : B \rightarrow \mathbb{F}_q$ respects at least αT_0 arrangements, where $T_0 = \beta^{2d-1}q^M$ and $0 < \alpha, \eta \leq 1$. Choose an integer $L \geq 2$ for which*

$$p > 2(L-1), \quad R_s(L) \geq \frac{4}{\alpha\eta}, \quad \beta^{2d-1}q \geq C_{k,s,L-1}L^s. \quad (\text{II.169.3})$$

There is $B' \subseteq B$ for which

$$G_\phi(B') \geq \frac{\alpha}{2}L^{-s}R_s(L)T_0, \quad \frac{G_\phi(B')}{T(B')} \geq \frac{1}{1+\eta}. \quad (\text{II.169.4})$$

More generally, for any L satisfying only the characteristic condition, the same construction gives a positive lower bound

$$G_\phi(B') \geq \left(\alpha L^{-s}R_s(L) - \frac{L^{-s}}{\eta} - \frac{C_{k,s,L-1}}{\eta\beta^{2d-1}q} \right) T_0 \quad (\text{II.169.5})$$

with the same good proportion whenever the displayed coefficient is strictly positive.

Proof. Use the random subset in (II.168.8). Lemma II.165.2 bounds the total family by T_0 ; Proposition II.168.3 supplies the good probability $a = L^{-s}R_s(L)$ and the nonexceptional bad probability $b = L^{-s}$. The exceptional count is at most $C_{k,s,L-1}q^{M-1}$ by Theorem II.167.3. The last inequality in (II.169.3) makes this at most bT_0 , and the middle inequality gives the gain needed in Lemma II.169.1. This proves (II.169.4). Using the full score lower bound instead gives (II.169.5). $\square$

Proof of Theorem F.45.1. Take L from (F.45.1). Lemma II.168.1 gives $R_s(L) \geq 2L/(s+1) \geq 4/(\alpha\eta)$. As $\alpha\eta \leq 1$,

$$L \leq \frac{2(s+1)}{\alpha\eta} + 1 \leq \frac{3(s+1)}{\alpha\eta}. \quad (\text{II.169.6})$$

Also

$$\begin{aligned} C_{k,s,L-1}L^s &\leq (k+1)[L(2L-1)]^s \\ &\leq (k+1)(2L^2)^s \\ &\leq (k+1) \left(\frac{18(s+1)^2}{(\alpha\eta)^2} \right)^s. \end{aligned}$$

Thus the field-size hypothesis implies the last condition in (II.169.3). Theorem II.169.2 yields a subset with

$$\begin{aligned} G_\phi(B') &\geq \frac{\alpha}{2} L^{-s} R_s(L) T_0 \\ &\geq \frac{\alpha}{s+1} L^{1-s} T_0 \\ &\geq \frac{\alpha}{s+1} \left(\frac{\alpha\eta}{3(s+1)} \right)^{s-1} T_0 = \Gamma_s(\alpha, \eta) T_0. \end{aligned}$$

Since $T(B') \geq G_\phi(B')$, this proves the arrangement lower bound. The good proportion is at least $1/(1+\eta)$, which is at least $1-\eta$ because their difference is $\eta^2/(1+\eta)$.

Write $\beta' = |B'|/q^{k+1}$. Applying Lemma II.165.2 to B' gives $\Gamma_s \beta'^{2d-1} q^M \leq T(B') \leq (\beta')^{2d-1} q^M$. Taking positive $(2d-1)$ st roots proves (F.45.4).

For prime $q = p$, put $X = (s+1)/(\alpha\eta) \geq 5$. The size bound implies $q \geq (18X^2)^s \geq 6X \geq 2L$ by (II.169.6), and hence $p > 2(L-1)$. $\square$

[write] **7 October 2026; sources 40–46.** *Improved by source 35* (written the same day, placed earlier, printed in Section II.144). Source 35's Theorem II.145.2 keeps the one-stage selector and the powers $\alpha^s \eta^{s-1}$ of this theorem, stratifies the coefficient arrays by degree, and lowers the field-size exponent from $2s$ to $E_{k,m} \sim 2s/k$ (23 against 128 at $d = 8, k = 2$), with retention $\alpha^s \eta^{s-1}/(2(s+2)^s)$, larger than $\alpha^s \eta^{s-1}/(3^{s-1}(s+1)^s)$ here for every $s \geq 2$. The intake's checks of this section (nullity one of the evaluation matrix for five (k, d) , the inequality $2L/(s+1) \leq R_s(L) \leq L$ for $s \leq 128, L \leq 300$, the constant chain in 36 exact cases) are recorded in the dossier.

Remark II.169.3 (Parameters at the endpoints). When $\alpha = 1$, every possible arrangement in B is already respected by Lemma II.165.2, so one may simply take $B' = B$. When $\eta = 1$, the requested lower proportion $1 - \eta$ is vacuous; our theorem still gives the stronger proportion at least one half. The displayed constants are uniform and are not optimized at either endpoint. If $G_\phi(B) = 0$, no positive α hypothesis holds.

II.170 Comparison with Gowers' Lemma 15.5

Source 40, delivered Section 7.

The source result concerns $d = 8$, so

$$s = 2^{k+4}, \quad M = 17k + 15, \quad E_k = 2^{2^{k+4}+k+3} = s2^{s-1}. \quad (\text{II.170.1})$$

In the repository's edited statement [192, Section 15], the retained arrangement lower bound is

$$\left(\frac{\alpha\eta}{4} \right)^{E_k} \beta^{15} N^{17k+15}, \quad (\text{II.170.2})$$

with sufficient largeness condition

$$N \geq k3^s \beta^{-15} \left(\frac{4}{\alpha\eta} \right)^{E_k}. \quad (\text{II.170.3})$$

The transcription explicitly notes that the printed statement did not quantify α and omitted a largeness condition used by its proof. We compare against the corrected, meaningful form, not the unqualified statement.

Corollary II.170.1 (Replacement for the eight-arrangement selection). *Under the setup of Gowers’ Lemma 15.5, with N prime and $0 < \alpha, \beta, \eta \leq 1$, it is enough to assume*

$$N \geq (k+1)\beta^{-15} \left(\frac{18(s+1)^2}{(\alpha\eta)^2} \right)^s, \quad s = 2^{k+4}. \quad (\text{II.170.4})$$

There is $B' \subseteq B$ containing at least

$$\frac{\alpha^s \eta^{s-1}}{3^{s-1}(s+1)^s} \beta^{15} N^{17k+15} \quad (\text{II.170.5})$$

arrangements, with at least a proportion $1 - \eta$ respected.

Proof. Apply Theorem F.45.1 with $d = 8$ and use the final prime-field observation in its proof. $\square$

[write] **7 October 2026; sources 40–46.** *Against the formal statement* (checked at HEAD 6d4942222). `lemma_15_5` (Sections14_15.lean, line 414) has the exact companion `lemma_15_5_holds` (Proofs15Restriction.lean, line 3116), with an existential threshold and retention $(\alpha\eta/4)^{2^{2^{k+4}+k+3}} \beta^{15} N^{17k+15}$, the displayed (II.170.2). This corollary would give the formal conclusion with the explicit threshold (II.170.4), provided that source 40’s count of labelled arrangements, which includes repeated vertices and zero sidelengths, matches the conventions of `generalArrangementCount` and `respectedGeneralArrangementCount` (lines 229 and 234), and that the purity $1/(1+\eta)$ gives the formal form; that matching was not checked, so the observation joins source 35’s marked question (item II.50). The formal statement is already exact; nothing formal depends on it.

II.170.1 Both the loss and the sufficient field size improve

For $s \geq 32$ and $0 < \alpha, \eta \leq 1$, the lower bound (II.170.5) is larger than (II.170.2). To see this, $E_k \geq s$ and $E_k \geq s - 1$, so the ratio is bounded below by

$$\frac{4^{E_k}}{3^{s-1}(s+1)^s} > 1.$$

The last inequality follows, after taking s th roots, from $4^{2^{s-1}} > 3(s+1)$.

The sufficient threshold (II.170.4) is also smaller than (II.170.3). With $\delta = \alpha\eta \leq 1$, the ratio of the old threshold to the new one is

$$\frac{k}{k+1} \frac{4^{E_k}}{[6(s+1)^2]^s} \delta^{-(E_k-2s)}.$$

Here $E_k \geq 2s$, $k/(k+1) \geq 1/2$, and $4^{2^{s-1}} > 12(s+1)^2$ for $s \geq 32$. These facts make the ratio larger than one. Thus the result is not merely a better retained-mass bound purchased by a worse ambient-size assumption.

II.170.2 Why increasing bandwidth helps

At $L = 2$ the normalized Fejér kernel is the original probability kernel $(1 + \cos \theta)/2$, and

$$b_{s,2} = 2^{-s}, \quad R_s(2) = 1 + 2^{1-s}.$$

With r independent stages, regular good and bad survival probabilities are $a_{s,2}^r$ and $b_{s,2}^r$; the ratio is $R_s(2)^r$. Making it at least a prescribed $Q > 1$ takes

$$r \geq \frac{\log Q}{\log(1 + 2^{1-s})} \sim 2^{s-1} \log Q \quad \text{as } s \rightarrow \infty.$$

This explains the large exponent in the original route. In contrast, $R_s(L) \geq 2L/(s+1)$: a single stage with L proportional to $(s+1)Q$ produces the required ratio and has $a_{s,L}$ of order L^{1-s} for fixed s .

The trade-off has not disappeared. The higher kernel degree requires excluding a larger bounded coefficient box. The exceptional count pays for that box, and the explicit field-size hypothesis makes its contribution no larger than the ordinary bad survival mass.

II.170.3 Scale illustration

For illustration only, set $\alpha = \eta = 0.1$ and $\beta = 1/2$. The table reports the negative base-ten logarithm of the coefficient multiplying $\beta^{15} N^{17k+15}$, and the base-ten logarithm of the new sufficient prime-field threshold. These are formula evaluations, not experiments constructing the selected subset.

k	s	Old $-\log_{10}$ loss	New $-\log_{10}$ loss	New $\log_{10} N$ threshold
1	32	1.788×10^{11}	126.38	270.17
2	64	1.536×10^{21}	273.09	573.38
3	128	5.667×10^{40}	585.75	1218.10

The improvement is enormous locally, while the new field thresholds are still far beyond a practical exhaustive construction. The theorem is a quantitative structural statement, not a claim of an efficient large-instance algorithm.

II.171 Vector targets and exact torsion dependence

Source 40, delivered Section 8.

II.171.1 Dimension-free simultaneous selection

Corollary II.171.1 (Vector-valued maps). *Theorems F.45.1 and II.169.2 hold, with unchanged constants, for $\phi : B \rightarrow \mathbb{F}_q^m$ for every $m \geq 1$, when respected means that the vector defect is zero. Consequently the same bounds hold for simultaneously respecting any finite family of scalar maps, provided the hypothesis counts arrangements simultaneously respected by all of them.*

Proof. Choose $t \in \mathbb{F}_q^m$ uniformly and replace $t\phi(v)$ in (II.168.8) by the dot product $t \cdot \phi(v)$. Orthogonality now gives $\mathbb{E}_t \chi(t \cdot z) = \mathbf{1}_{z=0}$ for $z \in \mathbb{F}_q^m$ by taking the product of the coordinate identities. All remaining steps are unchanged. A nonzero scalar $a \in \mathbb{F}_q$ cannot annihilate a nonzero vector defect. The only dimension dependence is the number of field coordinates in the random seed, not any counting constant. $\square$

The hypothesis is essential: knowing that each map separately respects many arrangements need not give a comparable intersection of their good arrangement families. The corollary does not manufacture this missing intersection.

II.171.2 General finite abelian targets

Let A be a finite abelian group, written additively, and $\phi : B \rightarrow A$. Define the defect by the same integer signed sum. Choose a character ψ of A uniformly from its character group $\hat{A}$ and choose $u \in \mathbb{F}_q$ uniformly. Use the probability

$$K_L(\psi(\phi(v))\chi(uF(v))). \quad (\text{II.171.1})$$

Character orthogonality on A says $\mathbb{E}_{\psi \in \hat{A}} \psi(a) = \mathbf{1}_{a=0}$; it follows by writing a finite abelian group as a product of cyclic groups and applying the finite geometric sum on each factor.

Proposition II.171.2 (Defect-order survival formula). *Assume $p > 2(L-1)$. For an $(L-1)$ -regular arrangement whose defect in A has order ν , its survival probability under (II.171.1) is exactly*

$$b_{s,L} R_{s,L}^{(\nu)}, \quad R_{s,L}^{(\nu)} = 1 + 2 \sum_{m=1}^{\lfloor (L-1)/\nu \rfloor} \left(1 - \frac{m\nu}{L}\right)^s. \quad (\text{II.171.2})$$

For a zero defect, take $\nu = 1$, so the probability is $a_{s,L}$. For a nonzero defect of order $\nu > L-1$, it is $b_{s,L}$.

Proof. The feature orthogonality still restricts coefficient vectors to $\eta = a\eta_0$. Target-character orthogonality then requires $a\Delta_\phi = 0$ in A , or equivalently $\nu \mid a$. Summing c_a^s over those multiples gives (II.171.2). Regularity gives distinct vertices, just as before. $\square$

Corollary II.171.3 (Targets without small torsion). *The selection theorems hold for $\phi : B \rightarrow A$ with unchanged constants provided A has no nonzero element killed by any integer $1 \leq a \leq L-1$. In particular, it suffices that every prime divisor of $|A|$ exceed $L-1$.*

Proof. Every nonzero defect then has order greater than $L-1$, so Proposition II.171.2 supplies exactly the bad probability $b_{s,L}$. Good arrangements, including repeated ones, retain the same lower bound by nonnegative coefficients. The score argument is unchanged. The sufficient condition on prime divisors implies that multiplication by each integer $1, \dots, L-1$ is an automorphism of A . $\square$

Remark II.171.4 (A concrete small-torsion obstruction). For fixed s and $\nu \geq 2$, Riemann sums in (II.171.2) show that

$$\frac{R_{s,L}^{(\nu)}}{R_s(L)} \longrightarrow \frac{1}{\nu} \quad (L \rightarrow \infty).$$

Thus the good-to-bad survival ratio against a defect of fixed order ν tends only to ν , rather than increasing without bound. One cannot extend the one-stage high-bandwidth conclusion to arbitrary small-torsion targets by reusing the same proof. This is an exact obstruction for this kernel calculation, not a nonexistence theorem for all selection methods.

II.172 A sharp exponent obstruction for positive Fourier kernels

Source 40, delivered Section 9.

This section explains in which precise sense the powers s and $s-1$ are natural. It does not claim a universal extremal theorem about all subsets or all probabilistic constructions.

Definition II.172.1 (The homogeneous positive-Fourier class). Let

$$W(e^{i\theta}) = \sum_{a=-H}^H c_a e^{ia\theta}$$

be a trigonometric polynomial with real coefficients $c_{-a} = c_a \geq 0$, with $c_0 > 0$, and $0 \leq W \leq 1$ on the unit circle. For a single signed relation using every one of s distinct vertices, define the intended-relation good and bad probabilities by

$$a(W) = \sum_{a=-H}^H c_a^s, \quad b(W) = c_0^s, \quad R(W) = a(W)/b(W). \quad (\text{II.172.1})$$

These are the exact probabilities on regular configurations in the same orthogonality calculation as above. The same kernel is used at every vertex; this is the meaning of homogeneous here.

Theorem II.172.2 (Gain-mass obstruction). *For every kernel in this class and every integer $s \geq 2$,*

$$R(W) \leq \frac{1}{c_0}, \quad a(W) \leq b(W)^{(s-1)/s}, \quad a(W) \leq R(W)^{-(s-1)}. \quad (\text{II.172.2})$$

Consequently a required gain $R(W) \geq Q \geq 1$ forces $a(W) \leq Q^{-(s-1)}$. The same conclusion holds for any finite sequence of independent stages from this class: if their combined gain is at least Q , their combined intended-relation good survival probability is at most $Q^{-(s-1)}$.

Proof. Fourier inversion and $W \geq 0$ imply

$$0 \leq c_a \leq \frac{1}{2\pi} \int_0^{2\pi} W(e^{i\theta}) d\theta = c_0.$$

Also $\sum_a c_a = W(1) \leq 1$. Hence

$$\sum_a c_a^s \leq c_0^{s-1} \sum_a c_a \leq c_0^{s-1}.$$

Dividing by c_0^s gives $R(W) \leq 1/c_0$, while the same inequality is $a(W) \leq b(W)^{(s-1)/s}$. Since $c_0 \leq 1/R(W)$, it also gives the third inequality. If $R(W) \geq Q$, this is at most $Q^{-(s-1)}$.

For independent stages $W_1, \dots, W_r$, the regular good and bad probabilities multiply, so the gains multiply as well. Apply the third inequality to each stage and multiply:

$$\prod_i a(W_i) \leq \left(\prod_i R(W_i) \right)^{-(s-1)}.$$

□

[write] **7 October 2026; sources 40–46.** This barrier concerns the scalar first-moment certificate within the homogeneous positive-Fourier class. It advances source 04's and source 17's retention questions (item II.7) and sits beside source 17's Proposition II.62.2, which settles the scalar certificate in another class; it is not a lower bound for every selection method, as source 40 says.

Proposition II.172.3 (Fejér kernels attain the exponent). *For fixed $s \geq 2$ and any $Q \geq 1$, there is a Fejér kernel with $R_s(L) \geq Q$ and*

$$a_{s,L} \geq \frac{2^s}{(s+1)(s+3)^{s-1}} Q^{-(s-1)}. \quad (\text{II.172.3})$$

Proof. Take $L = \lceil (s+1)Q/2 \rceil \geq 2$. Then $R_s(L) \geq 2L/(s+1) \geq Q$, and $L \leq (s+3)Q/2$ because $Q \geq 1$. Thus

$$a_{s,L} \geq \frac{2}{s+1} L^{1-s} \geq \frac{2^s}{(s+1)(s+3)^{s-1}} Q^{1-s}.$$

□

II.172.1 Exactly what is optimal

Theorems II.172.2 and Proposition II.172.3 determine the power $Q^{-(s-1)}$ in the gain–good–mass trade-off, up to constants depending on s , within the stated class. A first-moment purity certificate using only the lower bound αT_0 for the initial good mass and an upper bound T_0 for the total mass requires gain of order $1/(\alpha\eta)$. In that certificate, the quantity $\alpha a(W)$ therefore has natural scale $\alpha^s \eta^{s-1}$, and the Fejér choice attains those powers.

This is not a lower bound on the actual number of good arrangements in the best selected subset. It does not exclude improvements from negative Fourier coefficients with a different positivity argument, vertex-dependent kernels, adaptive correlated stages, additional geometric information, higher-rank relation families, or a method that avoids the coarse T_0 comparison altogether. It also does not optimize the s -dependent constant or the field-size threshold.

II.173 Source 44’s chapter: the grid core of Lemma 15.4 [write]

Added in the eighth write, 7 October 2026.

The next nine sections are source 44’s Sections 2–10, on the count of degenerate arrangements in Gowers’s Lemma 15.4. *Logically the chapter follows the degeneracy material of sources 18, 22, 25 and 27* (Sections II.65 and II.81): source 18 found the leading term, source 25 the codimension-one classification and source 27 the core directions for $p > 2k + 2$, the second coefficient for $d = 2$ and the second coefficient for general d up to one unknown statistic $b_{2,d,p}$; it is printed here because no number printed earlier may move. Source 44 calls sources 25 and 27 “Baseline A” and “Baseline B” (note in Section F.49). Its introduction is Section F.49; its verification, questions and reproduction appendix are in Part V.

What is proved. In every characteristic $p \geq 5$ the core directions have width two, so the core count $k(2^{2d} - 1) + 2\binom{k}{2}$ holds without source 27’s condition $p > 2k + 2$ (Lemma II.175.1, Corollary II.175.2); the union of all core events is counted exactly, by $\prod_{i < k} (1 - (2^{2d} - 1 + 2i)/q^2)$ for $p \geq 5$ and $\prod_{i < k} (1 - p^{2d-1+i}/q^2)$ for $p = 2, 3$ (Theorems II.176.2, II.176.3), with an explicit non-core remainder of order q^{-3} (Theorem II.177.2); the second Whitney coefficient $b_{2,d}$ of the cross-section arrangement is characteristic-independent for $p > \max(2d, 16)$ (Theorem II.178.1) and is computed for every d by a weighted double count over subsets of the nine-point grid $\{-1, 0, 1\}^2$, in $O(d^3)$ operations (Theorem II.179.1), compressed by a finite rational certificate to eight lattice-walk energies (Theorem II.180.1). At $d = 8$, $b_{2,8} = 3,280,234,631,541$, so the second coefficient of the degenerate count is $\binom{k}{2} - 2,519,909k - 3,280,234,631,541$ ($2^{16} - 1 - H_8 = -2,519,909$, $H_8 = 2,585,444$, source 18’s C_8 ; checked at the write). The deficit of $b_{2,d}$ from $\binom{H_d}{2}$ has order $49^d/d$ (Theorem II.181.2). The intake reproduced $b_{2,d} = 3, 889, 97,081$ for $d = 2, 3, 4$ by brute force over hyperplane pairs (3 is source 27’s $b_{2,2}$); $b_{2,8}$ rests on source 44’s certificate, whose run was repeated at the write with identical output. This answers source 27’s two questions (item II.38). The results are fixed- k asymptotics; core avoidance is not full nondegeneracy.

Relation to the formal statements (checked at HEAD 6d4942222). `lemma_15_4` (Sections14_15.lean, line 402) has the exact companion `lemma_15_4_holds` (Proofs15DegenerateArrangements.lean, line 1131), bound $3^{2d2^k} k N^{(2d+1)k+2d-2}$; source 44 follows its degeneracy definition (`GeneralArrangement.IsDegenerate`, line 354; `degenerateGeneralArrangementCount`, line 364), whose file has the blob it records. Nothing in this chapter is formalized.

II.174 Arrangements, coefficient directions, and the regular region

Source 44, delivered Section 2.

Fix $d \geq 2$, $k \geq 1$, and a finite field $\mathbb{F}_q$ of characteristic p . Write

$$m = 2d, \quad v = m2^k, \quad D = (m+1)k + m - 1, \quad w = (\underbrace{1, \dots, 1}_d, \underbrace{-1, \dots, -1}_d). \quad (\text{II.174.1})$$

The signs are interpreted in the field, even when $p = 2$. Since $w \neq 0$,

$$W = \{r \in \mathbb{F}_q^m : w \cdot r = 0\}$$

has dimension $m - 1$. A labelled arrangement consists of $h \in \mathbb{F}_q^k$, $x = (x_{ji}) \in \mathbb{F}_q^{m \times k}$, and $r \in W$, with vertices

$$\rho(\epsilon, j) = (x_{j1} + \epsilon_1 h_1, \dots, x_{jk} + \epsilon_k h_k, r_j), \quad \epsilon \in \{0, 1\}^k, \quad 1 \leq j \leq m. \quad (\text{II.174.2})$$

There are exactly q^D parameter tuples. No distinctness of vertices is assumed in this count.

Let $\mathcal{A}_p$ be the image of $\{-1, 0, 1\}$ in $\mathbb{F}_p$. For an array $\eta \in \mathcal{A}_p^{\{0,1\}^k \times [m]}$ and $A \subseteq [k+1]$, define

$$M_A(\eta) = \sum_{j, \epsilon} \eta(\epsilon, j) \prod_{i \in A} \rho(\epsilon, j)_i.$$

The empty set is included. Put

$$e(\epsilon, j) = (-1)^{\epsilon_1 + \dots + \epsilon_k} w_j.$$

The alternating cube identity, together with $\sum_j w_j = 0$ and $w \cdot r = 0$, proves $M_A(e) = 0$ for every A .

Definition II.174.1. An arrangement is *degenerate* if there exists such an η outside $\mathbb{F}_q e$ for which every $M_A(\eta)$ vanishes. Write $\Delta_{k,d}(q) = Z_{k,d}(q)/q^D$. Two admissible non-intrinsic arrays are in the same *direction* if $\eta' = a\eta + b e$ for some $a \neq 0$.

Equivalent arrays have exactly the same moment-zero event. Dividing pointwise by e turns the equivalence into affine equivalence of profiles $t' = at + b\mathbf{1}$. If nonconstant profiles take prime-field values, their relating scalars a, b lie in the prime field: two unequal coordinates determine a , and either coordinate then determines b .

An array is *column-parity* if $\eta(\epsilon, j) = (-1)^{|\epsilon|} a_j$ for every j . When all h_i are nonzero, its moment equations are precisely

$$\sum_j a_j = 0, \quad a \cdot r = 0. \quad (\text{II.174.3})$$

Here $a \in \mathcal{A}_p^m$, and a must not be proportional to w . Let $\mathcal{H}_{d,p}$ be the distinct hyperplanes in W so obtained, and set

$$W^\circ = W \setminus \bigcup_{H \in \mathcal{H}_{d,p}} H, \quad g_{d,p}(q) = \frac{|W^\circ|}{q^{m-1}}, \quad H_{d,p} = |\mathcal{H}_{d,p}|. \quad (\text{II.174.4})$$

Lemma II.174.2. *Every arrangement with some $h_i = 0$ is degenerate. If $r \in W^\circ$, its coordinates are pairwise distinct. The complement of the region $h_i \neq 0$ for all i and $r \in W^\circ$ is entirely degenerate.*

Proof. A zero side gives two equal labelled vertices. Coefficients $1, -1$ at these labels and zero elsewhere annihilate all moments, but cannot be a nonzero multiple of the full-support array e . This works in characteristic two as well. For distinct $u, t \in [m]$, the vector $a = \mathbf{e}_u - \mathbf{e}_t$ is alphabet-valued, has sum zero, and is not proportional to w , since $m \geq 4$. Thus $r_u = r_t$ is one of the forbidden hyperplanes. The final assertion follows from (II.174.3). $\square$

II.175 A width theorem with no dimension-dependent characteristic cutoff

Source 44, delivered Section 3.

The core directions from [200] can be written as

$$\eta(\epsilon, j) = e(\epsilon, j) \left(t_j + \sum_{i=1}^k b_i \epsilon_i \right), \quad b \neq 0, \quad (\text{II.175.1})$$

with all displayed profile values in $\mathcal{A}_p$. In particular, the slopes b_i are common to the columns. The elementary lemma below removes the earlier requirement $p > 2k + 2$.

Lemma II.175.1 (Characteristic-uniform width two). *Let $p \geq 5$. A nonconstant affine Boolean function $f(\epsilon) = t + \sum_i b_i \epsilon_i$ with values in $\mathcal{A}_p$ has at most two nonzero slopes. With one active coordinate, the two endpoint values are any two distinct alphabet elements. With two active coordinates, the slopes are ± 1 , and the offset is forced so that the three attained values are $-1, 0, 1$.*

Proof. The value at zero and every single-coordinate difference belong to $\mathbb{F}_p$, so all parameters are in that field. If A is a nonempty proper subset of $\mathbb{F}_p$ and $b \neq 0$, then $A + b \neq A$: otherwise translation by b would make A invariant under the whole additive group. Consequently $|A \cup (A + b)| \geq |A| + 1$. Adding active slopes successively grows the attained-value set by at least one until it fills the field. Three active slopes would therefore give at least four values, which is impossible when $p \geq 5$.

For two active slopes b, c , the four values are $t, t + b, t + c, t + b + c$. A collision, with both slopes nonzero, forces $b = c$ or $b = -c$. The resulting three values form an arithmetic progression. If they are exactly the ternary alphabet, their middle value is zero: their sum is three times that middle value, and $3 \neq 0$. The step is therefore 1 or -1 . The one-coordinate case requires only that its two endpoint values be distinct alphabet elements. $\square$

[write] **7 October 2026; sources 40–46.** This removes the condition $p > 2k + 2$ of source 27’s core classification (Theorem II.97.6), answering source 27’s question on intermediate characteristics $5 \leq p \leq 2k + 2$.

Corollary II.175.2. *For every $p \geq 5$, every $d \geq 2$, and every $k \geq 1$, the number of core directions is*

$$S_{k,d} = k(2^m - 1) + 2 \binom{k}{2}. \quad (\text{II.175.2})$$

Thus no new core families occur for $5 \leq p \leq 2k + 2$.

Proof. For a fixed single-coordinate slope direction, normalize a unit slope to 1. Each offset can be chosen in $\{-1, 0\}$. The two constant offset patterns are equivalent under common translation; all other binary patterns remain distinct. This gives $2^m - 1$ directions. A slope of absolute value two forces constant offsets and yields the already counted constant-offset direction after affine rescaling.

For two active coordinates, the normalized slope ratio is 1 or -1 . The width lemma forces a common offset, which disappears modulo constant translation. These give two directions for each coordinate pair. Distinct supports or slope ratios cannot be related by a single affine change of profile values. $\square$

This answers the intermediate-characteristic question in [200] without assuming that an integer lift of a long Boolean sum has small absolute value. The translation argument works directly in the prime field. Characteristics two and three are genuinely different: the alphabet is then the entire prime field and allows arbitrarily many active slopes.

II.176 Exact core-avoidance laws

Source 44, delivered Section 4.

Fix nonzero sides and a regular cross-section vector r . Define the paired linear map

$$L_r(t) = \left(\sum_j w_j t_j, \sum_j w_j r_j t_j \right), \quad Z_i = L_r((x_{ji}/h_i)_{j=1}^m) \in \mathbb{F}_q^2. \quad (\text{II.176.1})$$

Its two coefficient rows, w and $w \odot r$, are independent because r is not constant. Thus $Z_1, \dots, Z_k$ are independent uniform points of $\mathbb{F}_q^2$ when the bases x are uniform.

For a core profile (II.175.1), all but the two top moments vanish automatically. Expansion of those top moments gives the equivalent condition

$$\sum_i b_i Z_i = -L_r(t). \quad (\text{II.176.2})$$

Indeed each term ϵ_i contributes $1 + x_{ji}/h_i$ after division by the alternating top-cube factor. The extra common constant $\sum_i b_i$ vanishes under L_r , since $L_r(\mathbf{1}) = 0$.

II.176.1 Characteristics at least five: signed collisions

Put $L = 2^m - 1$ and define the binary offset set

$$\mathcal{C}_r = \{L_r(u) : u \in \{0, 1\}^m\} \subseteq \mathbb{F}_q^2. \quad (\text{II.176.3})$$

Lemma II.176.1. *For $p \geq 5$ and $r \in W^\circ$, the set $\mathcal{C}_r$ has exactly L elements, contains zero, and is invariant under negation.*

Proof. The all-zero and all-one vectors have the same image, namely zero. If two binary vectors u, u' have the same image, then $a = w \odot (u - u')$ is ternary, has sum zero, and satisfies $a \cdot r = 0$. Regularity forces $a = \lambda w$, hence $u - u' = \lambda \mathbf{1}$. Since a binary difference is 0, 1 or -1 , a nonzero constant difference occurs only for the all-one and all-zero pair. These are the only duplicate images. Finally $L_r(\mathbf{1} - u) = -L_r(u)$. $\square$

Theorem II.176.2 (Exact signed-collision product). *For every $p \geq 5$, nonzero h , and regular r , the probability that no core direction vanishes is*

$$F_{k,d,p}(q) = \prod_{i=0}^{k-1} \left(1 - \frac{2^m - 1 + 2i}{q^2} \right). \quad (\text{II.176.4})$$

Equivalently, the exact number of such base matrices is

$$q^{(m-2)k} \prod_{i=0}^{k-1} (q^2 - L - 2i). \quad (\text{II.176.5})$$

Proof. The single-coordinate core events are exactly $Z_i \in \mathcal{C}_r$ by (II.176.2) and the proof of Corollary II.175.2. The two-coordinate events are $Z_i = Z_j$ or $Z_i = -Z_j$. Outside $\mathcal{C}_r$, negation has no fixed points, because $0 \in \mathcal{C}_r$ and p is odd. There are $(q^2 - L)/2$ two-element sign orbits. Choose an ordered list of k distinct orbits and one of the two signs in each: the number of possible paired tuples is $\prod_{i < k} (q^2 - L - 2i)$. Each paired tuple has $q^{(m-2)k}$ preimages under the independent rank-two maps in (II.176.1). $\square$

If k exceeds the number of available orbits, the product is zero: a zero factor occurs before any negative factors. Thus the formula also covers the saturation range. If there are no regular cross-sections, the conditional statement is vacuous and the unconditional regular-region count below is zero.

II.176.2 Characteristics two and three: linear independence

Theorem II.176.3 (Exact prime-field rank product). *Let $p \in \{2, 3\}$ and $q = p^a$. For fixed nonzero sides and regular r ,*

$$F_{k,d,p}(q) = \prod_{i=0}^{k-1} \left(1 - \frac{p^{m-1+i}}{q^2} \right) \quad (\text{II.176.6})$$

is the exact probability that no core direction vanishes. Moreover,

$$g_{d,p}(q) = \prod_{j=0}^{m-3} \left(1 - \frac{p^j}{q} \right). \quad (\text{II.176.7})$$

Proof. The allowed offsets form all of $\mathbb{F}_p^m$. Let $C_r = L_r(\mathbb{F}_p^m)$, an $\mathbb{F}_p$ -subspace of $\mathbb{F}_q^2$. Its kernel consists exactly of the constant vectors. To see this, $L_r(t) = 0$ says that $c = w \odot t \in \mathbb{F}_p^m$ has sum zero and $c \cdot r = 0$. Since the alphabet is all of $\mathbb{F}_p$, regularity implies $c \in \mathbb{F}_p w$, or $t \in \mathbb{F}_p \mathbf{1}$. Therefore

$$\dim_{\mathbb{F}_p} C_r = m - 1.$$

A core relation exists precisely when a nonzero vector $b \in \mathbb{F}_p^k$ satisfies $\sum_i b_i Z_i \in C_r$. The images of the Z_i in the quotient $\mathbb{F}_q^2 / C_r$ must therefore be linearly independent. This quotient has dimension $2a - m + 1$. After i independent images have been chosen, the preimage of their span contains p^{m-1+i} of the q^2 possible next summaries. Multiplying the successive avoidance probabilities proves (II.176.6).

For (II.176.7), put

$$E_0 = \{c \in \mathbb{F}_p^m : \sum_j c_j = 0\} / \mathbb{F}_p w, \quad \dim_{\mathbb{F}_p} E_0 = m - 2.$$

A cross-section $r \in W$ induces the $\mathbb{F}_p$ -linear map $E_0 \rightarrow \mathbb{F}_q$, $c \mapsto c \cdot r$. The map from W onto the space of all such linear maps is surjective and has kernel $\mathbb{F}_q \mathbf{1}$. Indeed the annihilator of all coordinate-sum-zero vectors is the constant line, and the dimensions over $\mathbb{F}_q$ then give surjectivity. Regularity is exactly injectivity of the induced map on E_0 . The probability that $m - 2$ uniform elements of $\mathbb{F}_q$ are $\mathbb{F}_p$ -linearly independent is the product in (II.176.7). $\square$

Corollary II.176.4 (Universal obstructions). *In characteristics two and three, every arrangement is degenerate if $a < m - 2$ or $k > 2a - m + 1$. In characteristic at least five, every arrangement is degenerate if $k > (q^2 - 2^m + 1)/2$.*

Proof. Nondegeneracy requires nonzero sides, a regular cross-section, and core avoidance. The required injections or distinct sign orbits cannot exist beyond the displayed dimensions. If no regular cross-section exists, the conclusion follows already from Lemma II.174.2. $\square$

These are sufficient conditions for universal degeneracy, or equivalently necessary conditions for the existence of a nondegenerate arrangement. Their converses are not asserted.

II.177 From exact core avoidance to the full degeneracy count

Source 44, delivered Section 5.

The product formula is not, by itself, a formula for full nondegeneracy. Other coefficient directions remain. This section retains the cubic remainder from the earlier analysis [200], proves the needed rank statement, and substitutes the exact product in place of the earlier pairwise estimate.

II.177.1 The exact inventory of coefficient directions

For even ℓ , define

$$T_\ell(p) = \sum_{a \equiv 0 \pmod{p}} [z^a](z^{-1} + 1 + z)^\ell, \quad (\text{II.177.1})$$

$$B_\ell(p) = \sum_{j \in \mathbb{Z}} \binom{\ell}{\ell/2 + jp}. \quad (\text{II.177.2})$$

A binomial coefficient is zero outside its usual range. Let $Q_\ell(p)$ count nonconstant affine classes of alphabet-valued profiles with balanced signed coordinate sum, and let $U_\ell(p)$ count such classes without the balance requirement. Then

$$Q_\ell(p) = \frac{T_\ell(p) - 2B_\ell(p) + 1}{2}, \quad U_\ell(p) = \frac{3^\ell - 2^{\ell+1} + 1}{2} \quad (p \geq 5), \quad (\text{II.177.3})$$

$$Q_\ell(p) = \frac{p^{\ell-2} - 1}{p - 1}, \quad U_\ell(p) = \frac{p^{\ell-1} - 1}{p - 1} \quad (p = 2, 3). \quad (\text{II.177.4})$$

Here the balanced signs have equally many 1 and -1 entries.

For completeness, when $p \geq 5$ there are $T_\ell(p)$ balanced ternary profiles and $B_\ell(p)$ balanced binary profiles. There are three constant ternary profiles. Profiles using exactly two values give $(B_\ell(p) - 2)/2$ affine classes, because the underlying subset is identified with its complement. Profiles using all three values have only identity and negation as affine alphabet symmetries; they give

$(T_\ell(p) - 3B_\ell(p) + 3)/2$ classes. Their sum is (II.177.3). Removing balance replaces these two profile counts by 3^ℓ and 2^ℓ . In characteristics two and three the alphabet is the whole field. Quotient the vector space of profiles first by the constant line and then projectivize; this proves (II.177.4).

Consequently the relevant inventory is

$$H_{d,p} = Q_m(p), \quad R_{k,d,p} = Q_v(p) - U_m(p), \quad (\text{II.177.5})$$

where $R_{k,d,p}$ is the number of non-column-parity directions satisfying the empty moment. Indeed column-parity profiles are arbitrary profiles on m columns and automatically have zero empty moment. The core inventory is

$$S_{k,d,p} = \begin{cases} k(2^m - 1) + k(k - 1), & p \geq 5, \\ p^{m-1}(p^k - 1)/(p - 1), & p = 2, 3. \end{cases} \quad (\text{II.177.6})$$

The second line follows by choosing a projective nonzero slope in $\mathbb{F}_p^k$ and an offset modulo the constant line. In particular $R_{k,d,p} - S_{k,d,p}$ is nonnegative: it counts the remaining directions. The inventory formulae themselves are inherited from [200]; our improvement is that the large-characteristic core formula now holds for every $p \geq 5$.

II.177.2 Why every remaining direction costs three powers of the field size

For $A \subseteq [k]$ write

$$c_{A,j} = \sum_{\epsilon} \eta(\epsilon, j) \prod_{i \in A} \epsilon_i, \quad h_A = \prod_{i \in A} h_i.$$

The block moment satisfies the exact Boolean expansion

$$F_{A,j} := \sum_{\epsilon} \eta(\epsilon, j) \prod_{i \in A} (x_{ji} + \epsilon_i h_i) = \sum_{B \subseteq A} h_B c_{B,j} \prod_{i \in A \setminus B} x_{ji}. \quad (\text{II.177.7})$$

The two full moments associated with A are $\sum_j F_{A,j}$ and $\sum_j r_j F_{A,j}$. Boolean inversion, valid in every characteristic, shows that column-parity is equivalent to the vanishing of all vectors c_A with $A \subsetneq [k]$.

Lemma II.177.1 (Non-core remainder). *For a fixed non-column-parity direction which is not core, conditional on nonzero sides, the probability that its moments vanish and the cross-section is regular is at most q^{-3} .*

Proof. Let $s < k$ be the smallest degree for which some $c_A \neq 0$, $|A| = s$. The degree- s moments force

$$\sum_j c_{A,j} = 0, \quad c_A \cdot r = 0. \quad (\text{II.177.8})$$

If the first condition fails there are no solutions. For each $i \notin A$, (II.177.7) at $A \cup \{i\}$ is affine in the coordinate block $(x_{1i}, \dots, x_{mi})$, with coefficient vector $h_A c_A$. Its paired last-coordinate moment has coefficient vector $h_A(r \odot c_A)$. A nonzero vector of sum zero has at least two nonzero coordinates. Since regular r has pairwise distinct entries, these two rows have rank two.

If some minimal-degree c_A is not proportional to w , its cross-section constraint in (II.177.8) has codimension one in W . For each admissible regular r , the two base equations cost a further factor q^{-2} . Their joint probability is at most q^{-3} .

Suppose instead that every minimal-degree vector is proportional to w . If $s \leq k - 2$, choose $i, \ell \notin A$ distinct. The paired moments at $A \cup \{i\}$ and $A \cup \{\ell\}$ give four independent equations: the first pair has its rank-two rows in the i -coordinate block and the second in the ℓ -coordinate block. Their other terms depend only on the A -coordinates and the sides. Fixing those coordinates therefore gives probability at most q^{-4} , which is sufficient.

The remaining case has $s = k - 1$ and every proper coefficient vector proportional to w . Boolean inversion then says precisely $\eta/e = t_j + \sum_i b_i \epsilon_i$ with common slopes and $b \neq 0$. This is a core direction, contrary to the hypothesis. These cases exhaust the possibilities. $\square$

The assertion about the other terms is important. In (II.177.7), at $A \cup \{i\}$, every term involving x_{ji} has coefficient c_B with $B \subseteq A$. Minimality leaves only $B = A$. All other surviving terms use coordinates from A , not from another block outside A . Thus the rank-four step does not assume independence of unexamined right sides.

Let $F_{k,d,p}(q)$ be the product in Theorem II.176.2 or II.176.3, as appropriate, and put

$$\Phi_{k,d,p}(q) = (1 - q^{-1})^k g_{d,p}(q) F_{k,d,p}(q). \quad (\text{II.177.9})$$

When there are no regular cross-sections set $\Phi = 0$; this agrees with the product expression because $g = 0$.

Theorem II.177.2 (Exact principal part and explicit cubic remainder). *In every characteristic,*

$$0 \leq \Delta_{k,d}(q) - (1 - \Phi_{k,d,p}(q)) \leq (1 - q^{-1})^k \frac{R_{k,d,p} - S_{k,d,p}}{q^3}. \quad (\text{II.177.10})$$

The quantity Φ is the exact probability of simultaneously avoiding zero sides, all cross-section hyperplanes, and all core relations.

Proof. Every excluded zero side or cross-section is degenerate. On the remaining region, all core events have the exact avoidance probability already proved, independently of the particular regular r and nonzero h . This proves the interpretation of Φ and the lower inequality. Every additional degeneracy has a non-core witness. Sum Lemma II.177.1 over the $R - S$ directions, then multiply by the probability of nonzero sides. This proves the upper inequality. $\square$

For example, the earlier S/q^2 upper bound for the core union discards its exact intersections. The replacement is $1 - \prod_{i < k} (1 - (2^m - 1 + 2i)/q^2)$ in characteristics at least five. The improvement is an exact finite identity, not a claim that the non-core term is uniformly small when k grows. A convenient inherited coarse consequence remains

$$\Delta_{k,d}(q) \leq \frac{k + H_{d,p}}{q} + \frac{S_{k,d,p}}{q^2} + \frac{R_{k,d,p} - S_{k,d,p}}{q^3}. \quad (\text{II.177.11})$$

The exact expression (II.177.10) is preferable whenever the cross-section complement can itself be evaluated.

II.178 The second Whitney coefficient and a uniform characteristic cutoff

Source 44, delivered Section 6.

Work first over $\mathbb{Q}$. The cross-section arrangement is defined by the integer-balanced ternary vectors $a \in \{-1, 0, 1\}^m$, $\sum_j a_j = 0$, modulo the intrinsic line $\mathbb{Q}w$. Let $\mathcal{L}_2$ be its distinct codimension-two flats in W , and let ν_F be the number of hyperplanes containing F . Define

$$b_{2,d} = \sum_{F \in \mathcal{L}_2} (\nu_F - 1). \quad (\text{II.178.1})$$

This is the second Whitney coefficient of the characteristic polynomial; we will use only the finite inclusion–exclusion interpretation, not any structural theorem about arrangements.

Put

$$T_n = [z^0](z^{-1} + 1 + z)^n, \quad H_d = \frac{T_m - 2\binom{m}{d} + 1}{2}. \quad (\text{II.178.2})$$

The profile count (II.177.3) gives H_d in characteristic zero or greater than m . It does not alone establish that pair intersections have stabilized. The following determinant bound does.

Theorem II.178.1 (Rank-two stability beyond characteristic sixteen). *If $p > \max(m, 16)$, reduction from the rational arrangement to $\mathcal{H}_{d,p}$ preserves the hyperplanes, every rank-two flat, and every incidence between them. In particular $H_{d,p} = H_d$ and $b_{2,d,p} = b_{2,d}$.*

Proof. Eliminate r_m using $w_m = -1$ and $w \cdot r = 0$. The unnormalized restricted integer normal is

$$n(a) = (a_i + a_m w_i)_{1 \leq i < m}. \quad (\text{II.178.3})$$

For $t \leq 3$ normals $n(a^{(1)}), \dots, n(a^{(t)})$, each t by t minor is, up to sign, the determinant of the $(t+1)$ by $(t+1)$ matrix whose rows are $a^{(1)}, \dots, a^{(t)}, w$ restricted to the chosen t coordinates and coordinate m . This follows by adding suitable multiples of the last row to the preceding rows and expanding at the last column. All entries of this augmented matrix are in $\{-1, 0, 1\}$. Hadamard's inequality therefore bounds the absolute determinant by

$$(t+1)^{(t+1)/2} \leq 16.$$

A nonzero minor cannot become zero modulo $p > 16$; a zero integer minor remains zero. All ranks of collections of at most three normals are preserved. Nonzero normals and proportional pairs are consequently preserved. Membership of a third normal in the span of two independent ones is preserved as well. These are exactly the data determining the rank-two flats and their incident hyperplanes.

Finally $p > m$ means that every modularly balanced ternary vector is integer-balanced, since its integer coordinate sum has absolute value at most m . Thus no new normals are introduced by a modular balance condition. This proves the whole assertion. $\square$

The bound 16 is independent of d and k because only three restricted normals are needed. It does not claim that the entire intersection lattice stabilizes at that prime. Higher-rank minors can have larger determinants.

Lemma II.178.2 (A uniform two-term complement expansion). *For $p > \max(m, 16)$,*

$$g_{d,p}(q) = 1 - \frac{H_d}{q} + \frac{b_{2,d}}{q^2} + O_d(q^{-3}), \quad (\text{II.178.4})$$

uniformly over the indicated finite fields. One valid absolute remainder constant is

$$C_d = (1 + H_d + b_{2,d}) \binom{H_d}{3}. \quad (\text{II.178.5})$$

Proof. At a point outside all intersections of three linearly independent hyperplane normals, the incident normals have rank at most two. If there are s incident hyperplanes of rank two, all of them contain one unique rank-two flat and its correction is $s - 1$. Thus, at every such point,

$$\mathbf{1}_{\cup H} = \sum_{H \in \mathcal{H}_{d,p}} \mathbf{1}_H - \sum_{F \in \mathcal{L}_2} (\nu_F - 1) \mathbf{1}_F.$$

The identity is also true at rank zero or one. The exceptional points belong to a union of at most $\binom{H_d}{3}$ codimension-three subspaces, of total relative size at most $\binom{H_d}{3} q^{-3}$. The discrepancy of the displayed indicator formula has absolute value at most $1 + H_d + b_{2,d}$. Averaging gives the asserted error bound. Every hyperplane has relative size q^{-1} and every rank-two flat relative size q^{-2} . Theorem II.178.1 makes their coefficients independent of the characteristic. $\square$

Corollary II.178.3 (The coefficient to be computed). *For fixed k, d , uniformly for $p > \max(2d, 16)$,*

$$\Delta_{k,d}(q) = \frac{k + H_d}{q} \tag{II.178.6}$$

$$+ \frac{\binom{k}{2} + k(2^m - 1 - H_d) - b_{2,d}}{q^2} + O_{k,d}(q^{-3}). \tag{II.178.7}$$

Proof. For fixed k, d , the exact core product is $1 - S_{k,d}/q^2 + O_{k,d}(q^{-4})$. Substitute this, the binomial expansion of $(1 - q^{-1})^k$, and (II.178.4) into (II.177.9). Theorem II.177.2 gives an $O_{k,d}(q^{-3})$ remainder uniformly in the characteristic: the direction inventory is bounded by 3^v , independently of p . Since $S_{k,d} - \binom{k}{2} - kH_d = \binom{k}{2} + k(2^m - 1 - H_d)$, the coefficient is the one displayed. $\square$

The dependence on $b_{2,d,p}$ in this corollary was already identified in [200]. The new content so far is its uniform characteristic range and the exact principal product. The next section evaluates the remaining invariant in a number of operations polynomial in d .

II.179 A fixed nine-point grid computes every second coefficient

Source 44, delivered Section 7.

II.179.1 Affine profiles and rank-two flats

For an integer-balanced ternary normal a , put $z = w \odot a \in \{-1, 0, 1\}^m$. Then $w \cdot z = 0$. Two nonconstant profiles define the same hyperplane exactly when

$$z' = \lambda z + \mu \mathbf{1}, \quad \lambda \neq 0. \tag{II.179.1}$$

A profile using exactly two distinct values has six ternary representatives in its affine class. A profile using all three values has two, because the only affine symmetries of $\{-1, 0, 1\}$ over $\mathbb{Q}$ are identity and negation. These representative multiplicities will be retained, rather than replacing affine equivalence by sign equivalence.

Take an ordered pair of nonconstant balanced profiles z, z' which are independent modulo the constant line. The coordinate pairs form a set

$$S = \{(z_j, z'_j) : 1 \leq j \leq m\} \subseteq \mathcal{G} := \{-1, 0, 1\}^2. \tag{II.179.2}$$

Independence modulo constants is equivalent to S affinely spanning $\mathbb{Q}^2$. Let $\mathcal{S}$ denote all subsets of $\mathcal{G}$ with this property. There are only $2^9 = 512$ possible subsets before imposing it. For $S \in \mathcal{S}$ define

$$c_i(S) = \begin{cases} 6, & \text{the } i\text{th projection has two values,} \\ 2, & \text{it has three values,} \end{cases} \quad i = 1, 2. \quad (\text{II.179.3})$$

Both projections have at least two values, since S spans the plane.

Let $\nu(S)$ be the number of nonzero projective directions $(b : c)$ for which some affine function $a + bX + cY$ maps S into $\{-1, 0, 1\}$. Every such function produces a balanced ternary profile $a\mathbf{1} + bz + cz'$, because the three constituent profiles have signed sum zero. Its class gives a hyperplane containing the codimension-two flat defined by the original pair. Conversely every hyperplane through that flat arises this way. Therefore $\nu(S)$ is exactly its multiplicity.

There is a small exact algorithm for $\nu(S)$. Choose any three noncollinear points of S . Assign to them the 27 ordered triples of values in $\{-1, 0, 1\}^3$, solve for the unique affine function, and retain it if its values at the other points are in $\{-1, 0, 1\}$. Discard constant functions and identify proportional nonzero gradient vectors. This is an exhaustive rational computation, since an affine function is determined by three noncollinear values.

II.179.2 Balanced coordinate sequences and lattice energies

For any $T \subseteq \mathcal{G}$, let

$$P_T(X, Y) = \sum_{(u,v) \in T} X^u Y^v, \quad E_d(T) = \text{CT} \left(P_T(X, Y)^d P_T(X^{-1}, Y^{-1})^d \right). \quad (\text{II.179.4})$$

This counts ordered pairs of length- d sequences from T with equal vector sum. Equivalently, if $W_d^T(s)$ counts ordered d -step walks with steps in T and endpoint $s \in \mathbb{Z}^2$, then

$$W_0^T(s) = \mathbf{1}_{s=0}, \quad W_{j+1}^T(s) = \sum_{t \in T} W_j^T(s - t), \quad E_d(T) = \sum_s W_d^T(s)^2. \quad (\text{II.179.5})$$

For $d \geq 1$, $E_d(\emptyset) = 0$. Define the exact-support count

$$N_d(S) = \sum_{T \subseteq S} (-1)^{|S| - |T|} E_d(T). \quad (\text{II.179.6})$$

Inclusion–exclusion shows that $N_d(S)$ counts the balanced coordinate sequences whose combined support is exactly S . In particular it is a nonnegative integer, despite the alternating formula.

Theorem II.179.1 (Fixed-grid formula). *For every $d \geq 2$,*

$$b_{2,d} = \sum_{S \in \mathcal{S}} \frac{N_d(S)}{\nu(S) c_1(S) c_2(S)}. \quad (\text{II.179.7})$$

More precisely, if $f_{\nu,d}$ is the number of rank-two flats incident with exactly ν hyperplanes, then

$$f_{\nu,d} = \sum_{\substack{S \in \mathcal{S} \\ \nu(S) = \nu}} \frac{N_d(S)}{\nu(\nu - 1) c_1(S) c_2(S)}. \quad (\text{II.179.8})$$

Both formulae can be evaluated through d in $O(d^3)$ exact arithmetic operations and $O(d^2)$ memory, with constants independent of d .

Proof. Fix a rank-two flat F of multiplicity ν . It has $\nu(\nu - 1)$ ordered pairs of distinct incident hyperplanes. For an ordered pair, choose every ternary representative of each of its two profiles. There are $c(z)c(z')$ raw ordered pairs. The support S of each raw pair spans the plane; its multiplicity is ν , and its two projection representative counts are $c(z), c(z')$.

Give this raw pair weight $1/(\nu c(z)c(z'))$. All representatives of one ordered hyperplane pair contribute $1/\nu$. All ordered hyperplane pairs through F therefore contribute $\nu - 1$. On the other hand, raw balanced pairs with a specified support S are counted by $N_d(S)$: the first d coordinate pairs and the last d coordinate pairs must have equal sum. Summing the weights by support proves (II.179.7). Giving each raw pair instead weight $1/(\nu(\nu - 1)c(z)c(z'))$ proves (II.179.8).

For the operation count, at step j every walk endpoint lies in $[-j, j]^2$. The recurrence (II.179.5) uses at most nine additions per endpoint, so one step costs $O(j^2)$ operations for each of the fixed 512 supports. Summing for $j \leq d$ costs $O(d^3)$ operations, and only the current arrays, of total size $O(d^2)$, need be stored. Boolean Möbius inversion on the nine-bit subset lattice costs a fixed number of operations for each j . All rational weights and template multiplicities are independent of d . The final numbers are integers by the already proved counting interpretation. $\square$

The bound is an arithmetic-operation bound, not a unit-cost assertion for arbitrarily large integers. Walk counts have $O(d)$ bits, since there are at most 9^d walks; the same linear bit bound holds for the energies. Using ordinary schoolbook integer arithmetic still gives a polynomial bit-complexity bound. The algorithm replaces enumeration of exponentially many hyperplanes or their quadratically many pairs by a fixed collection of two-dimensional walk recurrences.

The formula also gives an independently checkable consistency identity:

$$\sum_{\nu} \binom{\nu}{2} f_{\nu,d} = \binom{H_d}{2}, \quad b_{2,d} = \sum_{\nu} (\nu - 1) f_{\nu,d}. \quad (\text{II.179.9})$$

The first identity says that every unordered pair of hyperplanes meets in one rank-two flat. Neither identity is used to guess the answer.

II.180 Eight lattice energies and the explicit eight-arrangement coefficient

Source 44, delivered Section 8.

II.180.1 A finite-certified compression of the general formula

Define the pair-overlap deficit

$$B_d = \binom{H_d}{2} - b_{2,d}. \quad (\text{II.180.1})$$

This notation is distinct from the modular binary count $B_{\ell}(p)$, which always has two arguments and was used only in the direction inventory. By (II.179.9),

$$B_d = \sum_{F \in \mathcal{L}_2} \binom{\nu_F - 1}{2} = \sum_{S \in \mathcal{S}} \frac{\nu(S) - 2}{2\nu(S)c_1(S)c_2(S)} N_d(S). \quad (\text{II.180.2})$$

The first equality makes positivity transparent. The second follows by the same weighted raw-pair count as Theorem II.179.1.

For a Laurent polynomial P define

$$\mathcal{E}_d(P) = \text{CT}(P(X, Y)^d P(X^{-1}, Y^{-1})^d).$$

Consider the following eight polynomials, each the indicator polynomial of a finite planar step set:

$$P_7 = 1 + X + X^{-1} + Y + Y^{-1} + XY^{-1} + X^{-1}Y, \quad (\text{II.180.3})$$

$$P_6 = 1 + X + Y + X^2 + XY + Y^2, \quad (\text{II.180.4})$$

$$P_{5a} = 1 + X + Y + XY + Y^2, \quad (\text{II.180.5})$$

$$P_{5b} = 1 + X + X^{-1} + Y + Y^{-1}, \quad (\text{II.180.6})$$

$$P_4 = 1 + X + Y + Y^2, \quad (\text{II.180.7})$$

$$P_3 = 1 + X + Y, \quad P_2 = 1 + X, \quad P_1 = 1. \quad (\text{II.180.8})$$

The subscripts record the number of points, not the arrangement dimension. In particular $\mathcal{E}_d(P_2) = \binom{2d}{d}$ and $\mathcal{E}_d(P_1) = 1$.

Theorem II.180.1 (Eight-shape compression; finite rational certificate). *For every $d \geq 1$, the fixed-grid expression gives*

$$\begin{aligned} B_d = & \frac{1}{12}\mathcal{E}_d(P_7) + \frac{1}{6}\mathcal{E}_d(P_6) - \frac{1}{2}\mathcal{E}_d(P_{5a}) + \frac{1}{8}\mathcal{E}_d(P_{5b}) \\ & - \frac{1}{2}\mathcal{E}_d(P_4) + \frac{7}{6}\mathcal{E}_d(P_3) - \binom{2d}{d} + \frac{19}{24}. \end{aligned} \quad (\text{II.180.9})$$

For $d = 1$ both H_d and $b_{2,d}$ are zero. The universal finite identity reducing (II.180.2) to (II.180.9) is certified by `code/verify.py` and `data/grid_certificate.js on`.

Proof and precise finite component. Substitute (II.179.6) into (II.180.2). For each $T \subseteq \mathcal{G}$, its rational coefficient is

$$\alpha_T = \sum_{\substack{S \in \mathcal{S} \\ T \text{ fortyfour} \subseteq S}} (-1)^{|S|-|T|} \frac{\nu(S) - 2}{2\nu(S)c_1(S)c_2(S)}. \quad (\text{II.180.10})$$

If two finite step sets are related by an invertible rational affine map, their energies are equal: a pair of d -term sums is equal before the map if and only if it is equal afterward. The common affine translation cancels because both sums have length d .

The finite certificate evaluates (II.180.10) on all 512 supports, not on a finite list of values of d . To classify rational affine shapes, map every ordered noncollinear triple of a planar support to $(0, 0), (1, 0), (0, 1)$ and choose the lexicographically least resulting set of rational coordinate pairs. The corresponding one-dimensional normalization uses ordered distinct pairs; empty sets and singletons are treated separately. Two supports have the same key exactly when they are rationally affinely equivalent. Summing the coefficients (II.180.10) by these keys gives the following complete nonzero list:

Shape	P_7	P_6	P_{5a}	P_{5b}	P_4	P_3	P_2	P_1	$\emptyset$
Coefficient	1/12	1/6	-1/2	1/8	-1/2	7/6	-1	19/24	-1/3

This table is the finite computational component of the theorem. Its checker reconstructs all template directions from the 27 affine assignments, computes every rational coefficient, and verifies equality of the full dictionaries of affine-shape coefficients. All zero shape coefficients are checked as well. The empty-set energy is zero when $d \geq 1$, yielding (II.180.9). $\square$

[write] **7 October 2026; sources 40–46.** At $d = 8$: $H_8 = 2,585,444$ is source 18's C_8 , $2^{16} - 1 - H_8 = -2,519,909$ (checked at the write), and the second coefficient of the degenerate count is $\binom{k}{2} - 2,519,909k - b_{2,8}$, $b_{2,8} = 3,280,234,631,541$ (the certificate's output, reproduced on a copy at the write). At $d = 2$ the formula gives source 27's $(k^2 + 21k - 6)/2$.

The general fixed-grid theorem does not depend on this compression or its finite certificate. Thus the main algorithm and its proof survive even if the eight-shape identity is not used. The certificate is not a proof-assistant theorem: it is an explicit finite exact-arithmetic component of an otherwise conventional proof.

In the implementation the grid is ordered lexicographically and a support is encoded by its nine-bit mask. Representative masks for the displayed shapes are 254, 95, 31, 124, 15, 11, 10, 8, respectively. The certificate includes the actual point sets, so this convention can be checked without trusting the names of the shapes. In total 458 supports span the plane. Their multiplicities are

$$\#\{S : \nu(S) = 2, 3, 4, 6\} = 178, 128, 76, 76, \quad (\text{II.180.11})$$

and no other multiplicity occurs in the enumeration.

II.180.2 Exact values and independent cross-checks

The recurrences (II.179.5) and the general formula produce the following values. The first three nontrivial rows were also checked by independent enumeration of rational hyperplane normals and all pair spans, using primitive exterior-product coordinates rather than grid supports.

d	H_d	$b_{2,d}$	$\binom{H_d}{2} - b_{2,d}$
2	4	3	3
3	51	889	386
4	484	97 081	19 805
5	4 225	8 063 205	859 995
6	35 971	611 183 390	35 755 045
7	304 682	44 934 144 969	1 481 263 252
8	2 585 444	3 280 234 631 541	62 024 414 305

The values for $d = 9, 10$, together with every intermediate count and the multiplicity histograms, are included in `data/verification.json`. The table entries are outputs of a proved formula with exact integer recurrences; the independent small- d enumeration is an additional check, not the sole justification for extrapolating to $d = 8$.

For $d = 8$, the multiplicity counts are

$$\begin{array}{c|c} \nu & f_{\nu,8} \\ \hline 2 & 3\,157\,571\,257\,708 \\ 3 & 60\,640\,725\,488 \\ 4 & 460\,052\,299 \\ 6 & 353\,192 \end{array} \quad (\text{II.180.12})$$

They satisfy both identities (II.179.9). In particular,

$$\binom{2\,585\,444}{2} = 3\,342\,259\,045\,846, \quad b_{2,8} = 3\,280\,234\,631\,541.$$

Since $2^{16} - 1 - H_8 = -2\,519\,909$, Corollary II.178.3 gives (F.49.2). The threshold $p > 16$ is enough for every fixed k : it is not necessary to impose $p > 16 \cdot 2^k$.

The first newly evaluated instance is already informative. For $d = 3$,

$$\Delta_{k,3}(q) = \frac{k+51}{q} + \frac{\binom{k}{2} + 12k - 889}{q^2} + O_k(q^{-3}) \quad (p > 16). \quad (\text{II.180.13})$$

For $d = 2$, the same formula reduces to the previously known coefficient $(k^2 + 21k - 6)/2$ [200]. This agreement tests the normalization of $b_{2,d}$ and the sign of its contribution.

II.181 The exponentially smaller pair-overlap deficit

Source 44, delivered Section 9.

The large count $b_{2,d}$ is close to the number of hyperplane pairs. The difference has its own growth scale. We derive that scale directly from the fixed-grid theorem, so the following asymptotic does not depend on the eight-shape finite certificate.

Lemma II.181.1 (The dominant seven-point support). *For every $S \in \mathcal{S}$, $\nu(S) \leq 6$. If $\nu(S) \geq 3$, then $|S| \leq 7$. Among seven-point supports there are exactly two with $\nu(S) \geq 3$: the central strips $|X + Y| \leq 1$ and $|X - Y| \leq 1$ inside $\mathcal{G}$. Each has $\nu(S) = 3$ and $c_1(S) = c_2(S) = 2$.*

Proof. Restrict any admissible nonconstant affine function to three noncollinear points of S . Modulo an affine change of its values, a nonconstant ternary profile on three labelled points has six possibilities: three bipartitions for two-valued profiles, and three orderings modulo reversal for three-valued profiles. Distinct gradient directions give distinct classes upon restriction, so $\nu(S) \leq 6$.

The two coordinate projections already give two directions. A third requires a function with both gradient coordinates nonzero. If $|S| \geq 8$, at least two horizontal rows are full. The three values on one full row are exactly $\{-1, 0, 1\}$, and the values on the other are a nonzero translate of that set. A finite nonempty subset of $\mathbb{Q}$ is not invariant under a nonzero translation. Thus $|S| \geq 8$ is impossible.

If $|S| = 7$, at least one row and one column are full. Their three-term arithmetic progressions force both gradient coordinates to be 1 or -1 , after the normalization that the output alphabet is $\{-1, 0, 1\}$. The allowed grid points lie in a strip of three consecutive levels of $X + Y$ or $X - Y$. A noncentral such strip has at most six grid points, whereas the central strip has exactly seven. These are therefore the only possibilities. On either central strip, the same full row and column argument shows that the only extra non-axis direction is its defining diagonal; the other diagonal takes more than three values. This proves $\nu = 3$. Both coordinate projections have three values, so $c_1 = c_2 = 2$. $\square$

The two seven-point supports are equivalent by reflection to the support of P_7 . Their combined weight in (II.180.2) is $1/12$. Every remaining contributing support has at most six points. Since $0 \leq N_d(S) \leq |S|^{2d}$ and all weights in (II.180.2) are at most $1/12$, the crude but explicit bound

$$\left| B_d - \frac{1}{12} \mathcal{E}_d(P_7) \right| \leq 44 \cdot 36^d \quad (\text{II.181.1})$$

follows. Indeed there are at most 512 remaining supports, and the sequences on the seven-point support missing a specified point number at most 6^{2d} . Summing the seven missing-point bounds contributes at most $(7/12)36^d$; $(512 + 7)/12 < 44$.

Theorem II.181.2 (Triangular-lattice deficit asymptotic). *As $d \rightarrow \infty$,*

$$B_d = \frac{7 \cdot 49^d}{96\pi\sqrt{3}d} \left(1 - \frac{5}{24d} + O(d^{-2}) \right). \quad (\text{II.181.2})$$

Furthermore,

$$b_{2,d} \sim \frac{3 \cdot 81^d}{64\pi d}, \quad \frac{B_d}{\binom{H_d}{2}} \sim \frac{14}{9\sqrt{3}} \left(\frac{49}{81} \right)^d. \quad (\text{II.181.3})$$

Proof. The support of P_7 is centrally symmetric, so $\mathcal{E}_d(P_7) = \text{CT } P_7^{2d}$. Fourier coefficient extraction gives

$$\mathcal{E}_d(P_7) = \frac{1}{(2\pi)^2} \int_{[-\pi, \pi]^2} (1 + 2\cos u + 2\cos v + 2\cos(u-v))^{2d} du dv. \quad (\text{II.181.4})$$

The absolute value of the bracket is at most seven, with equality only at $(0,0)$ on the torus. This follows from the triangle inequality for the seven unit complex terms: equality requires all of them to have the same phase, which the constant term forces to be one.

Put $Q_2 = u^2 + v^2 + (u-v)^2$ and $Q_4 = u^4 + v^4 + (u-v)^4$. Near zero, the logarithm of the bracket divided by seven is

$$-\frac{Q_2}{7} + \frac{Q_4}{84} - \frac{Q_2^2}{98} + O((u^2 + v^2)^3). \quad (\text{II.181.5})$$

After $(u, v) = \sqrt{7/(2d)}(s, t)$, the exponent $2d$ times this logarithm is

$$-Q_2(s, t) + \frac{1}{d} \left(\frac{7}{24} Q_4(s, t) - \frac{1}{4} Q_2(s, t)^2 \right) + O(d^{-2}(s^2 + t^2)^3).$$

The Gaussian integral is $\int_{\mathbb{R}^2} e^{-Q_2} ds dt = \pi/\sqrt{3}$. Under the normalized Gaussian its covariance matrix is

$$\begin{pmatrix} 1/3 & 1/6 \\ 1/6 & 1/3 \end{pmatrix}.$$

Hence $\mathbb{E}Q_4 = 1$ and $\mathbb{E}Q_2^2 = 2$. For example each of $s, t, s-t$ has variance $1/3$ and fourth moment $1/3$; also Q_2 is a sum of two squares after linear normalization, giving the stated second moment. The relative coefficient at order $1/d$ is therefore $7/24 - 1/2 = -5/24$.

Here is a remainder justification for this use of the expansion. Outside a fixed small neighborhood of zero the integrand is bounded by $(7 - \epsilon)^{2d}$ for some $\epsilon > 0$. Inside that neighborhood the real analytic logarithm has the displayed Taylor expansion and its quadratic form is positive definite. Restricting the scaled variables first to a ball of radius $d^{1/20}$ makes the integrated remainder, including the square of the fourth-order correction, bounded by d^{-2} times an integrable Gaussian times a fixed polynomial. The remaining scaled annulus is exponentially small in $d^{1/10}$, by the quadratic upper bound on the logarithm. Gaussian tails permit extension to $\mathbb{R}^2$. These bounds justify an $O(d^{-2})$ relative error. Thus

$$\mathcal{E}_d(P_7) = \frac{7 \cdot 49^d}{8\pi\sqrt{3}d} \left(1 - \frac{5}{24d} + O(d^{-2}) \right).$$

Combine this with (II.181.1); its exponential error is smaller than every inverse power correction on the scale $49^d/d$.

For the final assertions, the one-dimensional coefficient integral for T_{2d} has integrand $(1+2\cos u)^{2d}$. Its unique absolute maximum is three at zero, with normalized logarithm $-u^2/3 + O(u^4)$. The same Gaussian argument gives $T_{2d} \sim 9^d \sqrt{3}/(2\sqrt{2\pi d})$. The term $\binom{2d}{d} \leq 4^d$ is exponentially smaller, so $H_d \sim 9^d \sqrt{3}/(4\sqrt{2\pi d})$. Squaring and dividing by two gives $\binom{H_d}{2} \sim 3 \cdot 81^d/(64\pi d)$. The deficit is exponentially smaller, giving both statements in (II.181.3). $\square$

The dominant step set is a triangular-lattice hexagon with a holding step at its center. Its appearance is forced by the extremal grid support argument, not introduced as an analogy after the asymptotic was observed numerically. Further coefficients can be obtained from the same analytic integral, but their all-orders derivation is not needed here.

II.182 Contrasting growing-dimension laws

Source 44, delivered Section 10.

The exact products allow regimes inaccessible to a fixed-order inclusion–exclusion approximation. Their interpretation must remain precise: Φ is the probability of avoiding the classified obstructions, not necessarily of avoiding every ternary relation.

Theorem II.182.1 (Signed-collision scale). *Fix $d \geq 2$. Along any sequence of finite fields with $p \geq 5$ and $q \rightarrow \infty$, if $k/q \rightarrow c \in [0, \infty)$, then*

$$\Phi_{k,d,p}(q) \longrightarrow e^{-c-c^2}. \quad (\text{II.182.1})$$

Consequently the probability of full nondegeneracy has upper limit at most e^{-c-c^2} in this regime.

Proof. The number of cross-section hyperplanes is bounded in terms of d alone, even when the characteristic varies, so $g_{d,p}(q) = 1 + O_d(q^{-1})$. The nonzero-side probability converges to e^{-c} . With $L = 2^m - 1$,

$$\log F_{k,d,p}(q) = -\frac{kL + k(k-1)}{q^2} + O_d\left(\frac{k + k^3}{q^4}\right) \longrightarrow -c^2.$$

All factors are positive for large q in this regime. Multiplying proves (II.182.1). Full nondegeneracy implies avoidance of the classified obstructions, so its probability is at most Φ . $\square$

The linear term c is the zero-side cost; the quadratic term c^2 is the signed-collision cost. The finite binary offset constellation has fixed size and does not contribute at this scale.

Theorem II.182.2 (Small-characteristic rank window). *Fix $p \in \{2, 3\}$, $d \geq 2$, and an integer $s \geq 0$. For $q = p^a$ and $k = 2a - m + 1 - s$, as $a \rightarrow \infty$,*

$$\Phi_{k,d,p}(q) \longrightarrow \prod_{j=s+1}^{\infty} (1 - p^{-j}). \quad (\text{II.182.2})$$

If $k > 2a - m + 1$, every arrangement is degenerate.

Proof. The last assertion is Corollary II.176.4. In the specified window the exact core product is

$$\prod_{i=0}^{k-1} (1 - p^{m-1+i-2a}) = \prod_{j=s+1}^{2a-m+1} (1 - p^{-j}).$$

Its limit is the displayed convergent positive product, because $\sum_j p^{-j} < \infty$. The cross-section product in (II.176.7) and the nonzero-side probability tend to one; the latter uses $k = O(a)$ and $a/p^a \rightarrow 0$. $\square$

Thus the classified obstruction has a dimension scale of order q in characteristics at least five, but a rank threshold of order $\log q$ in characteristics two and three. Theorem II.177.2 does not turn these into full nondegeneracy limits: its inventory $R_{k,d,p}$ grows rapidly with k . Any such strengthening would require new control of non-core directions, not simply another expansion of the exact product.

II.183 Source 45's chapter: energy levels and the coset range [write]

Added in the eighth write, 7 October 2026.

The next two sections are source 45's Sections 2–3. *Logically they follow source 14's near-maximal energy material* (Theorem II.43.2 and the collision results of its Section II.43) and source 15's collision amplification (Section II.45); they are printed here because no number printed earlier may move. Source 45's introduction is Section F.50; its Sections 4–5 are in Part III (Section III.89).

What is proved. For $m \geq 5$ the three largest additive energies of m -element subsets of a torsion-free abelian group are M_m , $M_m - 4(m - 2)$ and $M_m - 8(m - 3)$, $M_m = (2m^3 + m)/3$; the sets at the second value are the affine images of $H_m = \{0, \dots, m - 2, m\}$ (Theorems II.184.1, II.184.10, II.184.11), through the exact identity $(M_m - E(A))/4 = \#\{x < y < z : x + z - y \notin A\}$ (Proposition II.184.2) and a unit-defect theorem for positive Schur triples. The first gap follows from the inverse Pollard theorem and Hegyvári's work, as source 45 says (Remark II.184.7); the classification and the third gap are new here, and the third level is not classified. Source 14's envelope $|A \triangle C| \leq \tau(\varepsilon)m$, proved for $\varepsilon \leq 1/100$, is extended to $\varepsilon < 1/9$ in every abelian group, with the canonical subgroup $\{d : |A \cap (A + d)| > m/2\}$, uniqueness, and all positive equality cases, which are exactly the punctured cosets $C \setminus K$, K a subcoset of index at least nine (Theorems II.185.4, II.185.8); a second, nested-hole envelope with optimal leading constant one (Theorem II.185.11); for coordinate-cube collisions, equality forces one punctured coordinate (Theorems II.185.14, II.185.15). The equality cases are the intake's punctured-coset observation recorded at item II.31, now with all equality cases on the larger range. The largest range is open.

Relation to the formal statements (checked at HEAD 6d4942222). `theorem_7_1` and `theorem_7_2` (Sections06_07.lean, lines 104 and 125) have, since the seventh write's pins, the exact companions `theorem_7_1_holds` and `theorem_7_2_holds` (Proofs07FreimanClosure.lean, lines 185 and 235); the exact energy levels and the coset envelope are different statements and are not formalized.

II.184 The first three additive-energy levels

Source 45, delivered Section 2.

The opening discussion of Section 7 of Gowers’s paper records an exact extremal fact: an arithmetic progression maximizes the additive energy of a fixed number of integers, and it is the only maximizer [1, Section 7, immediately before Theorem 7.2]. Here we examine the next two values below that maximum. This is a different endpoint from the subgroup-coset bound $E(A) \leq |A|^3$ used elsewhere in this article. The ordered setting has maximum $(2|A|^3 + |A|)/3$, and its first two positive defects have exact linear sizes.

The maximum, an endpoint-addition recurrence, and the congruence of energy modulo four belong to the existing literature. Hegyvári explicitly studies the set of attainable energies and computes the displaced-endpoint examples used below [189, Section 2.1]. The first gap also follows from the inverse Pollard theorem [190]; we give both its provenance and an elementary proof. The full second-level equality classification and the exact third level are extensions developed here beyond the statements located in the inspected sources and the pinned repository [202]. We make no assertion of global publication priority for them. Their proofs are self-contained.

II.184.1 Statement of the spectrum theorem

For a nonempty finite set $A \subset \mathbb{R}$, put

$$E(A) = \#\{(a, b, c, d) \in A^4 : a + b = c + d\}, \quad (\text{II.184.1})$$

$$M_m = \frac{2m^3 + m}{3}, \quad D(A) = \frac{M_m - E(A)}{4}, \quad m = |A|. \quad (\text{II.184.2})$$

The notation $D(A)$ in this section denotes a quarter of the deficit from the torsion-free maximum. Its integrality and nonnegativity will follow from a counting identity, rather than being assumed.

For $m \geq 3$, define

$$H_m = \{0, 1, \dots, m-2, m\}, \quad L_m = \{0, 2, 3, \dots, m\} = m - H_m. \quad (\text{II.184.3})$$

An affine image of a finite real set means its image under $x \mapsto u + vx$ with $v \neq 0$. In particular, reflection is allowed.

Theorem II.184.1 (The first three levels). *For every integer $m \geq 5$, the three largest distinct additive energies of m -element subsets of $\mathbb{R}$ are*

$$\boxed{M_m, \quad M_m - 4(m-2), \quad M_m - 8(m-3)}. \quad (\text{II.184.4})$$

The maximum occurs precisely for arithmetic progressions. The second value occurs precisely for affine images of H_m . If A belongs to neither of these two classes, then

$$E(A) \leq M_m - 8(m-3), \quad (\text{II.184.5})$$

and equality is attained by $\{0, 1, \dots, m\} \setminus \{2\}$. The same assertions hold for finite subsets of every torsion-free abelian group, with the affine models interpreted using a nonzero group element as their common step.

[write] **7 October 2026; sources 40–46.** Checked at the write by exhaustion over the m -subsets of $\{0, \dots, n\}$: the three largest energies are 85, 73, 69 for $m = 5$ ($n = 12$) and 146, 130, 122 for $m = 6$ ($n = 13$), as the formula gives; the intake’s search through $m = 8$ agrees and finds the third value also at shapes other than J_m (for example $\{0, 2, 3, 4, 6\}$ at $m = 5$), consistent with the third level being unclassified.

The theorem classifies every set at the second level; it does not classify all sets at the third level. The restriction $m \geq 5$ is necessary for the stated second-level classification. Small-cardinality exceptions are discussed in Subsection II.184.6.

II.184.2 An exact ordered-completion deficit

The following identity turns the energy deficit into a count of specific failed completions. It is also a convenient exact certificate for finite computations.

Proposition II.184.2 (Ordered-completion identity). *For every nonempty finite $A \subset \mathbb{R}$,*

$$D(A) = \#\{(x, y, z) \in A^3 : x < y < z, x + z - y \notin A\}. \quad (\text{II.184.6})$$

In particular $D(A)$ is a nonnegative integer and $E(A) \equiv |A| \pmod{4}$.

Proof. Write $A = \{a_1 < \dots < a_m\}$. For $m \geq 2$, let $B = A \setminus \{a_m\}$, $a = a_m$, and $n = m - 1$. Define

$$T(B, a) = \#\{(x, y, z) \in B^3 : x + y - z = a\}, \quad (\text{II.184.7})$$

$$e(B, a) = \binom{n}{2} - T(B, a). \quad (\text{II.184.8})$$

In every triple counted by $T(B, a)$ one has $x > z$, because $x - z = a - y > 0$. Conversely, a pair $z < x$ in B determines the only possible value $y = a - x + z$. Consequently

$$e(B, a) = \#\{(z, x) \in B^2 : z < x, a - x + z \notin B\} \geq 0. \quad (\text{II.184.9})$$

Count the additive quadruples in A by their occurrences of a . Quadruples with no occurrence contribute $E(B)$. Exactly one occurrence contributes $4T(B, a)$, one copy for each position. If there are exactly two occurrences, one must be on each side of the equation: placing both on the same side would require two smaller numbers to sum to $2a$. The remaining values must agree, giving $4n$ quadruples. Exactly three occurrences are impossible, and four occurrences contribute one. Therefore

$$E(A) = E(B) + 4m - 3 + 4T(B, a). \quad (\text{II.184.10})$$

This endpoint recurrence is also present, in difference-multiplicity notation, in Hegyvári's proof of the congruence modulo four [189, proof of Theorem 2.1].

The elementary identity

$$M_m - M_{m-1} = 4m - 3 + 4 \binom{m-1}{2}$$

now gives

$$D(A) = D(B) + e(B, a). \quad (\text{II.184.11})$$

Starting with a singleton, whose deficit is zero, and iterating proves (II.184.6). Indeed, for $z < x < a$, the completion $a - x + z$ lies strictly between z and a . Its membership in A is therefore equivalent to membership in the prefix preceding a . Finally $M_m \equiv m \pmod{4}$, since $M_m - m = 2m(m-1)(m+1)/3$ is divisible by four. The congruence follows. $\square$

The recurrence admits a useful equality statement.

Lemma II.184.3 (Zero endpoint defect). *Let $B \subset \mathbb{R}$ be finite and nonempty, and let $a > \max B$. Then $e(B, a) = 0$ if and only if $B \cup \{a\}$ is an arithmetic progression.*

Proof. The assertion is immediate for $|B| = 1$, so assume $|B| = n \geq 2$ and translate $\min B$ to zero. Let

$$D^+(B) = \{x - z : x, z \in B, x > z\}.$$

If $e(B, a) = 0$, then $a - d \in B \setminus \{0\}$ for every $d \in D^+(B)$. The exclusion of zero follows from $a - d \geq a - \max B > 0$. Hence $|D^+(B)| \leq n - 1$. The reverse inequality follows from $B \setminus \{0\} \subset D^+(B)$, and thus $D^+(B) = B \setminus \{0\}$.

Let d be the least positive element of B . Whenever $b \in B$ and $b > d$, the difference $b - d$ is again in B . Repeated subtraction must terminate, and a positive terminal value below d is impossible. Thus all elements are integer multiples of d , and all intermediate multiples up to the largest are present. Therefore $B = \{0, d, \dots, (n - 1)d\}$. The containment $a - D^+(B) \subset B \setminus \{0\}$ is between sets of the same size, so it is equality. Comparing their least elements gives $a = nd$. The converse follows directly by completing pairs in a progression. $\square$

Corollary II.184.4 (The classical maximum). *For every nonempty finite real set A , one has $E(A) \leq M_{|A|}$, with equality if and only if A is an arithmetic progression.*

Proof. The inequality follows from Proposition II.184.2. If $|A| \geq 2$ and equality holds, then both nonnegative terms in (II.184.11) vanish, and Lemma II.184.3 makes A a progression. Singletons are progressions as well. Conversely every completion in (II.184.6) succeeds for a progression. $\square$

II.184.3 Appending a point and the sharp first gap

Lemma II.184.5 (Appending a point to a progression). *Let $B = \{0, d, \dots, (n - 1)d\}$, where $d > 0$ and $n \geq 2$, and let $a > (n - 1)d$. If a/d is not an integer, then $T(B, a) = 0$. If $a = qd$ for an integer $q \geq n$, then*

$$T(B, a) = \sum_{h=\max\{1, q-n+1\}}^{n-1} (n - h), \quad (\text{II.184.12})$$

where an empty sum is zero. Consequently, if $B \cup \{a\}$ is not a progression, then $e(B, a) \geq n - 1$. For $n \geq 3$, equality in this last bound occurs precisely when $a = (n + 1)d$. If $n \geq 4$ and a is neither nd nor $(n + 1)d$, then

$$e(B, a) \geq 2n - 3. \quad (\text{II.184.13})$$

Proof. All values of $x + y - z$ on B^3 are integer multiples of d . For $a = qd$, a positive difference $hd = x - z$ has exactly $n - h$ representations in B , and its associated completion belongs to B exactly when $0 \leq q - h \leq n - 1$. This proves (II.184.12).

At $q = n$ the sum is $\binom{n}{2}$. For $q \geq n + 1$ it is at most $\binom{n-1}{2}$, attained only at $q = n + 1$ when $n \geq 3$. If a/d is not an integer, then $e(B, a) = \binom{n}{2} \geq n - 1$; this inequality is strict for $n \geq 3$. For $q \geq n + 2$, the sum is at most $\binom{n-2}{2}$, so the deficit is at least $2n - 3$. The nonintegral case also satisfies this bound because $\binom{n}{2} \geq 2n - 3$ for $n \geq 4$. $\square$

Theorem II.184.6 (Sharp first gap). *If $A \subset \mathbb{R}$ has $m \geq 3$ elements and is not an arithmetic progression, then*

$$D(A) \geq m - 2, \quad E(A) \leq M_m - 4(m - 2). \quad (\text{II.184.14})$$

Equality is attained by H_m .

Proof. For $m = 3$, remove the largest point. The remaining two-point set is an AP, and Lemma II.184.5 gives $D(A) = 1$ unless A is an AP. Now induct on m . Write $B = A \setminus \{\max A\}$. If B is an AP, Lemma II.184.5 gives $D(A) = e(B, \max A) \geq m - 2$. Otherwise the induction hypothesis gives $D(B) \geq m - 3$, and Lemma II.184.3 gives $e(B, \max A) \geq 1$. Their sum is at least $m - 2$. For H_m , append m to $\{0, \dots, m - 2\}$ and use the equality case in Lemma II.184.5. $\square$

Remark II.184.7 (Why the first gap is a consequence of earlier work). We record the precise relationship to inverse Pollard, so that the elementary proof above is not mistaken for an assertion of novelty of the bound. For an integer set A of size m , let

$$r_A(d) = |A \cap (A + d)|, \quad S_t(A) = \sum_d \min\{t, r_A(d)\}.$$

Embed A in a sufficiently large prime cyclic group, with no new two-sum equalities. Pollard's inequality gives $S_t(A) \geq t(2m - t)$. For $2 \leq t \leq m - 2$, the equality classification in [190, Theorem 3] says that a non-AP A gives strict inequality: none of the exceptional endpoint cases applies to $(A, -A)$. At $t = 1$, use the classical equality case in $|A - A| \geq 2m - 1$, or the recalled Vosper theorem in [190, Theorem 1]. A cyclic AP in these equality cases pulls back to an integer AP, using its consecutive three-term relations.

Symmetry $r_A(d) = r_A(-d)$ and $r_A(0) = m$ show that $S_t(A)$ has parity t , as does $t(2m - t)$. Thus each of these $m - 2$ strict inequalities improves by at least two. The layer-cake identity

$$E(A) = (2m - 1)m^2 - 2 \sum_{t=1}^{m-1} S_t(A)$$

then gives $M_m - E(A) \geq 4(m - 2)$. This is the first-gap bound. Hegyvári's formula for $\{1, \dots, m - 1, m + k\}$ already gives the extremal example at $k = 1$ [189, Section 2.1].

For a finite set in a torsion-free abelian group, identify its generated subgroup with $\mathbb{Z}^r$ and choose an integer linear functional avoiding the finitely many nonzero differences of its pair sums. Its restriction is a Freiman 2-isomorphism to an integer set. It preserves energy and the non-AP condition: an AP in the image pulls back using consecutive three-term relations. Thus the same prior implication covers real sets and general torsion-free sets.

II.184.4 A unit deficit in the positive Schur-triple problem

The next classification provides information that the numerical first gap alone does not supply. Positivity is essential here; we count ordered Schur triples with repeated entries allowed.

Lemma II.184.8 (Exactly one missing Schur triple). *Let $C = \{c_1 < \dots < c_n\} \subset (0, \infty)$, and put*

$$S(C) = \#\{(x, y, z) \in C^3 : x + y = z\}, \quad h(C) = \binom{n}{2} - S(C).$$

Then $h(C) \geq 0$, with equality precisely when $C = d\{1, 2, \dots, n\}$ for some $d > 0$. If $n \geq 4$, then

$$h(C) = 1 \iff C = d\{1, 2, \dots, n - 1, n + 1\} \quad (d > 0). \quad (\text{II.184.15})$$

Proof. Let r_j be the number of ordered representations $x + y = c_j$ in C . Both summands precede c_j , and each of the $j - 1$ possible first summands determines the second. Therefore

$$h(C) = \sum_{j=1}^n (j - 1 - r_j), \quad j - 1 - r_j \geq 0. \quad (\text{II.184.16})$$

Equality $r_j = j - 1$ says exactly that the prefix $\{c_1, \dots, c_{j-1}\}$ is invariant under the reflection $x \mapsto c_j - x$. If this holds at every index, induction gives $c_j = jd$, with $d = c_1$. This proves the zero-deficit assertion.

Suppose now that $h(C) = 1$. There is a unique deficient index k , whose contribution in (II.184.16) is one. Before that index, $c_i = id$. Necessarily $k \geq 2$.

First suppose $k \geq 3$. We have $r_k = k - 2 \geq 1$, so $c_k = qd$ for an integer $q \geq k$. The case $q = k$ has zero deficit and is excluded. For $k \leq q \leq 2k - 2$, the number of ordered pairs in $\{1, \dots, k - 1\}^2$ summing to q is $2k - 1 - q$; above this range it is zero. The equality $r_k = k - 2$ therefore forces $q = k + 1$. If $k < n$, zero deficit at the next index would require the prefix

$$\{d, 2d, \dots, (k - 1)d, (k + 1)d\}$$

to be invariant under reflection about $c_{k+1}/2$. Comparing its least and greatest elements gives $c_{k+1} = (k + 2)d$. But that reflection sends the present element $2d$ to the absent element kd , a contradiction. Thus $k = n$, giving the displayed model.

It remains to rule out $k = 2$. Here $c_2 \neq 2d$. Since $n \geq 4$, zero deficit at index three gives $c_3 = d + c_2$. Zero deficit at index four requires the three-point prefix $\{d, c_2, d + c_2\}$ to be centrally symmetric. Its middle point must be its center, so

$$2c_2 = d + (d + c_2),$$

forcing $c_2 = 2d$, a contradiction. Conversely, the model in (II.184.15) has $r_j = j - 1$ for $j < n$ and $r_n = n - 2$, and hence has deficit one. $\square$

Corollary II.184.9 (Unit endpoint defect). *Let $B \subset \mathbb{R}$ have $n \geq 4$ elements and $a > \max B$. If $e(B, a) = 1$, then $B \cup \{a\}$ is an affine image of L_{n+1} . More precisely, after translating $\min B$ to zero, there is a $d > 0$ such that*

$$a = (n + 1)d, \quad B = \{0, 2d, 3d, \dots, nd\}.$$

Proof. Set $C = a - B \subset (0, \infty)$. The bijection $(x, y, z) \mapsto (a - x, a - y, a - z)$ sends the equation $x + y - z = a$ to the Schur equation $(a - x) + (a - y) = a - z$. Thus $e(B, a) = h(C)$. Apply Lemma II.184.8. Once $\min B = 0$, the maximum of C is a , so its classified form gives exactly the stated values. $\square$

II.184.5 The second and third levels

Theorem II.184.10 (All second-level sets). *Let $A \subset \mathbb{R}$ have $m \geq 5$ elements. Then*

$$D(A) = m - 2 \iff A \text{ is an affine image of } H_m.$$

Proof. The models attain the value by Theorem II.184.6. Conversely, write $B = A \setminus \{a\}$, with $a = \max A$. If B is an AP, the equality statement in Lemma II.184.5 gives an affine image of H_m . If B is not an AP, then Theorem II.184.6 and Lemma II.184.3 give

$$D(B) \geq m - 3, \quad e(B, a) \geq 1.$$

Their sum is $m - 2$, so $e(B, a) = 1$. Since $|B| = m - 1 \geq 4$, Corollary II.184.9 applies and makes A an affine image of L_m , hence a reflected affine image of H_m . $\square$

Theorem II.184.11 (The sharp third gap). *If $m \geq 5$ and an m -element real set A is neither an AP nor an affine image of H_m , then $D(A) \geq 2m - 6$.*

Proof. Call the APs and the affine images of H_m the first two classes. For $m = 5$, Theorems II.184.6 and II.184.10 give $D(A) > 3$ outside those classes. Integrality then gives $D(A) \geq 4 = 2m - 6$.

Assume $m \geq 6$, put $n = m - 1$, and again let $B = A \setminus \{a\}$, $a = \max A$. There are three cases.

If B is an AP, normalize it as $\{0, 1, \dots, n - 1\}$. The values $a = n$ and $a = n + 1$ would put A in the first two classes. All other values satisfy $e(B, a) \geq 2n - 3$ by Lemma II.184.5, which is stronger than the desired $2n - 4 = 2m - 6$.

If B is a second-level set, normalize it by a translation and a positive dilation to either

$$B = H_n = \{0, 1, \dots, n - 2, n\} \quad \text{or} \quad B = L_n = \{0, 2, 3, \dots, n\}.$$

In both cases $D(B) = n - 2$, and the difference one has multiplicity $n - 2$. If a is nonintegral, every positive-difference completion $a - h$ is nonintegral, so $e(B, a) = \binom{n}{2} \geq n - 2$. If a is an integer at least $n + 2$, all the difference-one completions exceed $\max B$, again giving $e(B, a) \geq n - 2$. For the remaining value $a = n + 1$, the model L_n would extend to L_{n+1} and is excluded by the hypothesis on A . In the model H_n , difference two has multiplicity $n - 2$ and completion $n - 1$, which is absent. Thus $e(B, a) \geq n - 2$ in every admissible case, and $D(A) \geq 2n - 4$.

Finally, suppose B belongs to neither of the first two classes. Induction gives $D(B) \geq 2n - 6$. Endpoint defect zero would force A to be an AP by Lemma II.184.3, and endpoint defect one would force A into the second class by Corollary II.184.9. Hence $e(B, a) \geq 2$, and $D(A) \geq (2n - 6) + 2 = 2m - 6$. $\square$

Sharpness follows from the next exact formula, which also exhibits more of the energy spectrum near an interval.

Proposition II.184.12 (Deleting one point from an interval). *Let $m \geq 2$ and $1 \leq j \leq m - 1$. Then*

$$D(\{0, 1, \dots, m\} \setminus \{j\}) = j(m - j) - \min\{j, m - j\}. \quad (\text{II.184.17})$$

Proof. Put $A = \{0, 1, \dots, m\} \setminus \{j\}$. For $x < y < z$ in A , the completion $x + z - y$ lies in $[0, m]$, so it fails to belong to A precisely when it equals j . Solving for the middle element gives $y = x + z - j$. The strict inequalities $x < y < z$ are equivalent to $x < j < z$. There are $j(m - j)$ choices

$$0 \leq x \leq j - 1, \quad j + 1 \leq z \leq m.$$

Their determined middle value belongs to A except when $y = j$, or equivalently $x + z = 2j$. The excluded pairs are exactly $(j - t, j + t)$ with $1 \leq t \leq \min\{j, m - j\}$. Apply Proposition II.184.2 to finish the count. $\square$

At $j = 1$ the formula gives $D = m - 2$. At $j = 2$ and $m \geq 5$ it gives $D = 2m - 6$. In the latter model the unique gap of size two is interior, with a unit gap on each side, whereas in H_m and L_m that gap is first or last. Thus it belongs to neither of the first two classes. Since $0 < m - 2 < 2m - 6$ for $m \geq 5$, the bounds and examples prove (II.184.4) over $\mathbb{R}$.

II.184.6 Transfer, exact rigidity, and limitations

Proposition II.184.13 (Torsion-free transfer). *Theorems II.184.1, II.184.6, II.184.10, and II.184.11 hold for finite subsets of every torsion-free abelian group.*

Proof. The subgroup generated by a finite set A is a finitely generated torsion-free abelian group, hence isomorphic to $\mathbb{Z}^r$ for some finite r . Choose r real numbers linearly independent over $\mathbb{Q}$. They define an injective additive map $\mathbb{Z}^r \rightarrow \mathbb{R}$. This map preserves all additive quadruples, and hence $E(A)$ and $D(A)$.

It also preserves the stated equality classes in both directions. For an image AP, the common real step is the image of the difference between two consecutive points. Its relations pull back by injectivity. For an image of H_m or L_m with $m \geq 5$, there are adjacent model points separated by the unit step. Their preimages again supply an actual group element as the step, and injectivity pulls back every listed model point. The real theorems therefore give the asserted group theorems. Conversely, every nontrivial torsion-free abelian group contains an infinite cyclic subgroup, in which all the displayed models can be realized. $\square$

Corollary II.184.14 (An exact rigidity window). *Let A have $m \geq 5$ elements in a torsion-free abelian group. If*

$$E(A) > M_m - 8(m - 3),$$

then A is an AP or an affine image of H_m . In the latter case, deleting one point leaves an $(m - 1)$ -term AP. The strict energy threshold cannot be weakened to a non-strict one.

Proof. Apply Theorem II.184.11; remove the isolated end point in the H_m model. The single-hole model with $j = 2$ attains the threshold and belongs to neither permitted class. $\square$

For $m = 3$, every non-AP triple has energy $15 = M_3 - 4$; the two consecutive gaps can have any unequal ratio. For $m = 4$, the second-level classification also has extra families. For example, $\{0, 1, 4, 5\}$ has energy $36 = M_4 - 8$, but is not an affine image of H_4 . These examples explain why the equality classification and the three-level theorem start at $m = 5$.

The torsion-free assumption must be retained. A finite subgroup of size m has energy m^3 , exceeding M_m when $m > 1$. For a subset of a finite cyclic group, the conclusions are available only after an explicit *rectification*: a Freiman isomorphism of order two to a torsion-free set, preserving both directions of all two-sum relations. Merely choosing integer representatives does not establish such an isomorphism, because modular wraparound may create additional quadruples. This distinction is particularly relevant to Gowers's argument, which passes between integers and cyclic groups.

Finally, the window here has absolute width $O(m)$ around a quantity of order m^3 . Its relative width is therefore $O(m^{-2})$. It supplies exact rigidity at a fine discrete scale; it does not supply a constant-error near-extremizer theorem or a better global bound in Szemerédi's theorem. Shao's work addresses a different structural scale, obtaining large pieces in progressions of controlled rank from normalized energy inequalities [191]. The two types of result are complementary: the present arguments resolve exact finite energy levels and equality geometry close to Gowers's classical Section 7 endpoint.

II.185 A larger coset-stability range and the geometry of equality

Source 45, delivered Section 3.

The additive-energy endpoint relevant to Gowers's inverse and arrangement arguments is a subgroup coset. Quantitative information near that endpoint is useful only when it controls both the ambient approximation and the geometry of its errors. Source 14 of the existing repository report proves the sharp quadratic coset envelope below for defect at most $1/100$ (its delivered Theorem 4.2); its Question 4 asks for a larger validity range and for all equality cases. Source 15 subsequently develops collision-sensitive arrangement amplification and equality theory, while retaining that small-defect range. We use those results as the local comparison, and credit their envelope and collision framework [202]. Their place in the original argument is the energy and arrangement machinery of Gowers's proof [1].

This section extends the same envelope to defect strictly below $1/9$, constructs its subgroup directly from autocorrelation, and classifies every case of equality in that range. An exact remainder measures two separate obstructions to equality: points outside the closest coset, and the additive-energy defect of the missing points inside it. This also gives a quantitative approximation by a coset with a subcoset removed. Finally, for axis-cube collisions, equality forces the removed coset to occur in a single coordinate. The range $1/9$ is a proved sufficient range; its optimality is not asserted.

II.185.1 Autocorrelation and an intrinsic subgroup

Throughout this section, G is an abelian group and $A \subset G$ is finite and nonempty. The ambient group need not be finite. Write

$$m = |A|, \quad r(d) = |A \cap (A + d)|, \quad E(A) = \sum_{d \in G} r(d)^2, \quad \varepsilon = 1 - \frac{E(A)}{m^3}. \quad (\text{II.185.1})$$

Thus $E(A)$ is the number of ordered additive quadruples in A . All sums involving r have finite support. The number ε in (II.185.1) is the *actual* energy defect. An externally supplied upper bound for it will be denoted by ε_0 .

For a finite subgroup coset C of G , put $d_C(A) = |A \Delta C|$, where Δ denotes symmetric difference. We use the normalized distance

$$\delta(A) = \frac{1}{m} \min_C d_C(A). \quad (\text{II.185.2})$$

The minimum exists: singleton cosets provide a nonempty collection of finite, nonnegative integer distances. Only finite cosets need to be considered; an infinite coset has infinite symmetric difference with A . Set $E(\emptyset) = 0$ when an auxiliary missing set is empty.

The elementary identities

$$\sum_d r(d) = m^2, \quad m^3 - E(A) = \sum_{a,b \in A} (m - r(a - b)) \quad (\text{II.185.3})$$

will be used repeatedly. The second follows by grouping the ordered pairs (a, b) according to their difference. We also have

$$r(u - v) \geq r(u) + r(v) - m. \quad (\text{II.185.4})$$

Indeed, the subsets $A \cap (A + u)$ and $A \cap (A + v)$ of A have intersection of size at least $r(u) + r(v) - m$; translation of their intersection injects into a translate of the overlap counted by $r(u - v)$.

Lemma II.185.1 (A pointwise autocorrelation gap). *For every $d \in G$,*

$$\frac{r(d)}{m} \left(1 - \frac{r(d)}{m}\right) \leq 2\varepsilon. \quad (\text{II.185.5})$$

Proof. Let $I = \{x \in A : x + d \in A\}$, so $|I| = r(d)$. For $x \in I$ and $b \in A$, inequality (II.185.4), applied to $x - b$ and $x + d - b$, gives

$$m - r(d) \leq (m - r(x - b)) + (m - r(x + d - b)).$$

Sum over $I \times A$. The first sum on the right is bounded by $m^3 - E(A)$ because $I \subset A$, and the second has the same bound because $I + d \subset A$. Consequently

$$m r(d)(m - r(d)) \leq 2(m^3 - E(A)).$$

Division by m^3 proves the claim. $\square$

Lemma II.185.2 (Canonical subgroup and preliminary approximation). *Suppose $0 \leq \varepsilon < 1/9$, and define*

$$a = \frac{1 - \sqrt{1 - 8\varepsilon}}{2}, \quad H = \{d \in G : r(d) > m/2\}. \quad (\text{II.185.6})$$

Then H is a finite subgroup. There is a unique H -coset C containing more than $5m/6$ points of A . If

$$t = |A \setminus C|, \quad u = |C \setminus A|, \quad x = \frac{t}{m}, \quad \delta = \frac{t+u}{m}, \quad h = |H|, \quad (\text{II.185.7})$$

then

$$0 \leq x \leq \frac{a}{2} < \frac{1}{6}, \quad \delta \leq \frac{a - 2ax + 2x^2}{1 - a} \leq \frac{a}{1 - a} < \frac{1}{2}. \quad (\text{II.185.8})$$

Proof. The parameter a lies in $[0, 1/3)$ and satisfies $\varepsilon = a(1 - a)/2$. Lemma II.185.1 gives the dichotomy

$$\frac{r(d)}{m} \leq a \quad \text{or} \quad \frac{r(d)}{m} \geq 1 - a \quad (d \in G). \quad (\text{II.185.9})$$

Thus H consists precisely of the differences on the upper branch. It contains zero and is finite, since it is contained in $A - A$. If $d, e \in H$, then

$$\frac{r(d - e)}{m} \geq 1 - 2a > a.$$

The dichotomy forces $d - e \in H$. A nonempty finite set closed under differences is a subgroup.

Let n_j be the sizes of the intersections of A with the distinct H -cosets, including only the nonempty intersections, and write $S = \sum_j n_j^2$. Counting pairs whose difference lies in H gives $S = \sum_{d \in H} r(d)$. On H , we use $r(d)^2 \leq mr(d)$; off H , the lower branch gives $r(d)^2 \leq amr(d)$. Hence

$$(1 - \varepsilon)m^3 = E(A) \leq mS + am(m^2 - S),$$

and therefore

$$\frac{S}{m^2} \geq 1 - \frac{\varepsilon}{1 - a} = 1 - \frac{a}{2}. \quad (\text{II.185.10})$$

Because $\sum_j n_j/m = 1$,

$$\max_j \frac{n_j}{m} \geq \sum_j \left(\frac{n_j}{m}\right)^2 = \frac{S}{m^2}.$$

Choose the maximizing coset C . It contains at least $(1 - a/2)m > 5m/6$ points of A , so it is unique, and $x \leq a/2$.

The upper branch on H and the concentration in C also give

$$h(1 - a)m \leq S \leq (m - t)^2 + t^2.$$

For the second inequality, the sum of the squares of the remaining coset occupancies is at most the square of their sum t . Since $h/m = 1 + \delta - 2x$, rearrangement yields

$$\delta \leq \frac{a - 2ax + 2x^2}{1 - a}.$$

Here $0 \leq x \leq a/2 \leq a$, so $-2ax + 2x^2 \leq 0$. Finally $a < 1/3$ gives $a/(1 - a) < 1/2$. $\square$

II.185.2 An exact remainder around a coset

The next estimate is independent of the preceding construction. It separates the points outside a proposed coset from the points missing inside it, and retains the energy of the latter set.

Proposition II.185.3 (The outlier and missing-set remainder). *Let $C = c + H$ be any finite subgroup coset, and put*

$$A_0 = A \cap C, \quad T = A \setminus C, \quad K = C \setminus A, \quad b = |A_0|, \quad t = |T|, \quad u = |K|.$$

With $x = t/m$ and $\delta = (t + u)/m$, one has

$$E(A) \leq E(A_0) + 6bt^2 + 5t^3, \tag{II.185.11}$$

$$E(A_0) = b^3 - bu(b - u) - (u^3 - E(K)), \tag{II.185.12}$$

and consequently

$$\varepsilon \geq \delta(1 - \delta) + x(2 + \delta^2 - (8 + \delta)x + 2x^2) + \frac{u^3 - E(K)}{m^3}. \tag{II.185.13}$$

The coefficient of x in (II.185.13) is not asserted nonnegative for an arbitrary proposed coset.

Proof. An additive quadruple in A cannot have exactly one entry outside C : three entries in a subgroup coset force the fourth into that same coset. Quadruples with no entries in T contribute $E(A_0)$. For exactly two entries in T , there are six choices of their positions. After their values and one of the two inside values have been fixed, the final value is determined. These cases therefore contribute at most $6bt^2$. Exactly three entries in T contribute at most $4t^3$, and four entries contribute $E(T) \leq t^3$. This proves (II.185.11).

For (II.185.12), translate C to H and write $h = |H| = b + u$. Expanding the four factors of $\mathbf{1}_{A_0} = \mathbf{1}_H - \mathbf{1}_K$ in the additive-quadruple count gives

$$E(A_0) = h^3 - 4h^2u + 6hu^2 - 4u^3 + E(K).$$

For example, a term with two prescribed entries in K and two in H has hu^2 solutions: one H -entry is free and the last is determined in H . The other mixed terms are counted in the same way, regardless of the positions of the entries. Substitution of $h = b + u$ gives (II.185.12).

Finally combine the two estimates, use $b/m = 1 - x$ and $u/m = \delta - x$, and expand:

$$\begin{aligned} \frac{m^3 - E(A)}{m^3} &\geq 1 - (1 - x)^3 + (1 - x)(\delta - x)(1 - \delta) - 6(1 - x)x^2 - 5x^3 + \frac{u^3 - E(K)}{m^3} \\ &= \delta(1 - \delta) + x(2 + \delta^2 - (8 + \delta)x + 2x^2) + \frac{u^3 - E(K)}{m^3}. \end{aligned}$$

This is (II.185.13). □

II.185.3 The sharp envelope up to defect 1/9

For $0 \leq z \leq 1/4$, define

$$\tau(z) = \frac{1 - \sqrt{1 - 4z}}{2}, \quad \tau(z)(1 - \tau(z)) = z. \quad (\text{II.185.14})$$

Theorem II.185.4 (Expanded range of the quadratic coset envelope). *If $E(A) > 8m^3/9$, there is a unique finite subgroup coset C minimizing $|A\Delta C|$, and*

$$|A\Delta C| \leq \tau(\varepsilon)m. \quad (\text{II.185.15})$$

Its subgroup is the canonical set $H = \{d : r(d) > m/2\}$, and C is the unique H -coset containing more than half of A .

Proof. Use the coset and parameters of Lemma II.185.2. Define

$$F(\delta, x) = 2 + \delta^2 - (8 + \delta)x + 2x^2.$$

Since $x \leq \delta$ and $x < 1/6$, its derivative in δ is $2\delta - x \geq 0$, and therefore

$$F(\delta, x) \geq F(x, x) = 2 - 8x + 2x^2 > \frac{13}{18} > 0.$$

The last strict inequality follows because the quadratic decreases on $[0, 1/6]$ and takes the value $13/18$ at $1/6$. The missing-set defect $u^3 - E(K)$ is nonnegative. Hence Proposition II.185.3 gives $\delta(1 - \delta) \leq \varepsilon$. As $\delta < 1/2$, the increasing branch of this quadratic can be inverted, yielding $\delta \leq \tau(\varepsilon)$.

It remains to prove uniqueness among all finite subgroup cosets, not merely among H -cosets. Put $\tau = \tau(\varepsilon)$. We have

$$\tau < \tau(1/9) = \frac{3 - \sqrt{5}}{6} < \frac{1}{5}. \quad (\text{II.185.16})$$

Suppose that two cosets C, C' both have symmetric-difference distance at most τm from A . Then

$$|C \cap C'| \geq (1 - 2\tau)m, \quad |C|, |C'| \leq (1 + \tau)m.$$

Their intersection is larger than half of either coset, because $1 - 2\tau > (1 + \tau)/2$. A nonempty intersection of subgroup cosets is a coset of the intersection of their subgroups. Its index in either subgroup is a positive integer, so an intersection larger than half forces both indices to equal one. The subgroups, and then the cosets, coincide. Any coset closer to A than the constructed C would also satisfy the same τ -bound. This proves unique global minimality. The intrinsic description follows from Lemma II.185.2. □

[write] **7 October 2026; sources 40–46.** *Against source 14* (checked at the write). Source 14's Theorem II.43.2 proves the same envelope and uniqueness for $\varepsilon \leq 1/100$; here the range is $\varepsilon < 1/9$ ($\tau(1/9) = 0.1273$ against $\tau(1/100) = 0.0101$). Equality example recomputed exactly: $A = \mathbb{Z}/36\mathbb{Z} \setminus \{0, 9, 18, 27\}$ has $m = 32$, $E(A) = 29,184$, $\varepsilon = 7/64$ and $|A\Delta(\mathbb{Z}/36\mathbb{Z})|/m = 1/8 = \tau(7/64)$. The equality cases (Theorem II.185.8) are the punctured cosets of the intake observation at item II.31, which advances source 14's Question 4.

Corollary II.185.5 (A supplied upper bound for the defect). *If $0 \leq \varepsilon_0 < 1/9$ and $E(A) \geq (1-\varepsilon_0)m^3$, the same canonical closest coset satisfies*

$$|A\Delta C| \leq \tau(\varepsilon_0)m.$$

Proof. The actual defect satisfies $0 \leq \varepsilon \leq \varepsilon_0$. Apply Theorem II.185.4 and the monotonicity of τ . $\square$

Remark II.185.6 (What changes from the existing result). The function τ and its sharp small-defect interpretation are credited to source 14 [202]. The subgroup construction in Lemma II.185.2 replaces its preliminary small-difference-set argument, and makes the same envelope valid throughout $0 \leq \varepsilon < 1/9$. Neither this theorem nor the comparison claims that $1/9$ is the optimal endpoint. The statements also hold for finite sets in infinite abelian groups, since their canonical subgroup is contained in the finite set $A - A$.

II.185.4 Every exact envelope extremizer

From now on, C is the unique closest coset from Theorem II.185.4, and $\delta = \delta(A) = |A\Delta C|/m$. Keep x, t, u, K as in (II.185.7), and define the excess over the quadratic envelope by

$$\eta = \varepsilon - \delta(1 - \delta). \quad (\text{II.185.17})$$

Proposition II.185.7 (A structural remainder above the envelope). *If $\varepsilon < 1/9$, then*

$$\eta \geq (2 - 8\delta + 2\delta^2)x + \frac{u^3 - E(K)}{m^3} \geq x + \frac{u^3 - E(K)}{m^3}. \quad (\text{II.185.18})$$

Proof. For $0 \leq x \leq \delta < 1/5$, the polynomial $F(\delta, x)$ in the proof of Theorem II.185.4 decreases in x : its derivative is $-(8 + \delta) + 4x < 0$. Thus

$$F(\delta, x) \geq F(\delta, \delta) = 2 - 8\delta + 2\delta^2.$$

Insert this in (II.185.13). The last coefficient is itself decreasing on the relevant interval, and

$$2 - 8\tau(1/9) + 2\tau(1/9)^2 = \sqrt{5} - \frac{11}{9} > 1.$$

Since $\delta \leq \tau(\varepsilon) < \tau(1/9)$, the second inequality follows. $\square$

Theorem II.185.8 (All equality cases in the quadratic envelope). *Suppose $\varepsilon < 1/9$. Equality*

$$\delta(A) = \tau(\varepsilon) \quad (\text{II.185.19})$$

holds precisely in the following cases:

1. *A is a finite subgroup coset, and $\varepsilon = 0$;*

2. $A = C \setminus K$, where $C = c + H$ is a finite subgroup coset, K is a coset of a subgroup $L \leq H$ contained in C , and $r = [H : L] \geq 9$.

In the second case,

$$\delta(A) = \frac{1}{r-1}, \quad \varepsilon = \frac{r-2}{(r-1)^2}, \quad (\text{II.185.20})$$

and C is the unique closest coset.

Proof. Condition (II.185.19) is equivalent to $\eta = 0$. Proposition II.185.7 forces $x = 0$ and $E(K) = u^3$. Thus $A \subset C$. If $u = 0$, then $A = C$. If $u > 0$, maximal energy says that every ordered triple $x, y, z \in K$ satisfies $x - y + z \in K$. Translate one point of K to zero. The resulting finite set contains zero and is closed under negation and addition, hence is a subgroup L . Therefore K is a coset of L inside C . Writing $r = [H : L]$, we obtain $u = |L|$, $m = (r-1)|L|$, and $\delta = 1/(r-1)$. The strict inequality $\delta < \tau(1/9)$ implies $r \geq 9$.

Conversely, let $A = C \setminus K$ with the stated index. Since $E(K) = u^3$, identity (II.185.12) gives

$$m^3 - E(A) = mu(m - u).$$

Consequently $\varepsilon = \delta_0(1 - \delta_0)$ with $\delta_0 = u/m = 1/(r-1)$. For $r \geq 9$ this defect is less than $1/9$ and $\delta_0 < 1/2$, so $\delta_0 = \tau(\varepsilon)$. The displayed coset C satisfies the envelope bound with equality. The uniqueness part of Theorem II.185.4 identifies it with the closest coset, proving the converse and (II.185.20). $\square$

Corollary II.185.9 (The discrete equality parameters). *Across all finite abelian groups, the nonzero equality defects in the range $\varepsilon < 1/9$ are exactly*

$$\left\{ \frac{r-2}{(r-1)^2} : r \in \mathbb{N}, r \geq 9 \right\}.$$

In a fixed ambient group only indices of its finite subgroup inclusions can occur. In $\mathbb{F}_p^n$ the admissible indices are $r = p^j \geq 9$, with $1 \leq j \leq n$. In a prime cyclic group the nontrivial examples in this range are complements of one point, for $p \geq 11$.

Proof. Necessity follows from Theorem II.185.8. Every integer $r \geq 9$ is realized by a cyclic group H of order r with $L = \{0\}$. The remaining assertions follow from the possible subgroup indices in the indicated groups. $\square$

Remark II.185.10. The missing-subcoset examples already appear in a write note adjoining source 14's Question 4 [202]. Theorem II.185.8 proves that they exhaust equality in the enlarged range. In particular, sharpness of the function τ does not mean equality is attainable at every real defect parameter. Equality in Corollary II.185.5, with a supplied bound ε_0 , additionally forces the actual defect to equal ε_0 , by the strict monotonicity of τ .

II.185.5 Stability of the punctured-coset extremizers

The exact remainder controls the outliers and the missing-set defect through a common budget. Applying the coset envelope to the missing set, while keeping that budget intact, gives a second sharp envelope for repair. The relevant parameter is η/δ^3 , because the missing set has size approximately δm and energy scale $(\delta m)^3$.

Theorem II.185.11 (The nested-hole envelope and all equality cases). *Suppose $\varepsilon < 1/9$, $\delta = \delta(A) > 0$, and*

$$0 \leq s = \frac{\eta}{\delta^3} < \frac{1}{9}, \quad \eta = \varepsilon - \delta(1 - \delta). \quad (\text{II.185.21})$$

Let C be the canonical closest coset and $K = C \setminus A$. There is a unique closest subgroup coset D to K ; it is a nonempty proper subcoset of C . This same D minimizes the repair inside the fixed outer coset C . Write

$$\Delta_C(A) = \frac{1}{m} \min_{\substack{D' \subsetneq C \\ D' \text{ a nonempty subgroup coset}}} |A \Delta(C \setminus D')|.$$

If $s > 0$, then

$$\Delta_C(A) \leq \delta \tau(s) = \frac{\tau(s)}{s} \frac{\eta}{\delta^2} \leq (1 + 2s) \frac{\eta}{\delta^2}. \quad (\text{II.185.22})$$

Equality in the first bound holds precisely when

$$A = C \setminus (D \setminus J) = (C \setminus D) \cup J, \quad (\text{II.185.23})$$

where $J \subsetneq D \subsetneq C$ are nonempty subgroup cosets and the index of the subgroup underlying J in that underlying D is at least nine. The assertion fixes the canonical outer coset C . If $s = 0$, then $A = C \setminus D$ and $\Delta_C(A) = 0$.

Proof. Keep $x = |A \setminus C|/m$ and put $k = |K|/m = \delta - x$. The coupled remainder (II.185.18) gives $x \leq \eta = s\delta^3 < \delta$, so $k > 0$ and K is nonempty. Define its actual defect by $\zeta = 1 - E(K)/|K|^3$. The same remainder states that

$$\eta \geq x + k^3 \zeta. \quad (\text{II.185.24})$$

To control the full interval of possible outlier masses, define

$$z(y) = \frac{\eta - y}{(\delta - y)^3} \quad (0 \leq y \leq \eta).$$

Its denominator is positive, and

$$z'(y) = \frac{-\delta + 3\eta - 2y}{(\delta - y)^4} < 0,$$

where $3\eta = 3s\delta^3 < \delta/3$ uses $s < 1/9$ and $\delta < 1$. Thus $0 \leq z(y) \leq z(0) = s < 1/9$ throughout the interval. In particular (II.185.24) gives $0 \leq \zeta \leq z(x) < 1/9$.

Apply Theorem II.185.4 to K inside C , after translating C to its finite subgroup. There is a closest subcoset $D \subset C$ with

$$|K \Delta D| \leq \tau(\zeta)|K|. \quad (\text{II.185.25})$$

The ambient version of the same theorem makes D the unique closest coset even among those not contained in C . Moreover $|K| \leq \delta m < m/5$, so

$$|D| \leq (1 + \tau(\zeta))|K| < \frac{5}{4}|K| < \frac{m}{4}, \quad |C| \geq (1 - \delta)m > \frac{4m}{5}.$$

Hence D is proper. The outliers are disjoint from both sets inside C , giving

$$\Delta_C(A) = x + \frac{|K \Delta D|}{m} \leq x + k\tau(\zeta) \leq x + (\delta - x)\tau(z(x)). \quad (\text{II.185.26})$$

The equality on the left also proves the asserted minimization property of D .

Suppose $s > 0$ and define

$$F(y) = y + (\delta - y)\tau(z(y)) \quad (0 \leq y \leq \eta).$$

Write $k_y = \delta - y$ and $b_y = \tau(z(y))$. Then $0 \leq b_y < 1/2$ and $b_y(1 - b_y) = (\eta - y)/k_y^3$. Differentiating gives

$$\begin{aligned} F'(y) &= 1 - b_y + \frac{-k_y^{-2} + 3b_y(1 - b_y)}{1 - 2b_y} \\ &= \frac{1 - b_y^2 - k_y^{-2}}{1 - 2b_y} < 0, \end{aligned}$$

because $0 < k_y \leq \delta < \tau(1/9) < 1$. Thus (II.185.26) implies $\Delta_C(A) \leq F(x) \leq F(0) = \delta\tau(s)$. For the simpler estimate, put $b = \tau(s) < \tau(1/9) < 1/4$. Then

$$\frac{\tau(s)}{s} = \frac{1}{1 - b} = 1 + \frac{s}{(1 - b)^2} \leq 1 + \frac{16}{9}s \leq 1 + 2s.$$

When $s = 0$, Theorem II.185.8 gives the exact punctured-coset representation, with no division by s required.

Suppose next that $s > 0$ and equality holds in the first bound. Strict decrease of F forces $x = 0$, so $A \subset C$ and $k = \delta$. The exact complement identity now gives $\eta = \delta^3\zeta$, hence $\zeta = s$. Equality in (II.185.26) therefore requires

$$\frac{|K \triangle D|}{|K|} = \tau(\zeta).$$

The positive-defect equality classification in Theorem II.185.8, applied to K , says exactly that $K = D \setminus J$, where J is a nonempty subcoset of D and its underlying subgroup has index at least nine. This is (II.185.23). Conversely, under the theorem's hypotheses, such a representation makes D the unique closest coset to K by the same inner equality classification. The complement identity gives $\zeta = s$, and

$$\Delta_C(A) = \frac{|K \triangle D|}{m} = \delta\tau(s),$$

proving sufficiency as well. No minimization over different outer cosets is asserted in this equality statement. $\square$

Proposition II.185.12 (Attainment and the sharp leading constant). *The first bound in (II.185.22) is attained by nested-hole examples for every pair of integers $r \geq 10$ and $u \geq 8$, at $s = (u - 1)/u^2$. These examples have minimum repair cost exactly one point, even if the outer coset is allowed to vary. Consequently the scale η/δ^2 cannot be replaced by a little-oh bound, and the optimal uniform leading constant in $(C_0 + o(1))\eta/\delta^2$, as $\eta/\delta^3 \rightarrow 0$, is $C_0 = 1$. The assertion of sharpness concerns these attained families; it does not assert attainment for every real parameter.*

Proof. Let the ambient group H be cyclic of order $r(u + 1)$, let $L \leq H$ have order $u + 1$, and put

$$K = L \setminus \{0\}, \quad A = H \setminus K, \quad m = (r - 1)(u + 1) + 1.$$

The difference multiplicities of K inside L are u at zero and $u - 1$ at every nonzero element. Therefore

$$E(K) = u^2 + u(u - 1)^2 = u^3 - u^2 + u.$$

The exact complement identity gives

$$\delta_0 = \frac{u}{m}, \quad \eta_0 = \frac{u^2 - u}{m^3}, \quad \varepsilon = \delta_0(1 - \delta_0) + \eta_0. \quad (\text{II.185.27})$$

Since

$$\delta_0 < \frac{1}{r-1} \leq \frac{1}{9}, \quad \eta_0 < \delta_0^2,$$

we have $\varepsilon < \delta_0 < 1/9$. Also $\delta_0 < 1/2$ and $\varepsilon \geq \delta_0(1 - \delta_0)$, so the coset H satisfies $|A \triangle H|/m = \delta_0 \leq \tau(\varepsilon)$. Uniqueness in Theorem II.185.4 makes H the canonical closest coset. Hence $\delta = \delta_0$, $\eta = \eta_0$, and

$$s = \frac{\eta}{\delta^3} = \frac{u-1}{u^2} \leq \frac{7}{64} < \frac{1}{9}, \quad \tau(s) = \frac{1}{u}.$$

The bound on s uses $u \geq 8$ and decrease of $(u-1)/u^2$ for $u > 2$.

The punctured coset $H \setminus L$ differs from A by one point. There is no zero-edit representation $A = C' \setminus D'$ by nested subgroup cosets in this ambient group. Indeed $|A| > |H|/2$, so a coset C' containing A must equal H : every proper subgroup coset of the finite group H has size at most $|H|/2$. An exact representation would then require $D' = K$. But a subgroup coset contained in L has size dividing $|L| = u+1$, whereas $|K| = u$ does not divide $u+1$ for $u > 1$. Thus the minimum edit count is exactly one, and

$$\Delta_H(A) = \frac{1}{m} = \delta\tau(s).$$

This proves finite attainment with all the stated numerical conditions. Finally

$$\frac{\eta}{\delta^2} = \frac{1-1/u}{m}, \quad \frac{1/m}{\eta/\delta^2} = \frac{u}{u-1} \rightarrow 1, \quad s \rightarrow 0 \quad (u \rightarrow \infty). \quad (\text{II.185.28})$$

The upper bound in Theorem II.185.11 has multiplier $\tau(s)/s = 1 + s + O(s^2)$, which tends to one. The attained family proves that no smaller uniform asymptotic leading constant is possible. $\square$

II.185.6 Axis-cube collisions and coordinate splitting

We now distinguish ordinary additive energy from the more restrictive axis-cube collision count used in the arrangement framework. Let

$$G = \prod_{i=1}^k G_i, \quad k \geq 1,$$

where the G_i are abelian groups. For $g \in G$, let $e_i(g)$ denote the element with i th coordinate g_i and all other coordinates zero. For $x, h \in G$, define the axis cube

$$\text{Cube}(x, h) = \{x + \omega \cdot h : \omega \in \{0, 1\}^k\}, \quad \omega \cdot h = (\omega_1 h_1, \dots, \omega_k h_k). \quad (\text{II.185.29})$$

Degenerate cubes are included. For a finite set $A \subset G$, let

$$\mathcal{Q}(A) = \#\{(x, z, h) : \text{Cube}(x, h), \text{Cube}(z, h) \subset A\}. \quad (\text{II.185.30})$$

This count is finite even if the ambient groups are infinite: the endpoints x and $x+h$ determine h from two elements of A .

For completeness, if $\phi : A \rightarrow W$ takes values in an abelian group, define on a cube contained in A

$$D_h\phi(x) = \sum_{\omega \in \{0,1\}^k} (-1)^{|\omega|} \phi(x + \omega \cdot h).$$

Let $\mathcal{Q}_\phi(A)$ count the triples in (II.185.30) for which $D_h\phi(x) = D_h\phi(z)$. This is the label-respected collision count. Changing all signs by a common factor changes neither the equality condition nor the count.

Lemma II.185.13 (Collision and corner bounds). *For every finite nonempty A of size m ,*

$$\mathcal{Q}_\phi(A) \leq \mathcal{Q}(A) \leq E(A) \leq m^3. \quad (\text{II.185.31})$$

If

$$C_i(A) = \#\{(x, w) \in A^2 : x + e_i(w - x) \in A\},$$

then

$$\mathcal{Q}(A) \leq mC_i(A) \quad (1 \leq i \leq k). \quad (\text{II.185.32})$$

Proof. Send (x, z, h) to $(x, z, w = x + h)$. This map is injective. A valid cube pair has $x, z, w, z + w - x \in A$, so its image is an additive-energy triple. This proves the middle inequality in (II.185.31); the other inequalities are immediate. For the same image, the corner $x + e_i(w - x)$ belongs to A . For each admissible pair (x, w) there are at most m choices of z , which proves (II.185.32). $\square$

Theorem II.185.14 (Product-coset stability below defect $1/9$). *Suppose*

$$\mathcal{Q}(A) \geq (1 - \varepsilon_0)m^3, \quad 0 \leq \varepsilon_0 < 1/9.$$

Then the unique closest finite subgroup coset to A is a coordinate product

$$C = \prod_{i=1}^k (c_i + H_i), \quad H_i \leq G_i, \quad (\text{II.185.33})$$

and $|A \triangle C| \leq \tau(\varepsilon_0)m$. The conclusion also follows from the same lower bound on $\mathcal{Q}_\phi(A)$.

Proof. By (II.185.31) and Corollary II.185.5, the unique closest coset $C = c + H$ exists. Write $h = |H|$, $t = |A \setminus C|$, $x = t/m$, and $\delta = |A \triangle C|/m$. Then

$$x \leq \delta \leq \tau(\varepsilon_0) < 1/5, \quad h/m = 1 + \delta - 2x.$$

We prove $e_i H \subset H$ for each i .

If this inclusion failed, the homomorphism

$$F_i : H \times H \longrightarrow G, \quad F_i(y, w) = y + e_i(w - y),$$

would have image $H + e_i H$. Its image contains H by taking $y = w$, and contains $e_i H$ by taking $y = 0$; the reverse inclusion follows from the formula. Since $e_i H \not\subset H$, this image has at least $2h$ elements. Every nonempty fiber consequently has size at most $h/2$.

After translation by c , at most $mh/2$ pairs in C^2 have their mixed corner in A . At most $m^2 - (m - t)^2$ pairs in A^2 are outside C^2 . We infer

$$\begin{aligned} \frac{C_i(A)}{m^2} &\leq 1 - (1 - x)^2 + \frac{1 + \delta - 2x}{2} \\ &= \frac{1}{2} + \frac{\delta}{2} + x - x^2 \leq \frac{1}{2} + \frac{3\delta}{2} < \frac{4}{5}. \end{aligned}$$

But (II.185.32) and the hypothesis give $C_i(A)/m^2 \geq Q(A)/m^3 > 8/9$, a contradiction. Thus every coordinate component of every element of H lies in H . If H_i is its projection to G_i , summing these coordinate components shows $H = \prod_i H_i$. This proves (II.185.33); the distance bound and uniqueness were already obtained. The label-respected case follows from $Q_\phi \leq Q$. $\square$

II.185.7 Positive-defect equality requires one punctured coordinate

The energy theorem allows a missing subgroup coset with an arbitrary orientation inside the closest coset. Collision equality is more rigid.

Theorem II.185.15 (All positive-defect collision-envelope extremizers). *Let*

$$\varepsilon_{\text{cube}} = 1 - \frac{Q(A)}{m^3}, \quad 0 < \varepsilon_{\text{cube}} < 1/9.$$

Then

$$\delta(A) = \tau(\varepsilon_{\text{cube}}) \tag{II.185.34}$$

if and only if, after translation, there are finite subgroups $H_i \leq G_i$ and one coordinate j such that

$$A = (H_j \setminus K_j) \times \prod_{i \neq j} H_i, \tag{II.185.35}$$

where K_j is a coset of a subgroup $L_j \leq H_j$ and $[H_j : L_j] \geq 9$. Its unique closest coset is $C = \prod_i H_i$, translated back to the original coordinates. At zero defect, $Q(A) = m^3$ holds precisely for coordinate product cosets.

Proof. Let $\varepsilon = 1 - E(A)/m^3$ be the actual additive-energy defect. If (II.185.34) holds, then

$$\delta(A) \leq \tau(\varepsilon) \leq \tau(\varepsilon_{\text{cube}}) = \delta(A).$$

Strict monotonicity of τ forces $\varepsilon = \varepsilon_{\text{cube}}$, so $E(A) = Q(A)$. Theorem II.185.8 gives $A = C \setminus K$, where K is a subgroup coset inside C , and Theorem II.185.14 makes C a coordinate product.

We first show that A is closed under coordinate mixing. Suppose $x, w \in A$ and $v = x + e_i(w - x) \notin A$. Since $A \subset C$ and $|C| = m(1 + \delta) < 2m$, there is $z \in A$ with $z + w - x \in A$: the two relevant translates of A inside C have intersection of size at least $2m - |C| > 0$. Thus (x, z, w) is an additive-energy triple, but its uniquely corresponding cube pair, with side $w - x$, fails at the corner v . The injection in Lemma II.185.13 is therefore not surjective, contrary to $E(A) = Q(A)$. Every such mixed corner must lie in A .

A nonempty set closed under replacing one coordinate by the corresponding coordinate of any other member is the Cartesian product of its coordinate projections. To verify this, start with any member and successively replace coordinates to obtain any prescribed tuple from those projections. After translating C to $H = \prod_i H_i$, write

$$A = \prod_i A_i, \quad A_i \subset H_i, \quad K = b + L = H \setminus A.$$

All A_i are nonempty, and at least one is proper because the defect is positive. Suppose two coordinates have proper A_i . For every coordinate i , choose a different coordinate j with $A_j \neq H_j$, and fix its value in $H_j \setminus A_j$. The entire i th-coordinate fiber, with the other coordinates fixed

arbitrarily, then lies in K . Differences within this fiber imply $e_i H_i \subset L$. This holds for every i , so $L = H$ and $K = H$, contradicting $A \neq \emptyset$. Exactly one coordinate, say j , is proper. Therefore

$$K = (H_j \setminus A_j) \times \prod_{i \neq j} H_i.$$

Projection of the coset K shows that $H_j \setminus A_j$ is a subgroup coset K_j . This gives (II.185.35), and its index is the index $[H : L] \geq 9$ from Theorem II.185.8.

Conversely, let A have the form (II.185.35). Both additive energy and axis-cube collisions factor over Cartesian products. In a full subgroup coordinate, every triple of the two bases and the side is valid, giving $|H_i|^3$. In the sole punctured coordinate, a one-dimensional cube pair is exactly an additive quadruple, so its collision count equals its energy. Hence $\mathcal{Q}(A) = E(A)$. Theorem II.185.8 proves (II.185.34) and identifies the closest coset.

At zero defect, (II.185.31) and Theorem II.185.14 force A itself to be a coordinate product coset. Every such coset has $\mathcal{Q}(A) = m^3$, proving the last assertion. $\square$

Corollary II.185.16 (What equality says for labels). *If $\varepsilon_\phi = 1 - \mathcal{Q}_\phi(A)/m^3 < 1/9$ and $\delta(A) = \tau(\varepsilon_\phi)$, then*

$$\mathcal{Q}_\phi(A) = \mathcal{Q}(A) = E(A).$$

At positive defect the domain has the form (II.185.35); at zero defect it is a coordinate product coset. Constant labels attain equality on every domain in these classifications.

Proof. The chain (II.185.31), the energy envelope, and the strict monotonicity of τ force equality of all three counts. Apply Theorem II.185.15. For a constant label, the two full alternating sums agree on every valid cube pair, so $\mathcal{Q}_\phi(A) = \mathcal{Q}(A)$. $\square$

The last corollary classifies the necessary domain geometry and supplies sufficient constant-label examples. It does not classify all admissible labels. A label classification must retain arbitrary lower-coordinate terms, as the exact endpoint theory in sources 14–15 already emphasizes [202]. Quantitative repair of those labels on the punctured products is a further problem.

Part III

Cube and progression counts

Contents. Counting consequences of uniformity. Sections III.1–III.2: source 03, delivered Sections 5–6 (progression counting by a density-weighted telescope; the exact fourth-order term of the centered cube count on every finite abelian group, its torsion correction, sharpness for sets, higher coefficients). Sections III.3–III.4: source 04, delivered Sections 6–7 (the sharp real centered gap $\|f\|_{U^3}^8 \geq 2\|f\|_{U^2}^8$ on odd-order groups, the sharp leading constant $6\sqrt{2}$ of the three-cube bound, the fractional correction exponent $16/3$, and density-weighted progression counting with the lifting lemma).

Overlaps (dated notes). Cancellation through degree three and the quartic expansion (03 on every group, 04 on odd-order groups; $P_d = R_d$); the $\mathbb{Z}/3\mathbb{Z}$ cosine polynomial (identical in both); the generalized von Neumann bound and the telescoping theorem (independently written in both). **Cross-source answers.** Source 04’s Theorem III.3.4 answers source 03’s Research question V.14.1 for $d = 3$, with $c_3^{\text{odd}} = 2^{-1/2}$. Source 04’s Lemma III.4.5 is the only statement of the five sources that is formalized (`hasNatAP_of_short_modular_sequence`).

Reading conventions of this Part (the full dictionary is Section F.3).

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
cube count	03: $Q_d(F)$, $m = 2^d$ vertices, $\eta = \ f\ _{U^d}$; 04: $Q_d(W)$, $q = 2^d$, $u = \ f\ _{U^d}$, $v = \ f\ _{U^2}$. <i>04’s q here is not its kernel degree q of Part II.</i>
R_d, P_d, T_d	03: R_d = number of ordinary parallelograms, T_d = binary tetrahedra, $K_d = R_d + T_d$, $\mathcal{R}_d$ the remainder; 04: P_d = number of parallelograms (= 03’s R_d), R_d, R_6, R_7 remainders. <i>04’s R_d is not 03’s R_d.</i>
$\mathcal{E}, B$	03: $\mathcal{E}(f) = \ f\ _{U^2}^4$, $\mathcal{E}_{(2)}(f)$ the order-two (quotient) energy, $B(S)$ the telescoping recursion; 04: $\mathcal{E}(\lambda)$ the additive energy of $\lambda_r = a_r ^2$, $B_5(f)$ the quintic correlation, $D(S)$ the recursion (= 03’s $B(S)$).
slopes, α	03: slopes a_i with invertible differences, Λ_a , $\eta = \ 1_A - \delta\ _{U^{k-1}}$; 04: admissible slopes c_i , Λ_c , u . Both: Gowers’s α -uniformity means $\ f\ _{U^d}^{2^d} \leq \alpha$; <i>α is a norm power, not a norm.</i>

Added in the second write (6 October 2026): sources 06–10. Contents. Section III.5: source 06, delivered Section 3 (a generalized von Neumann bound keeping two distinguished functions, first and second telescoping, a progression discrepancy quadratic in the uniformity norm, the sharp three-term variance factor, an explicit modular existence criterion). Sections III.6–III.15: source 08, delivered Sections 2–10 and Appendix A (cancellation through degree three, the exact quartic term with its order-two correction, the complete odd-order three-cube polynomial, the counterexample to the quartic lower bound with its exact certificate, sharpness for sets, Fourier stability, inhomogeneous weights, the character-kernel survival criterion). Sections III.16–III.27: source 09, delivered Sections 2–10, 13 and Appendices A–B, the fullest treatment of the cube count (complete four- and five-vertex classifications on every finite abelian group with Stirling multiplicities, the exact fourth and fifth orders, signs and sharpness through order six, the determinant-five configuration and the all-prime family, heterogeneous expansions, and the relation to progression bounds). Sections III.28, III.29 and III.30: source 10, delivered Sections 5, 6 and 9 (a torsion-sensitive mixed- L^p generalized von Neumann inequality and its sharpness; density-weighted counting and modular criteria; the exact dimension threshold for polynomial colourings).

Overlaps (dated notes at both ends). Cancellation through degree three: 03, 04, 08, 09. The exact quartic term on every group: 03, 08, 09 ($R_d = P_d$, T_d , $K_d = F_d = A_d$). The complete odd-order three-cube polynomial: 08’s Theorem III.9.2 contains 04’s support count and is the $d = 3$ case of 09’s Theorem III.21.1. The quartic lower bound with coefficient 12 is false: 03 (on $\mathbb{Z}/3\mathbb{Z}$), 08 (on $\mathbb{Z}/11\mathbb{Z}$, with the explicit ratio $15337/1296$) and 09 (on primes $q \geq 17$) show it; Remark W1 keeps it on record with the counterexample.

Sharpness for sets by rounding: 03, 04, 08, 09. Progression counting: the linear telescope of 03 and 04 is also 06's Theorem III.5.2 and 10's Theorem III.29.1; 06 adds a quadratic bound, 10 the torsion kernels.

Reading conventions for the sections of sources 06–10 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
cube count	08: $\mathcal{C}_d(F)$, $p = 2^d$, $t = \ f\ _{U^d}$, $\mathcal{D}_d(F) = \mathcal{C}_d(F) - \delta^p$; 09: $\mathcal{C}_d(F)$, $m = 2^d$, $\varepsilon = \ f\ _{U^d}$, $a_\chi = \widehat{f}(\chi)$. Both are 03's and 04's Q_d . 08's p is not a prime.
$R_d, P_d, T_d, F_d, A_d, K_d$	Parallelograms: 08's $R_d = 09$'s $P_d = 03$'s $R_d = 04$'s P_d . Non-parallelogram binary planes: 08's $T_d = 09$'s $T_d = 03$'s T_d . All binary planes: 08's $F_d = 09$'s $A_d = 03$'s K_d . 08's $K_d = \sum_{r \geq 4} \binom{p}{r}$ is not 03's K_d ; 08's F_d is not the floor count F_k of Part IV.
Q_d, S_d	09: Q_d the number of star supports, S_d of ternary supports. 08: $Q_d(f) = R_d E_4(f) + T_d E_{\langle 2 \rangle}(f)$, the quartic coefficient. <i>Neither is the cube count Q_d of 03 and 04.</i>
Fourier statistics	$E_4(f)$ (08) = $E_4(f)$ (09) = $\mathcal{E}(f)$ (03) = $\ f\ _{U^2}^4$; $E_{\langle 2 \rangle}(f)$ (08) = $\mathcal{T}_2(f)$ (09) = $\mathcal{E}_{\langle 2 \rangle}(f)$ (03); $S_5(f)$ (08) = $M_5(f)$ (09) = $B_5(f)$ (04); $\mathcal{T}_{3,5}(f)$ (09) = $M_{S_3}(f)$ (03); κ_d^{odd} (08) = c_d^{odd} (03); the subset moments $\Lambda_S(f)$ (08) = $T_S(f)$ (09) = $M_S(f)$ (03).
progressions	06: Λ_a , $\varepsilon = \ 1_A - \delta\ _{U^{k-1}}$ (a norm), $S_k(\delta)$, $B_k(\delta) = \sum_t (t+1)\delta^t$, E_k . 10: $\kappa_G(c) = G[c] $, the kernel product K , $\tau_j(G)$, B_j , D_j , $T_{k,G}(\delta)$, $S_k(\delta)$ (= 06's). 06's $B_k(\delta)$ is not the translation budget B_k of Part IV; 10's κ_G is none of the other κ 's.
colourings, $h(\ell)$	10, Section III.30: $k = 2m$, a prime $p > k$, a colouring Q with degrees D_ℓ , $s_\ell = \lceil D_\ell/2 \rceil$, $B = \sum_\ell s_\ell^2$, the field norm N_t (<i>this m is $k/2$</i>). 09: $h(\ell)$ the least support with isolated ℓ -torsion, $\mathcal{L}_S$ the row lattice, $K_G(S)$ the character constraint group.

Added in the third write (6 October 2026): sources 11–14. Contents. Sections III.31–III.33: source 13, delivered Sections 7–9 (centered cube counts over $\mathbb{F}_p^n$: coloop cancellation, the exact quartic coefficient, the three-cube table and an exact spectral identity with orbit moments and a spectral deficit; interval discrepancy with the sharp exponent $1/4$ for Lemma 3.5; telescoping progression counts). Sections III.34–III.38: source 14, delivered Sections 2, 3, 6, 7 and Appendix A (the exact secondary coefficient $(9/4)^{1/3}$ of the three-cube extremal problem, two-harmonic rigidity and indicator sharpness; exponent six on groups of exponent five; exact supersaturation for polynomial colourings; quantitative examples; the support certificate).

Overlaps (dated notes). The three-cube identity: source 08 on every odd-order group, source 13 over $\mathbb{F}_p^n$, source 09 for every d ; the table $(1, 0, 0, 0, 12, 8, 28, 8, 1)$: 04, 08, 13, 14; the quartic coefficient: 03, 08, 09, 13; the telescope: 03, 04, 06, 10, 13; the colouring threshold: 10, reproved by 14. **Cross-source answers.** Source 04's Question 1 is *settled* by source 14 (Remark W4): the secondary coefficient exists and equals $(9/4)^{1/3}$. Source 04's Question 2 is answered in U^2 and fails in L^2 (source 14's Theorem III.34.3 and the remark after it).

Reading conventions for the sections of sources 11–14 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
cube count	13: $\mathcal{Q}_d(\delta + f)$, $m = 2^d$, $\eta = \ f\ _{U^d}$, $\rho = \ f\ _{U^2}$ (<i>a norm</i>), $\sigma^2 = \mathbb{E}f^2$, $\zeta = \max f $; 14: $Q_3(W) = \ W\ _{U^3}^8$, $u = \ f\ _{U^3}$, $S = \ f\ _{U^2}^4$, $M = \sum a_r ^8$, $\rho = a_\xi $ and $b = a_{2\xi} $ (<i>half of 04's a and b</i>), D a tail fourth mass, $\eta = S_0 - S$, $t = u/\delta$, β_* (= half of 04's c), $C_* = (9/4)^{1/3}$, $\kappa = 2^{5/4}/12$. All are 03's and 04's Q_d .
moments	13: T_5 (= 04's B_5 for real f), B_1, B_2, B_3 six-point orbit moments (<i>not 04's or 06's B_k</i>), T_7 , $c_{d,p}(j)$ coloopleless counts (= 08's survivor coefficients), P_d (= 03's R_d). 14: $T(s, t)$ (= 04's), B_5 (= 04's), $M_\delta(u)$ <i>over all groups of order coprime to 6 and norm at most u</i> (04's (Q1) uses primes above 16 and norm exactly u ; Remark W4).
intervals, progressions	13: $D_N(M)$ the exact interval constant (<i>not a difference set</i>), $b = \min(\beta, 1 - \beta)$, $S_k(\delta) = \sum_{j \leq k-3} \delta^j$ (= 03's S_{k-2}).
colourings	14: $k = 2m$, D_ℓ , $s_\ell = \lceil D_\ell/2 \rceil$, $B = \sum s_\ell^2$ (= 10's B), q a field size (<i>10 works over primes</i>), $S_z(Q)$ symmetric directions, A_k^{sym} ordered counts.

Added in the fourth write (6 October 2026): sources 15–20. Contents. Section III.39: source 16, delivered Section 8 (fourth and fifth cube coefficients in every dimension; sharp quintic-moment bounds; optimality of the exponent $4/2^d$ for sets). Section III.40: source 18, delivered Section 3 (the expansion through order five on every finite abelian group, small minors and Smith forms, the centered cube bound, sharpness for sets). Sections III.41–III.48 are source 20's chapter: a guide and its delivered Sections 2–8 (directional cubes; two marked functions; the sharp directional-to-global comparison; second-order telescoping and quadratic counting; pair correlations; supersaturation; the sharp three-term obstruction).

Overlaps (dated notes). The expansion through order five: source 09 (on every group), sources 16 and 18 again; the quartic part also 03 and 08. Sharpness for sets: 03, 04, 09, 16, 18. Two-function counting and quadratic error: source 06's Section III.5 first, source 20 general and sharper; torsion: source 10, source 20 sharp per subgroup tuple. **Cross-source answers.** Source 06's Question 7 is answered for the norm-conversion step and its Question 6 advanced by source 20 (items III.9, III.8); source 18's question on odd-order coefficients is settled at $d = 3$ by source 04 (item III.1).

Reading conventions for the sections of sources 15–20 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
cube coefficients	16: $m = 2^d$, $\mathcal{Q}_d(\delta + tf)$ (= 03's and 04's Q_d), P_d (= 03's R_d), T_d , F_d , H_d (= 09's Q_d , S_d), $Q(f) = \ f\ _{U^2}^4$, Q_2 its order-two part, D (= 04's B_5 , 09's M_5), D_3 (= 09's $T_{3,5}$). 18: ℓ or d the cube dimension, $\mathcal{C}_\ell(g) = \ g\ _{U^\ell}^{2^\ell}$ (= 03's Q_d), R_ℓ , B_ℓ , Q_ℓ , S_ℓ (<i>18's Q_ℓ counts circuits; it is not a cube count</i>), V_4 , E_2 , T_5 , E_3 .
counting	20: Λ_k , Λ_L progression and system averages, “admissible” (multiplication by $1, \dots, k-1$ invertible), $D_{H_1, \dots, H_s}$ directional seminorms, κ_i torsion costs, $\sigma = \sqrt{\delta(1-\delta)}$, $R_m(\delta)$, $B_k(\delta)$ (<i>not 06's B_k</i>), $u = \ 1_A - \delta\ _{U^{k-1}}$, w_{ij} , $Q_d(f, g)$ a pair correlation, T_k^* (as 03's).

Added in the fifth write (6 October 2026): sources 21–27. Contents. Sections III.49–III.59 are source 21's chapter: a guide, its delivered Sections 2–9 (Fourier identities and the quartic deficit; the sixth- and seventh-degree terms with a retained tail; the order-five resonance; the sharp optimization and phase envelope; rigidity; the next coefficient on $\mathbb{Z}/5\mathbb{Z}$; indicator sharpness; a projection consequence of cube Cauchy–Schwarz), then source 23's delivered Section 7 and Appendix A (the same theorem again, a five-point model). Sections III.60–III.65 are source 22's chapter: a guide and its delivered Sections 6–10 (polynomial zero sets and prescribed equality patterns; progression specializations; quadratic classification; why additive blocks cannot extend the norm colouring; a global obstruction in characteristic-divisible degrees).

Overlaps (dated notes). The exponent-five coefficient: source 14's Theorem III.35.2 (exponent six and the lower model), then sources 21 and 23 independently (the sharp coefficient). The quartic gap is source 04's

Theorem III.3.4. Polynomial colourings: source 10's Section III.30, source 14's Section III.36, then source 22 (every degree, every pattern; Warning's second theorem and the Delsarte–Goethals–MacWilliams theorem are classical and credited). **Cross-source answers.** Source 14's Question 1 is answered by sources 21 and 23 (item III.23); its Question 7 is advanced and its Question 8 has a first instance by source 22 (items III.19, III.20).

Reading conventions for the sections of sources 21–27 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
exponent five	21: $Q_3(W) = \ W\ _{U^3}^8$, a_r Fourier coefficients, $\lambda_r = a_r ^2$, $S = \ f\ _{U^2}^4$, $M = \sum a_r ^8$, $T(s, t)$, $\mathcal{E}(\lambda)$, ρ , D the fourth-power tail (<i>not a dimension</i>), B_5 (= 04's), C_6 , C_7 (<i>not 01's or 06's C_k</i>), H , J , K six-vertex sums, $b = a_{2\xi} $, $\theta = 2\alpha - \beta$, $\phi = 3\alpha + \beta$, C_5 , β_5 , $\eta = S_0 - S$, $t = u/\delta$, $M_{\delta,5}(u)$. 23: $Q(W)$, A_6 , B_6 , C_6 (<i>23's C_6 is one of three forms; 21's C_6 is their sum</i>), $\kappa = 2^{1/4}/6$ (= 21's β_5), $\theta = \arg a_\xi$ (<i>not 21's θ</i>).
colourings	22: q the field size, $Q: \mathbb{F}_q^n \rightarrow \mathbb{F}_q^r$ a colouring with degree caps D_a , Π an equality pattern, $S_z(Q)$ successful directions, $B(\Pi, D)$, B_{sym} , B_{mono} budgets (= 14's B ; <i>not 18's B_d</i>), N_t norm forms, $T_b(R)$ third-difference supports, E_t field extensions.

Added in the sixth write (6 October 2026): sources 28–33. Contents. Sections III.66–III.70: a guide, source 29's delivered Sections 2–4 (Fourier identities; positive autocorrelation moments; consequences for the higher norm constants) and source 28's Section 8 (a stronger real norm gap and a higher-order obstruction).

Overlaps (dated notes). Source 28's universal bound is superseded by source 29's; the number 222 is computed by both, independently. **Cross-source answers.** Source 03's Research question 1 and source 04's Question 3 are advanced for $d \geq 4$ (item III.1); the sub-question whether real parts of characters are extremal is answered (no) for $d \geq 4$ by source 28.

Reading conventions for the sections of sources 28–33 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
odd constants	29: $c_f(h)$ the autocorrelation, $\lambda_\chi = \widehat{f}(\chi) ^2$, $S = \ f\ _{U^2}^4$, $m = 2^{d-2}$, C_m , B_d , $K_m(\tau)$, τ the self-inverse fraction, P_d the quartic cube coefficient (= 03's R_d on odd groups). 28: the same c_d^{odd} , f_b , F two-harmonic functions, $R_d(b)$ a ratio (<i>not 03's R_d</i>), $P(b)$ a polynomial, p the largest-pair mass (<i>not a prime</i>).

Added in the seventh write (6 October 2026): sources 34–39. Contents. Sections III.71–III.72: source 34's Section 10 (a stronger fourth-dimensional norm comparison) and source 35's Section 6 (a stronger gap between real centered uniformity norms), continuing the chapter on c_d^{odd} . Sections III.73–III.81: a guide and source 34's Sections 2–9 (Fourier constraints and the row quotient; the determinant reduction; exact first cases; a positive detector; consecutive binary determinants; optimal cyclic support; universal positivity; the exact quartic term). Sections III.82–III.86: a guide and source 38's Sections 2–5 (Fourier identities; exact reduction to a five-point quotient; the five-point profile; cyclic reduction for every fixed odd exponent). Sections III.87–III.88: a guide and source 38's Section 7 (an exact six-term extension defect).

Overlaps (dated notes). Source 34's lower example, dual identity and single-pair non-extremality are source 28's; sources 34 and 35 are independent same-day proofs of better coefficients, source 34's the stronger. **Cross-source answers.** Source 09's prime-onset question is answered by source 34 (item III.16); three of source 21's questions by source 38 (item III.27); item III.1 is advanced to $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$.

Reading conventions for the sections of sources 34–39 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
odd constants	34: $a_\xi = \widehat{f}(\xi)$, $S = \ f\ _{U^2}^4$, p_j pair masses and p the largest (<i>not a prime</i>), C_m (= 29's), $H_m(p)$, D_4 the fourth dual operator, ϕ_j real characters, $K = 222^{1/4}/2$, $L = 27q_3^{1/4} + q_5^{1/4}$, β_d coupled bounds. 35: $\lambda_r = a_r ^2$, S , $M = \sum \lambda^4$ (<i>not 35's M of Part II</i>), $J(\lambda)$, A , B , $D = 1 - p$ (<i>not a divisor</i>).
prime torsion	34: M_S the augmented Boolean matrix, A_S its row quotient, $h(p)$, $h_{\text{cyc}}(m)$, $h_{\text{pos}}(m)$, $D_{\text{div}}(p)$, $\text{row}_{\mathbb{Z}}$; $h(p) = 09$'s $h(\ell)$.
exponent five	38: $\mathcal{C}_3(W) = \ W\ _{U^3}^8$ (<i>not $\mathbb{Q}$</i>), $\mathcal{M}_{\delta,G}(u)$, $u = \ f\ _{U^3}$, c_{10} , c_{12} , m an odd exponent; its $\mathcal{M}_{\delta,G}$ is 21's $M_{\delta,G}$.
norm colourings	38: N_d norm maps, e_2 the quadratic coefficient of the quintic norm, A_6^{sym} the six-term count, R the independent addition (<i>not a radius</i>).

Added in the eighth write (7 October 2026): sources 40–46. Contents. Sections III.89–III.91: a guide and source 45's Sections 4–5 (a quantitative real fourth-uniformity gap; applications to cube counting and structured holes), continuing the chapter on c_d^{odd} .

Overlaps (dated notes). Source 45's single-pair non-extremality and dual identity are sources 28's and 34's, its moment bound sources 29's and 34's, its three-pairing count that of sources 21, 35 and 38; it cites none of them. **Cross-source answers.** Item III.1 is advanced to $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$.

Reading conventions for the sections of sources 40–46 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
odd constants	45: $Q_d = \ f\ _{U^d}^{2^d}$, $S = Q_2$ (= 29's S), v , w the mean and the rest of $Q_2(g)$, $t(h)$, $w(h)$ derivative statistics, V , W their averages, $P(t)$ the scalar certificate, $\kappa = (832/4795)^{1/4}$ (<i>not 34's or 38's κ</i>), ϕ_j real characters, $\mathcal{D}_4$ the dual operator (= 34's D_4), $P_d = (6^d - 2 \cdot 4^d + 2^d)/8$ (= 04's quartic coefficient).

III.1 Progression counting with fewer error terms

Source 03, delivered Section 5.

For integers $a_1, \dots, a_k$ and functions $g_i: G \rightarrow \mathbb{C}$, define

$$\Lambda_{\mathbf{a}}(g_1, \dots, g_k) = \mathbb{E}_{x, t \in G} \prod_{i=1}^k g_i(x + a_i t).$$

We say that the slopes have invertible differences on G if each map $x \mapsto (a_i - a_j)x$, $i \neq j$, is an automorphism. For $G = \mathbb{Z}/N\mathbb{Z}$ this means $\gcd(a_i - a_j, N) = 1$. Consecutive slopes satisfy the condition whenever $\gcd(N, (k-1)!) = 1$, which is weaker than primality of N .

Lemma III.1.1 (Generalized von Neumann inequality). *Suppose the slopes have invertible differences and $k \geq 2$. For $|F_i| \leq 1$,*

$$|\Lambda_{\mathbf{a}}(F_1, \dots, F_k)| \leq \|F_k\|_{U^{k-1}(G)}.$$

The same bound holds with any one of the functions distinguished.

Proof. For $k = 2$, the map $(x, t) \mapsto (x + a_1 t, x + a_2 t)$ is a bijection, so the average factors and is at most $|\mathbb{E}F_2| = \|F_2\|_{U^1}$. For the inductive step replace x by $y - a_1 t$, apply Cauchy–Schwarz in y , and remove the bounded factor $F_1(y)$. On expanding the square, write the two step variables as t and $t + u$. With $D_h F(z) = F(z)F(z + h)$, the resulting expression is

$$\mathbb{E}_u \mathbb{E}_{y,t} \prod_{i=2}^k D_{(a_i - a_1)u} F_i(y + (a_i - a_1)t).$$

Its absolute value is at most $\mathbb{E}_u \|D_{(a_k - a_1)u} F_k\|_{U^{k-2}}$ by induction. Hölder and the invertibility of $a_k - a_1$ bound this by

$$\left(\mathbb{E}_h \|D_h F_k\|_{U^{k-2}}^{2^{k-2}} \right)^{1/2^{k-2}} = \|F_k\|_{U^{k-1}}^2.$$

This bounds the square of the original average. Permuting the indices allows any function to be distinguished. $\square$

Theorem III.1.2 (Density-weighted telescoping). *Assume the slopes have invertible differences. Let $0 \leq g_i \leq 1$, $\delta_i = \mathbb{E}g_i$, and $f_i = g_i - \delta_i$. For any permutation π of $\{1, \dots, k\}$,*

$$\left| \Lambda_a(g_1, \dots, g_k) - \prod_i \delta_i \right| \leq \sum_{j=3}^k \left(\prod_{\ell=j+1}^k \delta_{\pi(\ell)} \right) \|f_{\pi(j)}\|_{U^{j-1}}. \quad (\text{III.1.1})$$

For $k = 2$ the error is zero.

Proof. Expand by replacing the functions with their means one at a time, starting with the last function in the chosen order. The exact difference is a sum of k terms. Term j has coefficient $\prod_{\ell > j} \delta_{\pi(\ell)}$ and an average containing $g_{\pi(1)}, \dots, g_{\pi(j-1)}, f_{\pi(j)}$. The first term vanishes because $f_{\pi(1)}$ has mean zero. The second vanishes by the two-variable bijection used in Lemma III.1.1. Apply that lemma to each remaining term, with its j slopes. $\square$

[write] **6 October 2026; sources 11–14.** Source 13’s Theorem III.33.2 and Corollary III.33.3 prove this telescope and criterion again (its S_k is S_{k-2} here), with an explicit $\mathbb{Z}/3\mathbb{Z}$ example showing that the invertibility hypothesis of the generalized von Neumann bound cannot simply be dropped.

In the setting of Corollary 3.3, use the original index order. The normalized uniformity norms that occur in (III.1.1) are then at most its parameter α . Therefore its bound $2^k \alpha$ may be replaced by

$$\alpha \sum_{j=3}^k \prod_{i=j+1}^k \delta_i \leq (k-2)\alpha.$$

The operation is a telescoping expansion, which has one discrepancy per replacement. It avoids the unnecessary 2^k -term expansion of all balanced factors simultaneously. This is a standard multilinear technique; its role here is to record the stronger bound with the exact inhomogeneous parameters used by the source.

III.1.1 Optimizing the order of replacement

If all available norms in (III.1.1) are bounded by the same η , arrange the densities in nonincreasing order. This minimizes the displayed upper bound: every tail product then consists of the smallest

densities of the required size. When distinct functions have different norms at different levels, define for a set of indices S

$$B(S) = 0 \quad (|S| \leq 2), \quad B(S) = \min_{i \in S} \{ \|f_i\|_{U^{|S|-1}} + \delta_i B(S \setminus \{i\}) \} \quad (|S| \geq 3).$$

This finite recursion computes the best bound among these telescoping orders in $O(k2^k)$ arithmetic operations once the norms are supplied. It is an optimization of the bound, not a claim that the bound is the exact counting error. For fixed small k , this separates analytic estimates from a finite, reproducible choice of order.

Corollary III.1.3 (An explicit modular progression criterion). *Let $k \geq 3$, let $|G| = N$, and suppose multiplication by each of $1, \dots, k-1$ is an automorphism of G . Let $A \subset G$ have density $0 < \delta \leq 1$, and set*

$$\eta = \|1_A - \delta\|_{U^{k-1}}, \quad S_{k-2}(\delta) = 1 + \delta + \dots + \delta^{k-3}.$$

The number of ordered pairs (x, t) with $t \neq 0$ and $x, x+t, \dots, x+(k-1)t \in A$ is at least

$$N^2(\delta^k - \eta S_{k-2}(\delta)) - \delta N. \quad (\text{III.1.2})$$

In particular, if

$$\eta \leq \frac{\delta^k}{2S_{k-2}(\delta)}, \quad N \geq 4\delta^{1-k}, \quad (\text{III.1.3})$$

there are at least $\delta^k N^2/4$ such pairs. Each has k distinct vertices. In the notation of the source, it suffices that

$$\alpha \leq \left(\frac{\delta^k}{2S_{k-2}(\delta)} \right)^{2^{k-1}}$$

when A is α -uniform of degree $k-2$.

Proof. Gowers norm monotonicity gives $\|1_A - \delta\|_{U^{j-1}} \leq \eta$ for $3 \leq j \leq k$. Apply Theorem III.1.2 to equal functions and consecutive slopes. Exactly $|A| = \delta N$ parameter pairs have $t = 0$. For $t \neq 0$, equality of vertices with indices i, j would imply $(i-j)t = 0$, contrary to the automorphism assumption. Under (III.1.3), the right side of (III.1.2) is at least $\delta^k N^2/4$. $\square$

Remark III.1.4 (Modular and integer progressions). Corollary III.1.3 concerns progressions in the group. They do not automatically become ordinary integer progressions under the representative map to $\{0, \dots, N-1\}$. One sufficient rectification condition is that every representative vertex lies in an interval of length H with $2(H-1) < N$. Its consecutive second differences are zero modulo N and have absolute value below N , so they are zero as integers. This proves rectification, but obtaining the necessary interval control is additional information. The general modular counting criterion by itself supplies no such localization.

[write] **6 October 2026.** This rectification argument is formalized, in the form of source 04's Lemma III.4.5 (note there): Lean's `hasNatAP_of_short_modular_sequence` takes representatives in $\{0, \dots, n\}$ with $2n < N$. The remark's interval of H consecutive integers reduces to that case by a translation, a step not stated in Lean. Sections III.1 and III.4 prove the same telescoping bound independently; see the note after Theorem III.4.3.

Remark III.1.5 (Why small torsion cannot simply be ignored). For $G = \mathbb{Z}/2\mathbb{Z}$, slopes 0, 1, 2 have a noninvertible difference. Taking the nontrivial real character f , the average $\mathbb{E}_{x,t} f(x)f(x+2t)$ equals one, although $\mathbb{E}f = 0$. The two centered factors are evaluated at the same point. Thus the pair cancellation used above really can fail when the slope hypothesis is removed.

III.2 The exact fourth-order term in the cube count

Source 03, delivered Section 6.

Gowers' Lemma 3.10 bounds a cube count by applying the triangle inequality to the Gowers norm. The resulting estimate is convenient, but it discards the mean-zero condition on the balanced function after that condition has been used to define uniformity. Retaining it has a substantial local effect: the first three error terms vanish, and the fourth can be computed exactly. The computation also identifies precisely what changes when the ambient finite abelian group has a nontrivial quotient of exponent two.

All results in this section concern the same labelled cubes as [1, Lemmas 3.7–3.10]; coincident vertices are allowed. The refinements are elementary consequences of the cube expansion, character orthogonality, and Gowers–Cauchy–Schwarz. Their proofs are included in full. They are useful sharpenings of the displayed lemma; we do not claim a new inverse theorem or a change in the best known quantitative bounds for Szemerédi's theorem.

III.2.1 Normalization and the centered expansion

Let G be a finite abelian group, with all averages normalized by the cardinality of their domain. Write $V_d = \{0, 1\}^d$, $m = 2^d$, and

$$L_v(x, h) = x + \sum_{i=1}^d v_i h_i \quad (v \in V_d).$$

For a real function $F : G \rightarrow \mathbb{R}$, define

$$Q_d(F) = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{v \in V_d} F(L_v(x, h)). \quad (\text{III.2.1})$$

Thus $Q_d(F) = \|F\|_{U^d}^m$; the usual conjugations in the definition of U^d have no effect for real functions. In particular, $Q_d(F) \geq 0$. If $F = \mathbf{1}_A$, the number of labelled cubes in A is $|G|^{d+1} Q_d(F)$.

Put $\delta = \mathbb{E}F$ and $f = F - \delta$. For $S \subseteq V_d$, put

$$M_S(f) = \mathbb{E}_{x, h} \prod_{v \in S} f(L_v(x, h)), \quad M_\emptyset(f) = 1. \quad (\text{III.2.2})$$

The exact finite expansion is

$$Q_d(\delta + f) = \sum_{S \subseteq V_d} \delta^{m-|S|} M_S(f). \quad (\text{III.2.3})$$

No limiting argument or regularity assumption is involved.

For real functions $g_v : G \rightarrow \mathbb{R}$, the normalized Gowers–Cauchy–Schwarz inequality gives

$$\left| \mathbb{E}_{x, h} \prod_{v \in V_d} g_v(L_v(x, h)) \right| \leq \prod_{v \in V_d} \|g_v\|_{U^d}. \quad (\text{III.2.4})$$

This is [1, Lemma 3.8] with normalized sums; its proof by successive Cauchy–Schwarz inequalities works on every finite abelian group. Taking $g_v = f$ on S and $g_v = 1$ elsewhere shows that, if $\eta = \|f\|_{U^d}$,

$$|M_S(f)| \leq \eta^{|S|}. \quad (\text{III.2.5})$$

We use also the standard monotonicity $\|f\|_{U^2} \leq \|f\|_{U^d}$ for $d \geq 2$.

Lemma III.2.1 (Cancellation through degree three). *If $\mathbb{E}f = 0$ and $1 \leq |S| \leq 3$, then $M_S(f) = 0$ on every finite abelian group.*

Proof. For $|S| = 1$, average over x . Otherwise choose a coordinate in which the distinct selected vertices are not all equal. For two or three vertices, one side of this coordinate contains exactly one selected vertex. Reflect that coordinate if necessary, so that this vertex is the only one with coordinate 1. A coordinate reflection preserves the average: it corresponds to the bijective change of variables $x' = x + h_i$, $h'_i = -h_i$, leaving the other h_j unchanged. After the reflection, h_i occurs in exactly one factor in the product defining M_S . Its average is $\mathbb{E}f = 0$. $\square$

Corollary III.2.2 (First refinement of Lemma 3.10). *For $d \geq 2$, $\delta \geq 0$, and real mean-zero f ,*

$$|Q_d(\delta + f) - \delta^m| \leq \sum_{j=4}^m \binom{m}{j} \delta^{m-j} \eta^j. \quad (\text{III.2.6})$$

Consequently the cube-count error is $O_{d,\delta}(\eta^4)$ as $\eta \rightarrow 0$ with d and positive δ fixed.

Proof. Expand using (III.2.3), discard the terms that vanish by Lemma III.2.1, and apply (III.2.5) to every remaining term. $\square$

The coefficient $\binom{m}{4}$ in (III.2.6) is itself far from necessary. Most four-vertex supports vanish as well.

III.2.2 Fourier energies and the quotient by doubling

Let $\widehat{G}$ be the character group, with characters written multiplicatively, and use normalized Fourier coefficients

$$\widehat{f}(\chi) = \mathbb{E}_{x \in G} f(x) \overline{\chi(x)}.$$

Write 1 for the trivial character. For real mean-zero f , set

$$\mathcal{E}(f) = \sum_{\chi \in \widehat{G}} |\widehat{f}(\chi)|^4 = \|f\|_{U^2}^4, \quad (\text{III.2.7})$$

$$\mathcal{E}_{(2)}(f) = \sum_{\substack{\chi \in \widehat{G} \setminus \{1\} \\ \chi^2 = 1}} |\widehat{f}(\chi)|^4. \quad (\text{III.2.8})$$

The omitted trivial-character term is zero. In particular,

$$0 \leq \mathcal{E}_{(2)}(f) \leq \mathcal{E}(f) \leq \eta^4. \quad (\text{III.2.9})$$

The second energy has a concrete quotient interpretation. Let $2G = \{2x : x \in G\}$ and

$$P_2 f(x) = \mathbb{E}_{z \in 2G} f(x + z).$$

This is the conditional average of f on the cosets of $2G$. A character survives this average exactly when it annihilates $2G$, equivalently when $\chi^2 = 1$. Fourier orthogonality therefore gives

$$\mathcal{E}_{(2)}(f) = \|P_2 f\|_{U^2(G)}^4. \quad (\text{III.2.10})$$

Thus the correction below measures the part of f visible in $G/2G$. If $|G|$ is odd, $2G = G$ and this correction is zero. If every element of G has order dividing two, then $P_2 f = f$.

III.2.3 A complete classification of four-vertex supports

Call a four-element subset $S \subseteq V_d$ an *ordinary parallelogram* if its vertices can be ordered a, b, c, e with $a + b = c + e$ as vectors in $\mathbb{Z}^d$. Call it a *binary tetrahedron* if

$$\bigoplus_{v \in S} v = 0$$

under coordinatewise addition modulo two, but S is not an ordinary parallelogram. This terminology describes the support in the Boolean cube, rather than a nondegeneracy condition on its image in G .

Lemma III.2.3 (The three possible fourth-order contributions). *For real mean-zero f and a four-element $S \subseteq V_d$,*

$$M_S(f) = \begin{cases} \mathcal{E}(f), & S \text{ is an ordinary parallelogram,} \\ \mathcal{E}_{(2)}(f), & S \text{ is a binary tetrahedron,} \\ 0, & \bigoplus_{v \in S} v \neq 0. \end{cases} \quad (\text{III.2.11})$$

These cases exhaust all four-element subsets.

Proof. If the XOR of the four vertices is nonzero, some coordinate has an odd number of ones, namely one or three. Reflect this coordinate when there are three. As in Lemma III.2.1, one difference variable then appears in exactly one centered factor, so the average vanishes.

Suppose that the XOR is zero. Reflect coordinates so that one chosen vertex becomes 0, and denote the other three vertices by u, v, w . The reflection preserves both the averages and the property of being an ordinary parallelogram. We have $u + v + w = 0$ over $\mathbf{F}_2$. Accordingly the only possible coordinate patterns across these three rows are

$$000, \quad 110, \quad 101, \quad 011.$$

At least two of the three nonzero patterns occur, because u, v, w are nonzero and pairwise distinct. Sum the independent variables h_i over coordinates of each of the three nonzero types, naming the sums r, s, t respectively. Every nonempty sum is uniform on G , and the nonempty sums are mutually independent.

If exactly two types occur, the four arguments, in an appropriate order, are

$$x, \quad x + r, \quad x + s, \quad x + r + s.$$

Their coefficient vectors form an ordinary parallelogram, and the average of the product of the four real f values is $\|f\|_{U^2}^4 = \mathcal{E}(f)$.

If all three types occur, the four arguments are

$$x, \quad x + r + s, \quad x + r + t, \quad x + s + t. \quad (\text{III.2.12})$$

There is no pairing with equal sums of coefficient vectors. For example, each possible pairing is ruled out by one of the three occupied coordinate types. Thus this is precisely the binary tetrahedron case.

It remains to evaluate (III.2.12). Substitute the Fourier expansion of f into all four factors, assigning characters $\chi_0, \chi_1, \chi_2, \chi_3$ in the displayed order. Averaging over r, s, t imposes

$$\chi_1 \chi_2 = 1, \quad \chi_1 \chi_3 = 1, \quad \chi_2 \chi_3 = 1.$$

Hence $\chi_1 = \chi_2 = \chi_3 = \chi$ with $\chi^2 = 1$. The average over x then forces $\chi_0 = \chi$. The correlation is therefore

$$\sum_{\chi^2=1} \widehat{f}(\chi)^4.$$

For such characters $\chi(x) \in \{-1, 1\}$, so $\widehat{f}(\chi)$ is real. The trivial character has coefficient zero, and the last display equals (III.2.8). $\square$

Remark III.2.4 (Why integer rank alone is insufficient). The four vectors in (III.2.12), including the coefficient of x , form a matrix of determinant ± 2 . They are independent over $\mathbb{Q}$ but need not give independent uniform values on G . Discarding all rationally independent supports would incorrectly omit $\mathcal{E}_{(2)}(f)$. The three Smith types for a four-vertex support are $(1, 1, 1, 0)$, $(1, 1, 1, 2)$, and $(1, 1, 1, 1)$, corresponding respectively to an ordinary parallelogram, a binary tetrahedron, and the final case of Lemma III.2.3. In the first type the final zero records rank three; for $d = 2$ the rectangular matrix has only three nonzero invariant factors.

Lemma III.2.5 (Exact multiplicities). *The numbers of ordinary parallelograms and binary tetrahedra in V_d are respectively*

$$R_d = \frac{6^d - 2 \cdot 4^d + 2^d}{8}, \quad (\text{III.2.13})$$

$$T_d = \frac{8^d - 3 \cdot 6^d + 3 \cdot 4^d - 2^d}{24}. \quad (\text{III.2.14})$$

Their sum is

$$K_d = R_d + T_d = \frac{m(m-1)(m-2)}{24}. \quad (\text{III.2.15})$$

Proof. Count ordered quadruples satisfying $a + b = c + e$ in $\mathbb{Z}^d$. There are six possible coordinate patterns, so the total is 6^d . The degeneracies $a = c$, $b = e$ and $a = e$, $b = c$ each contribute 4^d , and their intersection contributes 2^d . These are all degeneracies: for example, $a = b$ forces $c = e = a$ coordinatewise. An ordinary parallelogram with four distinct vertices has exactly one pairing into two equal-sum pairs. Ordering both pairs and ordering the pairs gives eight ordered solutions. This proves (III.2.13).

For the XOR count, choose distinct ordered vertices a, b, c arbitrarily and put $e = a \oplus b \oplus c$. The fourth vertex differs from each of the first three. Every unordered four-element XOR-zero subset is counted 24 times. The total is thus $m(m-1)(m-2)/24$. Every ordinary parallelogram has XOR zero, and the other XOR-zero subsets are exactly the binary tetrahedra. Subtracting R_d gives (III.2.14). $\square$

For orientation, the first coefficients are

d	m	R_d	T_d	K_d
2	4	1	0	1
3	8	12	2	14
4	16	100	40	140
5	32	720	520	1240

For comparison, $\binom{m}{4}$ equals 70, 1820, 35960 when $d = 3, 4, 5$. Even after the first three terms have been removed, counting every fourth-order support by its absolute upper bound wastes most of the available cancellation.

III.2.4 The sharpened cube-count theorem

Theorem III.2.6 (Exact fourth-order expansion with explicit remainder). *Let $d \geq 2$, $m = 2^d$, let G be a finite abelian group, and let $F : G \rightarrow \mathbb{R}$ have mean $\delta \geq 0$. Put $f = F - \delta$ and $\eta = \|f\|_{U^d}$. Then*

$$Q_d(F) = \delta^m + \delta^{m-4}(R_d\mathcal{E}(f) + T_d\mathcal{E}_{(2)}(f)) + \mathcal{R}_d(F), \quad (\text{III.2.16})$$

where

$$|\mathcal{R}_d(F)| \leq \sum_{j=5}^m \binom{m}{j} \delta^{m-j} \eta^j. \quad (\text{III.2.17})$$

An empty sum is zero. In particular, the formula for $d = 2$ is exact with no remainder.

Proof. Use (III.2.3). The constant term is δ^m , and the terms of degrees one, two, and three vanish by Lemma III.2.1. Lemmas III.2.3 and III.2.5 give the total fourth-order term. The terms of degrees at least five satisfy (III.2.17) by (III.2.5) and the triangle inequality. $\square$

The formula holds in particular for arbitrary weights $0 \leq F \leq 1$, as well as for characteristic functions. The energies in the fourth term are nonnegative, even though the higher-order remainder can have either sign.

Corollary III.2.7 (Uniformity-parameter form). *Let $A \subseteq G$ have density δ , and suppose $\|\mathbf{1}_A - \delta\|_{U^d}^m \leq \alpha$. Then*

$$Q_d(\mathbf{1}_A) \leq \delta^m + K_d \delta^{m-4} \alpha^{4/m} + \sum_{j=5}^m \binom{m}{j} \delta^{m-j} \alpha^{j/m}. \quad (\text{III.2.18})$$

If $|G|$ is odd, the coefficient K_d in the fourth-order term can be replaced by R_d . The latter replacement also holds on an arbitrary group whenever $P_2(\mathbf{1}_A - \delta) = 0$.

Proof. Apply (III.2.9) and Theorem III.2.6. The vanishing of the quotient energy follows from (III.2.10). $\square$

In the notation of Gowers' Lemma 3.10, the old upper bound is $(\delta + \alpha^{1/m})^m$. For fixed d and positive δ , its displayed excess is of order $\alpha^{1/m}$; the new bound has excess of order $\alpha^{4/m}$. This comparison concerns the strength of the cube-count estimate under exactly the same norm hypothesis. It does not replace the arithmetic-progression counting or inverse arguments elsewhere in the proof.

For example, on an odd-order group and with $d = 3$,

$$Q_3(F) = \delta^8 + 12\delta^4 \|f\|_{U^2}^4 + \mathcal{R}_3(F), \quad (\text{III.2.19})$$

$$|\mathcal{R}_3(F)| \leq 56\delta^3 \eta^5 + 28\delta^2 \eta^6 + 8\delta \eta^7 + \eta^8. \quad (\text{III.2.20})$$

On an arbitrary group the exact fourth-order term has the additional $2\delta^4 \mathcal{E}_{(2)}(f)$.

If one prefers a single remainder expression, Taylor's theorem applied to $(\delta + t)^m$ gives, for $m \geq 5$,

$$\sum_{j=5}^m \binom{m}{j} \delta^{m-j} \eta^j \leq \binom{m}{5} \eta^5 (\delta + \eta)^{m-5}. \quad (\text{III.2.21})$$

The polynomial bound (III.2.17) usually retains more useful information when the density is small.

III.2.5 Sharpness and a necessary torsion correction

Proposition III.2.8 (The fourth power cannot be increased). *Fix $d \geq 2$ and $0 < \delta < 1$. Even if one restricts to odd-order finite abelian groups and weights $F : G \rightarrow [0, 1]$ of mean δ , there is no bound*

$$Q_d(F) - \delta^m = O_{d,\delta}(\|F - \delta\|_{U^d}^q) \quad (q > 4)$$

valid as the centered norm tends to zero. Among all finite abelian groups, K_d is the optimal leading coefficient in (III.2.18), expressed in terms of $\eta = \alpha^{1/m}$.

Proof. On $G = \mathbb{Z}/3\mathbb{Z}$, let $g(x) = \cos(2\pi x/3)$ and $F_t(x) = \delta + tg(x)$. For positive sufficiently small t , the weights lie in $[0, 1]$ and have mean δ . The two nonzero Fourier coefficients of g are $1/2$, so $\mathcal{E}(g) = 1/8$. Theorem III.2.6 gives

$$Q_d(F_t) - \delta^m = \frac{R_d}{8} \delta^{m-4} t^4 + O_{d,\delta}(t^5), \quad (\text{III.2.22})$$

where the remainder is identically zero when $d = 2$. Since $\|F_t - \delta\|_{U^d} = t \|g\|_{U^d}$ and $\|g\|_{U^d} > 0$, the exponent $q > 4$ is impossible.

For the coefficient over unrestricted groups, take a nontrivial character $\chi : G \rightarrow \{-1, 1\}$ and $F_t = \delta + t\chi$. Then $\|t\chi\|_{U^d} = t$ and $\mathcal{E}(t\chi) = \mathcal{E}_{(2)}(t\chi) = t^4$. Therefore

$$Q_d(F_t) - \delta^m = K_d \delta^{m-4} t^4 + O_{d,\delta}(t^5). \quad (\text{III.2.23})$$

Any smaller universal leading coefficient would fail for small t . □

The same example proves that the torsion correction cannot be dropped. For a particularly transparent case, on $\mathbb{Z}/2\mathbb{Z}$ and with $d = 3$ one can compute the whole polynomial:

$$Q_3(\delta + t\chi) = \delta^8 + 14\delta^4 t^4 + t^8. \quad (\text{III.2.24})$$

Indeed, a subset S contributes precisely when both $|S|$ and every coordinate sum of its vertices are even. For the three-dimensional cube the only nonempty such supports have sizes four and eight: there are fourteen supports of size four and one of size eight. For size six, taking the complement would give two distinct vertices with equal XOR, which is impossible. Formula (III.2.24) directly distinguishes the correct coefficient 14 from the odd-order coefficient 12.

Remark III.2.9 (What sharpness has and has not shown). The identity determines the exact fourth-order coefficient in terms of the two Fourier energies. The constant K_d is also sharp when those energies are bounded only by η^4 over all groups. We have not asserted that R_d is the optimal leading constant in terms of η^4 when all groups are required to have odd order. That separate optimization involves the possible ratios $\|f\|_{U^2}^4 / \|f\|_{U^d}^4$ for real centered functions.

[write] 6 October 2026. *Settled for $d = 3$ by source 04.* By source 04's Theorem III.3.4, $\|f\|_{U^2}^4 \leq 2^{-1/2} \|f\|_{U^3}^4$ for real centered f on odd-order groups, with equality for $f = 2\text{Re}(c\xi)$. Hence on odd-order groups the best leading constant in terms of $\eta^4 = \|f\|_{U^3}^4$ is $R_3 \cdot 2^{-1/2} = 6\sqrt{2} < 12 = R_3$ (source 04's Theorem III.3.6 and Proposition III.3.7); the proof is in the note after Theorem III.3.4. For $d \geq 4$ the question remains open (Research question V.14.1).

III.2.6 Sharpness can be transferred to actual sets

The use of small real weights in the previous proposition is not an essential restriction on the exponent. The following rounding argument records the quantitative reason.

Lemma III.2.10 (Rounding a bounded weight in a cube norm). *Let $p : G \rightarrow [0, 1]$ and $d \geq 2$, and choose a random subset A by including the elements of G independently with probabilities $p(x)$. For $e = \mathbf{1}_A - p$ and $m = 2^d$,*

$$\mathbb{E}_A \|e\|_{U^d}^m \leq \frac{\binom{m}{2}}{|G|}. \quad (\text{III.2.25})$$

Here $\mathbb{E}_A$ denotes expectation over the choice of the set, distinct from the averages over group elements.

Proof. Expand the Gowers norm as a cube average. When its m vertex values are pairwise distinct, independence and $\mathbb{E}_A e(x) = 0$ show that the expected product is zero. Every other product has absolute value at most one. For distinct vertices $u, v \in V_d$, the difference $L_u - L_v$ has a coefficient 1 or -1 on at least one of the independent variables h_i , and is therefore uniform on G . The probability of a collision between this pair is $|G|^{-1}$. The union bound over pairs proves (III.2.25). $\square$

Corollary III.2.11 (Optimal order and universal constant for sets). *For every fixed $d \geq 2$ and $0 < \delta < 1$, there are finite abelian groups G_n with $|G_n| \rightarrow \infty$ and subsets $A_n \subseteq G_n$ whose densities δ_n tend to δ , such that, writing $\eta_n = \|\mathbf{1}_{A_n} - \delta_n\|_{U^d}$, we have $\eta_n \rightarrow 0$ and*

$$\frac{Q_d(\mathbf{1}_{A_n}) - \delta_n^m}{\delta_n^{m-4} \eta_n^4} \rightarrow K_d. \quad (\text{III.2.26})$$

If the groups are required to have odd order, the power four is still optimal, although this argument does not identify the best leading constant in that restricted setting.

Proof. First take $G_n = (\mathbb{Z}/2\mathbb{Z})^n$, $N = |G_n|$, and a nontrivial real character χ_n . Put $t = N^{-1/(10m)}$ and $p = \delta + t\chi_n$, which lies in $[0, 1]$ for large n . Lemma III.2.10 and Markov's inequality give a realization of A_n with

$$\|\mathbf{1}_{A_n} - p\|_{U^d} \leq N^{-1/(2m)} = t^5$$

for all sufficiently large n , since the failure probability is at most $\binom{m}{2}N^{-1/2}$. The inequality $|\mathbb{E}e| \leq \|e\|_{U^d}$ implies $|\delta_n - \delta| \leq t^5$. After centering, the error in U^d is at most $2t^5$, so $\eta_n = t + O(t^5)$.

Both $\mathbf{1}_{A_n}$ and p have U^d norm at most one. The norm triangle inequality and $|a^m - b^m| \leq m|a - b|$ for $a, b \in [0, 1]$ show that

$$|Q_d(\mathbf{1}_{A_n}) - Q_d(p)| \leq mt^5.$$

The change from δ^m to δ_n^m is at most mt^5 as well. Combining these estimates with (III.2.23) proves (III.2.26).

For odd-order groups use $G_n = (\mathbb{Z}/3\mathbb{Z})^n$ and let g_n be the cosine of a nontrivial character. Its U^d norm is the same fixed positive number as the function g on $\mathbb{Z}/3\mathbb{Z}$ in Proposition III.2.8. Round $p = \delta + N^{-1/(10m)}g_n$ in exactly the same way. Equation (III.2.22) gives a strictly positive limit after division by η_n^4 . Consequently no exponent greater than four can hold uniformly even for characteristic functions on odd-order groups. $\square$

[write] **6 October 2026; sources 15–20.** Proved again by source 18 (Theorem III.40.12) and, for sets of exact density $1/3$ in odd cyclic groups, by source 16 (Proposition III.39.10).

Corollary III.2.12 (Exactly prescribed compatible rational densities). *If $0 < \delta < 1$ is rational, the sharp universal limit in (III.2.26) can be achieved with $\delta_n = \delta$ for every n . If the denominator of δ is odd, the odd-order sharpness of the fourth power can likewise be achieved at exactly that density.*

Proof. Write $\delta = a/q$ and use $G_n = (\mathbb{Z}/q\mathbb{Z}) \times (\mathbb{Z}/2\mathbb{Z})^n$, so $N = |G_n|$ makes δN an integer. Let χ_n be a nontrivial real character, put $t = N^{-1/(10m^2)}$, and round $p = \delta + t\chi_n$. The same Markov argument as before gives a realization A with

$$\|\mathbf{1}_A - p\|_{U^d} \leq N^{-1/(2m)} = t^{5m}.$$

Its density differs from δ by at most t^{5m} . Add or remove at most Nt^{5m} memberships to obtain a set B of cardinality exactly δN . If $e = \mathbf{1}_B - \mathbf{1}_A$ is supported on a fraction θ of the group, then $|e| \leq 1$ and

$$\|e\|_{U^d}^m \leq \mathbb{E}_{x,h} \left| \prod_v e(L_v(x, h)) \right| \leq \mathbb{E}_x \mathbf{1}_{\text{supp } e}(x) = \theta.$$

Thus the alteration costs at most t^5 in U^d norm. We obtain $\|\mathbf{1}_B - p\|_{U^d} = O(t^5)$, $\|\mathbf{1}_B - \delta\|_{U^d} = t + O(t^5)$, and $Q_d(\mathbf{1}_B) = Q_d(p) + O(t^5)$. Equation (III.2.23) gives the required limit. If q is odd, replace the second factor of G_n by $(\mathbb{Z}/3\mathbb{Z})^n$ and use the cosine of an order-three character. The same alteration argument and (III.2.22) prove optimality of the fourth power on odd-order groups at exactly the chosen density. $\square$

III.2.7 An exact formula for every higher coefficient

The fourth-order theorem is the first nontrivial instance of a complete Fourier description of the centered expansion. For a support $S \subseteq V_d$, define

$$\mathcal{K}_S(G) = \left\{ (\chi_v)_{v \in S} \in (\widehat{G} \setminus \{1\})^S : \prod_{v \in S} \chi_v = 1, \quad \prod_{v \in S} \chi_v^{v_i} = 1 \ (1 \leq i \leq d) \right\}.$$

All assigned characters are required to be nontrivial because f is centered. Character orthogonality gives the exact identity

$$M_S(f) = \sum_{(\chi_v) \in \mathcal{K}_S(G)} \prod_{v \in S} \widehat{f}(\chi_v). \quad (\text{III.2.27})$$

To prove it, expand each factor in (III.2.2); averaging over x gives the first character equation, and averaging over h_i gives the equation indexed by i . These equations are also sufficient for a Fourier term to survive. This is a finite exact formula, and it is valid without assumptions on the exponent or rank of G .

For groups of prime exponent, the equations can be studied as linear relations among the vectors $(1, v)$ over the prime field. For general finite abelian groups, their integer relation matrices and Smith invariant factors retain the additional torsion information. At four vertices, the only nontrivial invariant factor that can arise is two; this is why the single quotient energy in (III.2.8) suffices. Higher coefficients offer a concrete continuation: classify their support matrices, remove the supports for which (III.2.27) is empty, and estimate the remaining explicit Fourier correlations. The formula supplies an algorithmic route without assuming that the resulting classification will have a simple closed form.

III.2.8 The fifth-order remainder is also necessary

Proposition III.2.13 (Sharp order of the remainder). *Fix $d \geq 3$ and $0 < \delta < 1$. For weights $F : G \rightarrow [0, 1]$ on odd-order finite abelian groups, the remainder after the exact fourth-order term in Theorem III.2.6 cannot in general be bounded by $O_{d,\delta}(\|F - \delta\|_{U^d}^q)$ for any $q > 5$.*

Proof. Let $G = \mathbb{Z}/3\mathbb{Z}$, $g(x) = \cos(2\pi x/3)$, and $F_t = \delta + tg$ for positive sufficiently small t . Both nontrivial Fourier coefficients of g equal $1/2$, and its trivial coefficient is zero. Fourier expansion and character orthogonality show that every support moment $M_S(g)$ is nonnegative: each surviving term is a product of nonnegative Fourier coefficients.

In dimension at least three, consider the five-vertex support

$$S = \{0, e_1, e_2, e_3, e_1 + e_2 + e_3\}.$$

Its moment is

$$\mathbb{E}_{x,a,b,c} g(x)g(x+a)g(x+b)g(x+c)g(x+a+b+c) = \frac{1}{16}.$$

Indeed, assigning a nontrivial character χ to the last factor forces the three middle characters to be χ^{-1} and the first character to be χ^2 . Each of the two choices for χ therefore contributes $(1/2)^5$. Consequently

$$c_d := \sum_{|S|=5} M_S(g) \geq \frac{1}{16} > 0.$$

The exact finite expansion gives

$$\mathcal{R}_d(F_t) = c_d \delta^{m-5} t^5 + O_{d,\delta}(t^6),$$

whereas $\|F_t - \delta\|_{U^d} = t \|g\|_{U^d}$. Since $\|g\|_{U^d} > 0$, no exponent $q > 5$ can hold. $\square$

In dimension three the entire polynomial is especially simple:

$$Q_3(\delta + tg) = \delta^8 + \frac{3}{2}\delta^4 t^4 + \frac{1}{2}\delta^3 t^5 + \frac{1}{2}\delta^2 t^6 + \frac{1}{32}t^8. \quad (\text{III.2.28})$$

For a direct verification, put $a = \delta + t$ and $b = \delta - t/2$, the two possible weight values. Group the triples (h_1, h_2, h_3) by their number r of nonzero entries. Coordinate reflections allow each nonzero difference to be replaced by 1 when summing over x . For $r = 0, 1, 2, 3$ there are respectively 1, 6, 12, 8 difference triples, and their sums over x are respectively

$$a^8 + 2b^8, \quad 2a^4b^4 + b^8, \quad a^4b^4 + 2a^2b^6, \quad a^2b^6 + 2a^3b^5.$$

It follows that

$$81Q_3(F_t) = a^8 + 8b^8 + 24a^4b^4 + 32a^2b^6 + 16a^3b^5.$$

Substitution and expansion give (III.2.28). Its t^5 coefficient supplies a concrete witness to Proposition III.2.13.

[write] 6 October 2026. (III.2.28) is identical to source 04's (III.3.19), computed there by counting the 81 cube parameters by the number of vertices at 0; credited to both. The five-vertex support S above is the representative $\{000, 100, 010, 001, 111\}$ of source 04's eight surviving quintic supports (Lemma III.3.3), so $M_S(g) = B_5(g)$; the value $1/16$ is (III.3.8) with $a_{\pm 1} = 1/2$ and $2\xi = -\xi$ on $\mathbb{Z}/3\mathbb{Z}$.

Replacing t by $-t$ in (III.2.28) makes its fifth-order term negative. For sufficiently small positive t , this gives

$$Q_3(\delta - tg) < \delta^8 + 12\delta^4 \|tg\|_{U^2}^4.$$

Thus the exact quartic term is not, by itself, an unconditional lower bound for the whole excess; the sign of the remainder matters.

Remark W1 (The quartic lower bound with coefficient 12 is false; second write, 6 October 2026). For real $F = \delta + f$ with $\mathbb{E}f = 0$ on an odd-order group, the exact quartic term invites the lower bound

$$Q_3(F) \stackrel{?}{\geq} \delta^8 + 12\delta^4 \|f\|_{U^2}^4 \quad (0 \leq F \leq 1).$$

It is false. The display above shows this on $\mathbb{Z}/3\mathbb{Z}$ for sufficiently small t (source 03). Source 08 (Theorem III.10.1) and source 09 (Proposition III.22.2) prove it on $\mathbb{Z}/11\mathbb{Z}$ and on $\mathbb{Z}/q\mathbb{Z}$ for every prime $q \geq 17$, and source 08 gives an explicit instance with comfortable margins. *Counterexample.* On $G = \mathbb{Z}/11\mathbb{Z}$ let $h(x) = \cos(2\pi x/11) - \cos(4\pi x/11)$, $\delta = 1/2$, $\eta = 1/12$ and $F = \delta + \eta h$, so $1/3 \leq F \leq 2/3$. The nonzero Fourier coefficients of h are $\hat{h}(\pm 1) = 1/2$ and $\hat{h}(\pm 2) = -1/2$, so $\|\eta h\|_{U^2}^4 = \eta^4/4$, and the exact cube polynomial is

$$Q_3(\delta + \eta h) = \delta^8 + 3\delta^4 \eta^4 - \frac{1}{2}\delta^3 \eta^5 + \frac{3}{2}\delta^2 \eta^6 + \frac{1}{4}\eta^8.$$

Hence $(Q_3(F) - \delta^8)/(\delta^4 \|F - \delta\|_{U^2}^4) = 12 - 2s + 6s^2 + s^4$ with $s = \eta/\delta = 1/6$, which equals $15337/1296 \approx 11.834 < 12$. The polynomial is source 08's (III.10.3) and source 09's (III.22.4) at $\sigma = -1$. *Independent check at the write:* the polynomial was recomputed exactly by summing the Fourier products over all 11^4 free frequency choices of the eight cube vertices (exact rational arithmetic), and the value $Q_3(F) = 0.0039151672\dots$ was confirmed by direct floating-point summation over all 11^4 cubes. What survives is the lower bound $Q_3(F) - \delta^8 \geq 2\delta^4 \|f\|_{U^2}^4$ (source 08's (III.12.2)); the best constant lies in $[2, 15337/1296]$ (source 08's question, Section V.2, item III.10).

III.2.9 A five-vertex correlation that detects order three

The next evaluated support illustrates why a higher-order classification will require more than the order-two energy. Consider the five vertices

$$S_3 = \{0000, 1110, 1101, 1011, 0111\} \subseteq \{0, 1\}^4.$$

For every real centered function f on a finite abelian group,

$$M_{S_3}(f) = \sum_{\substack{\chi \neq 1 \\ \chi^3 = 1}} \hat{f}(\chi)^4 \overline{\hat{f}(\chi)}. \quad (\text{III.2.29})$$

Here the four nonzero vertices are the all-ones vector with one entry removed. To prove (III.2.29), assign characters $\chi_0, \chi_1, \dots, \chi_4$ to the five factors, with χ_j corresponding to the vertex omitting coordinate j . Averaging over h_j imposes $\prod_{i \neq j, i \geq 1} \chi_i = 1$. Dividing any two such equations shows $\chi_1 = \dots = \chi_4 = \chi$; each equation then says $\chi^3 = 1$. The x -equation gives $\chi_0 = \chi^{-1}$. Fourier inversion and real-valuedness of f yield the formula.

This correlation vanishes if 3 does not divide $|G|$. On $\mathbb{Z}/3\mathbb{Z}$ with $f(x) = \cos(2\pi x/3)$ it equals $1/16$, and replacing f by $-f$ changes it to $-1/16$. In particular it is not a nonnegative energy of the fourth-order kind. We have evaluated this one support; we do not assert that it exhausts all possible fifth-order types.

[write] **6 October 2026; sources 06–10.** *The fifth order is now classified (source 09).* Source 09's Theorem III.20.1 shows, on every finite abelian group and in every dimension, that a five-vertex centered moment can be nonzero only for two support types up to cube symmetry: the star $\{0, u, v, w, u + v + w\}$, whose moment is source 04's $B_5(f)$ ((III.3.5); source 08's S_5), and the ternary type $\{0, u + v + w, u + v + z, u + w + z, v + w + z\}$, whose moment is (III.2.29) (source 09's $T_{3,5}$). The support S_3 above is the ternary type with one coordinate per block; the support S in Proposition III.2.13 is a star. Source 09's Theorem III.21.1 gives the exact fifth-order coefficient $\delta^{m-5}(Q_d M_5 + S_d T_{3,5})$ with $Q_d = 2^d \binom{d+1}{4}$ and $S_d = 2^d \binom{d+1}{5}$. The four-vertex Smith types of Remark III.2.4 agree with source 09's Theorem III.19.1 (indices one and two only), and source 08's Lemma III.8.1 proves the same classification. At six vertices source 09's Theorem III.23.1 exhibits a support with row-lattice index five (checked at the write: $\det B = -5$, $M_S r = (10, 5, 5, 5, 5, 5)$, Smith form $1, 1, 1, 1, 1, 5$), so order-five torsion enters at order six. The exact quartic term of Theorem III.2.6 is also proved independently by source 08 (Theorem III.8.3) and source 09 (Theorem III.21.1), with the same coefficients (R_d, T_d ; source 09 writes P_d) and the same order-two energy.

III.3 Sharp centered refinements of the cube-counting lemma

Source 04, delivered Section 6.

Gowers' Lemma 3.10 bounds the number of d -dimensional cubes by applying the triangle inequality to the constant and balanced parts of an indicator. Centering contains additional information that this application of the triangle inequality discards. We retain it, first by identifying correlations that vanish, and then by proving a sharp comparison between the second and third uniformity norms of real centered functions. These results strengthen the stated cube-counting lemma; no historical priority beyond that comparison is asserted. As Gowers explains, this lemma is supplementary to his main density-increment argument, so an improvement here does not by itself imply an improved global bound in Szemerédi's theorem.

Throughout this section, averages on a finite abelian group G are normalized. For $d \geq 2$, put $q = 2^d$, $V_d = \{0, 1\}^d$, and

$$L_v(x, h) = x + v \cdot h, \quad Q_d(W) = \mathbb{E}_{x, h_1, \dots, h_d \in G} \prod_{v \in V_d} W(L_v(x, h)).$$

For real W , conjugation has no effect, so $Q_d(W) = \|W\|_{U^d}^q$. For an indicator, $|G|^{d+1} Q_d(1_A)$ is exactly Gowers' ordered cube count, including degenerate cubes. Write $W = \delta + f$, where $\delta \geq 0$, f is real, and $\mathbb{E}f = 0$; these are standing assumptions throughout the section. Set $u = \|f\|_{U^d}$. No bound on f is needed for the inequalities below.

III.3.1 Cancellation, parallelograms, and support counts

Lemma III.3.1 (Cancellation through degree three). *Any at most three distinct forms L_v are jointly uniform on the corresponding power of G , for every finite abelian group G . Consequently, if $\delta \geq 0$,*

$$|Q_d(\delta + f) - \delta^q| \leq \sum_{r=4}^q \binom{q}{r} \delta^{q-r} u^r. \quad (\text{III.3.1})$$

Proof. Reflect coordinates of the Boolean cube to move the first selected vertex to 0; these reflections correspond to invertible changes of the averaging variables. For three vertices the others are distinct nonzero Boolean vectors a, b . Two coordinates give a 2×2 minor of the matrix with rows a, b equal

to 1 or -1 : use two coordinates distinguishing their supports, or one in their intersection and one in their difference if the supports are nested. Thus the map to $(x, x + a \cdot h, x + b \cdot h)$ is surjective, with equally sized fibers, on every abelian group. The cases of one or two vertices are immediate.

Expand the cube product according to the support on which f is chosen. Every term with one, two, or three factors of f vanishes. For a support of size r , the cube Cauchy–Schwarz inequality, with constant 1 at all other vertices, bounds its correlation in absolute value by u^r . Summation proves the assertion. $\square$

[write] **6 October 2026.** Lemma III.3.1 has the same statement and bound as source 03’s Lemma III.2.1 with Corollary III.2.2 (this u is 03’s η , this $q = 2^d$ is 03’s m). Second route: source 03 uses coordinate reflections, this proof joint uniformity through 2×2 minors. Credited to both.

Odd group order permits a much more precise fourth-order term.

Proposition III.3.2 (Exact quartic coefficient). *Suppose $|G|$ is odd, and put $v = \|f\|_{U^2}$. Then*

$$Q_d(\delta + f) = \delta^q + P_d \delta^{q-4} v^4 + R_d, \quad (\text{III.3.2})$$

$$|R_d| \leq \sum_{r=5}^q \binom{q}{r} \delta^{q-r} u^r, \quad (\text{III.3.3})$$

$$P_d = 2^{d-3} (3^d - 2^{d+1} + 1). \quad (\text{III.3.4})$$

In particular, $P_2 = 1$, $P_3 = 12$, $P_4 = 100$, and $P_5 = 720$.

Proof. Four distinct Boolean vertices are either affinely independent or form a parallelogram. Indeed, any three are affinely independent. If four are dependent, their affine span is a plane, and some projection onto two coordinate axes is injective on that plane. The four images must be all four vertices of the unit square. The affine inverse of this projection preserves its parallelogram relation.

If the four vertices are independent, a 3×3 Boolean minor after this translation has determinant ± 1 or ± 2 . The determinant bound follows by adjoining a row and column of ones, changing binary entries b to $1 - 2b$, and applying Hadamard’s inequality to the resulting 4×4 matrix. Multiplication by either determinant is invertible on an odd-order group. Thus the four forms are jointly uniform and their centered correlation is zero. On a parallelogram, any three forms are jointly uniform by Lemma III.3.1, while the fourth is their alternating sum. Its correlation is therefore exactly v^4 .

To count parallelograms, choose the k coordinates in which a pair of opposite vertices differs and fix the other coordinates. Around that center there are 2^{k-1} opposite pairs; choose two of them. The diagonal midpoint is unique, so

$$P_d = \sum_{k=2}^d \binom{d}{k} 2^{d-k} \binom{2^{k-1}}{2} = 2^{d-3} (3^d - 2^{d+1} + 1).$$

Bound the terms of degree at least five by cube Cauchy–Schwarz as before. $\square$

[write] **6 October 2026.** Proposition III.3.2 is the odd-order case of source 03’s Theorem III.2.6, which holds on every finite abelian group with the extra term $T_d \delta^{q-4} \mathcal{E}_{(2)}(f)$; that term vanishes on odd-order groups by (III.2.10). This P_d is source 03’s R_d : $2^{d-3} (3^d - 2^{d+1} + 1) = (6^d - 2 \cdot 4^d + 2^d)/8$ (both give 1, 12, 100, 720). Second route: affine independence and Boolean minors $\pm 1, \pm 2$ in place of source 03’s XOR classification. Do not read this remainder R_d as source 03’s count R_d , or as the binomial sum $R_d(H)$ of Section IV.6 (Section F.3).

A general organizing principle is useful. Over $G = \mathbb{F}_p^n$, consider the vector matroid of the coefficient vectors $(1, v)$. If a selected support has a coloop, its centered correlation vanishes. Indeed, linear algebra gives a direction on which that form has coefficient 1 and all other selected forms have coefficient 0. Averaging along that direction averages one factor of f to zero. Thus only supports with no coloop need to be counted.

For $d = 3$ this count can be made completely explicit, and the result also holds on every odd-order abelian group.

Lemma III.3.3 (The surviving supports of a 3-cube). *Suppose that G has odd order. The numbers of supports with no coloop, in sizes $0, 1, \dots, 8$, are*

$$1, 0, 0, 0, 12, 8, 28, 8, 1.$$

All twelve quartic correlations equal $\|f\|_{U^2}^4$. The eight quintic correlations are equal to

$$B_5(f) = \mathbb{E}_{x,a,b,c} f(x)f(x+a)f(x+b)f(x+c)f(x+a+b+c). \quad (\text{III.3.5})$$

Consequently, with $u = \|f\|_{U^3}$ and $v = \|f\|_{U^2}$,

$$Q_3(\delta + f) = \delta^8 + 12\delta^4 v^4 + 8\delta^3 B_5(f) + R_6 + R_7 + u^8, \quad (\text{III.3.6})$$

$$|R_6| \leq 28\delta^2 u^6, \quad |R_7| \leq 8\delta u^7. \quad (\text{III.3.7})$$

Proof. The twelve coplanar quadruples are the six faces and six diagonal rectangles. A plane contains at most four Boolean vertices: some projection onto two coordinate axes is injective on the plane, and its Boolean image has at most four points. A five-set therefore has rank four and has a coloop exactly when it contains a coplanar quadruple. Each of the twelve quadruples has four extensions to a five-set. No five-set contains two such quadruples, since distinct planes meet in a line and a line contains at most two Boolean vertices. Thus $\binom{8}{5} - 12 \cdot 4 = 8$ five-sets survive. Every set of size at least six remains rank four after a deletion.

The eight surviving five-sets consist of one parity tetrahedron and one vertex of the opposite parity. Cube symmetries act transitively on them; a representative is $\{000, 100, 010, 001, 111\}$. The corresponding changes of averaging variables prove (III.3.5). These arguments remain valid on odd-order groups: any four independent cube forms have a minor ± 1 or ± 2 , hence are jointly uniform; an extra vertex outside a parallelogram is therefore independent of its three determining forms. Finally apply cube Cauchy–Schwarz to the 28 sextic and 8 septic supports. $\square$

For comparison, in characteristic two the support counts are $1, 0, 0, 0, 14, 0, 28, 8, 1$: the parity tetrahedra become two additional affine planes. The odd-order hypothesis is therefore a substantive restriction.

[write] 6 October 2026; sources 06–10. *The complete three-cube polynomial in two more sources.* Source 08’s Theorem III.9.2 proves the exact identity behind (III.3.6) on every odd-order group, $Q_3(\delta + f) = \delta^8 + 12\delta^4 v^4 + 8\delta^3 S_5(f) + \delta^2(12A_6 + 12B_6 + 4C_6) + 8\delta A_7 + Q_3(f)$, with the same support counts $12, 8, 28, 8, 1$; its S_5 is B_5 here (the summands of the two Fourier forms are complex conjugates, and the sums are real). Source 09’s Theorem III.21.1 at $d = 3$ gives $\delta^4(12E_4 + 2T_2) + 8\delta^3 M_5$ on every finite abelian group; its T_2 vanishes in odd order. The characteristic-two counts 14 quartic supports above agree with source 08’s $F_3 = 14$ and source 09’s $A_3 = 14$. Sources 08 and 09 bound the quartic term by $12\delta^4 u^4$ in odd order; Theorem III.3.6 below has the sharp $6\sqrt{2}$.

III.3.2 A sharp gap between the real centered U^2 and U^3 norms

Use normalized Fourier coefficients

$$a_\xi = \widehat{f}(\xi) = \mathbb{E}_{x \in G} f(x) \overline{\xi(x)}, \quad \xi \in \widehat{G},$$

and write the dual group additively. Fourier inversion in (III.3.5) gives

$$B_5(f) = \sum_{\xi \in \widehat{G}} a_{2\xi} a_{-\xi}^3 a_\xi. \quad (\text{III.3.8})$$

For real centered f on an odd-order group, $a_{-\xi} = \overline{a_\xi}$, $a_0 = 0$, and the nonzero coefficients occur in distinct pairs. Therefore, with $\rho = \max_\xi |a_\xi|$,

$$|B_5(f)| \leq \rho \|f\|_{U^2}^4 \leq 2^{-1/4} \|f\|_{U^2}^5. \quad (\text{III.3.9})$$

Theorem III.3.4 (Sharp real centered norm gap). *Let G have odd order and let $f : G \rightarrow \mathbb{R}$ have mean zero. Then*

$$\|f\|_{U^3}^8 \geq 2 \|f\|_{U^2}^8. \quad (\text{III.3.10})$$

For nonzero f , equality holds exactly when

$$f(x) = 2 \operatorname{Re}(c \xi(x))$$

for a nontrivial character ξ and a nonzero complex number c .

Proof. We first use the Fourier identity

$$\begin{aligned} \|f\|_{U^3}^8 &= \sum_{s, t \in \widehat{G}} |T(s, t)|^2, \\ T(s, t) &= \sum_{r \in \widehat{G}} a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}. \end{aligned} \quad (\text{III.3.11})$$

The Fourier coefficients are normalized, but all sums in (III.3.11) are unnormalized. To verify the identity, expand the original cube in Fourier series. The four orthogonality equations say precisely that its frequency variables form an affine cube:

$$r_v = r_{000} + v_1(r_{100} - r_{000}) + v_2(r_{010} - r_{000}) + v_3(r_{001} - r_{000}).$$

These equations are solved without division. Grouping the two parallel faces gives (III.3.11).

Put

$$\lambda_r = |a_r|^2, \quad S = \sum_r \lambda_r^2 = \|f\|_{U^2}^4, \quad M = \sum_r \lambda_r^4.$$

Retain only the two coordinate axes in the nonnegative sum (III.3.11). Since $T(0, t) = \sum_r \lambda_r \lambda_{r+t}$, this gives

$$\|f\|_{U^3}^8 \geq 2\mathcal{E}(\lambda) - S^2, \quad \mathcal{E}(\lambda) = \sum_{r+s=t+w} \lambda_r \lambda_s \lambda_t \lambda_w. \quad (\text{III.3.12})$$

The subtraction corrects the double counting of the origin.

The energy summands are nonnegative. Retain the union of three families:

$$\begin{aligned} \mathcal{A}: & \quad r = t, \quad s = w, \\ \mathcal{B}: & \quad r = w, \quad s = t, \\ \mathcal{C}: & \quad s = -r, \quad w = -t. \end{aligned}$$

Each family contributes S^2 , because λ is even. Each pairwise intersection contributes M . Their triple intersection has $2r = 0$; odd group order and $\lambda_0 = 0$ make its contribution zero. Thus

$$\mathcal{E}(\lambda) \geq 3S^2 - 3M,$$

and hence

$$\|f\|_{U^3}^8 \geq 5S^2 - 6M. \quad (\text{III.3.13})$$

Group nonzero frequencies into pairs $\{r, -r\}$, and let b_j denote λ_r^2 for a representative of each pair. Then

$$S = 2 \sum_j b_j, \quad M = 2 \sum_j b_j^2 \leq \frac{S^2}{2}.$$

This proves (III.3.10).

Equality in (III.3.10) forces equality in the last inequality, so only one Fourier pair can be nonzero. Conversely, a parallelogram on a two-point subset of an odd-order group is degenerate in at least one direction. If the Fourier support is $\{\xi, -\xi\}$, all nonzero terms in (III.3.11) therefore lie on its coordinate axes. Directly, the two norm powers are $8|a_\xi|^8$ and $4|a_\xi|^8$, respectively. $\square$

[write] 6 October 2026. *This answers source 03's Research question V.14.1 for $d = 3$ (cross-source finding of the intake; proof at the write).* Let G have odd order and $f : G \rightarrow \mathbb{R}$ be centered and nonzero; then $|G| \geq 3$, since on the trivial group a centered function vanishes. By (III.3.10),

$$\frac{\|f\|_{U^2}^4}{\|f\|_{U^3}^4} = \left(\frac{\|f\|_{U^2}^8}{\|f\|_{U^3}^8} \right)^{1/2} \leq 2^{-1/2},$$

with equality exactly for $f = 2 \operatorname{Re}(c\xi)$, ξ a nontrivial character and $c \neq 0$; such f exist on every odd-order group with $|G| \geq 3$. Hence $c_3^{\text{odd}} = 2^{-1/2}$, the supremum is attained, and the attaining functions are the real parts of characters. The best odd-order leading coefficient in source 03's reduction is $R_3 c_3^{\text{odd}} = 12 \cdot 2^{-1/2} = 6\sqrt{2}$, which is Theorem III.3.6 with Proposition III.3.7. This also settles source 03's Remark III.2.9 at $d = 3$: $R_3 = 12$ is not the optimal odd-order constant, $6\sqrt{2}$ is. For $d \geq 4$ the question is open; it is source 04's own Question 3 (Section V.2, item III.1).

[write] 6 October 2026; sources 11–14. Source 14 reproves this gap and the leading term $6\sqrt{2}$ (its Section III.34, equation (III.34.8)) on the way to the exact secondary coefficient.

[write] 6 October 2026; sources 15–20. Source 18 asks for the best odd-order fourth-order coefficient “especially in dimension four” (its Question 7) without citing this theorem, which settles $d = 3$. Source 16's Proposition III.39.8 reproves the bound on B_5 with $2^{-1/4}$ and adds $2^{-1/2}$ without three-torsion.

[write] 6 October 2026; sources 28–33. *Advanced for $d \geq 4$, not settled* (sources 28 and 29, Section III.66). Source 29 proves $\|f\|_{U^d}^{2^d} \geq 2^{-m} \binom{2m}{m} \|f\|_{U^2}^{2^d}$, $m = 2^{d-2}$, hence $c_4^{\text{odd}} \leq (8/35)^{1/4}$ and $c_d^{\text{odd}} \leq B_d \downarrow 1/2$, and $c_d^{\text{odd}} \geq 1/3$ for every d (Corollary III.69.1, Proposition III.69.2); source 28 proves $c_4^{\text{odd}} \geq 0.5587294$ and that a real part of a character is not extremal for $d \geq 4$ (Corollary III.70.8, Theorem III.70.9); the intake's certificate gives $c_4^{\text{odd}} \geq 0.5587725$. So $0.5587725 \leq c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ among sources 01–33; later placed sources record better upper bounds (item III.1).

[write] 6 October 2026; sources 34–39. *The upper end improved again* (sources 34 and 35, Sections III.71–III.72). Source 34 proves $\|f\|_{U^2}^4 \leq (2/3) \|f\|_{U^4}^4$, that is the coefficient $81/16$ in source 29's normalization (Theorem III.71.1); source 35, the same day, proves the coefficient 5 (Theorem III.72.1); for $5 \leq d \leq 8$ source 34's coupled bounds slightly improve source 29's (Remark III.71.10). So $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$ among sources 01–39; source 45, placed and not yet written, records $(832/4795)^{1/4} = 0.6454070$ (item III.1).

[write] **7 October 2026; sources 40–46.** *The upper end improved again* (source 45, Section III.89): $\|f\|_{U^4}^{16} \geq (4795/832) \|f\|_{U^2}^{16}$ (Theorem III.90.1), so $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ among sources 01–46; source 49, placed by f8bc5e2ec and not yet written in, records $29/4$, that is $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$ (for its write) (item III.1).

Corollary III.3.5 (Stability of the norm gap). *Suppose that G has odd order. If $f \neq 0$, $0 \leq \varepsilon < 3$, and*

$$\|f\|_{U^3}^8 \leq (2 + \varepsilon) \|f\|_{U^2}^8,$$

then some nontrivial character ξ , with $c = \widehat{f}(\xi)$, satisfies

$$\|f - 2 \operatorname{Re}(c\xi)\|_{U^2} \leq (\varepsilon/3)^{1/4} \|f\|_{U^2}. \quad (\text{III.3.14})$$

Proof. Equation (III.3.13) implies $M/S^2 \geq 1/2 - \varepsilon/6$. For the pair masses $p_j = 2b_j/S$, we have $\sum_j p_j = 1$ and $\sum_j p_j^2 \geq 1 - \varepsilon/3$. Since $\max_j p_j \geq \sum_j p_j^2$, one pair carries at least $1 - \varepsilon/3$ of the Fourier fourth-power mass. Removing it and using the Fourier formula for U^2 proves the claim. $\square$

This is a statement of stability in U^2 , not an assertion of approximation in L^2 . A large amount of Fourier square mass can be spread over many small coefficients.

III.3.3 The sharp leading cube bound and its models

Theorem III.3.6 (Refined form of Lemma 3.10 in dimension three). *Let G have odd order, $f : G \rightarrow \mathbb{R}$ have mean zero, $\delta \geq 0$, and $u = \|f\|_{U^3}$. Then*

$$\begin{aligned} Q_3(\delta + f) &\leq \delta^8 + 6\sqrt{2}\delta^4 u^4 + 2^{17/8}\delta^3 u^5 \\ &\quad + 28\delta^2 u^6 + 8\delta u^7 + u^8. \end{aligned} \quad (\text{III.3.15})$$

Consequently, if A is α -uniform of degree two in Gowers' convention,

$$\begin{aligned} Q_3(1_A) &\leq \delta^8 + 6\sqrt{2}\delta^4 \alpha^{1/2} + 2^{17/8}\delta^3 \alpha^{5/8} \\ &\quad + 28\delta^2 \alpha^{3/4} + 8\delta \alpha^{7/8} + \alpha. \end{aligned} \quad (\text{III.3.16})$$

Proof. In (III.3.6), use $v^4 \leq u^4/\sqrt{2}$ from Theorem III.3.4 and

$$|B_5(f)| \leq 2^{-1/4} v^5 \leq 2^{-7/8} u^5.$$

The remainder bounds give (III.3.15). Gowers' parameter satisfies $u^8 \leq \alpha$, which yields (III.3.16). $\square$

The leading error at fixed density is now $\alpha^{1/2}$, with an optimal constant, in place of the $\alpha^{1/8}$ term in $(\delta + \alpha^{1/8})^8$. In higher dimensions, monotonicity and Theorem III.3.4 similarly improve the quartic term in Proposition III.3.2 to $P_d \delta^{q-4} u^4 / \sqrt{2}$ for $d \geq 3$; sharpness of that higher-dimensional constant is not established here.

Proposition III.3.7 (An exact model for the leading constant). *Let $p > 8$ be prime and $f(x) = t \cos(2\pi x/p)$ on $\mathbb{Z}/p\mathbb{Z}$. Then*

$$\|f\|_{U^2}^4 = t^4/8, \quad \|f\|_{U^3}^8 = t^8/32, \quad (\text{III.3.17})$$

$$Q_3(\delta + f) = \delta^8 + \tfrac{3}{2}\delta^4 t^4 + t^8/32 = \delta^8 + 6\sqrt{2}\delta^4 u^4 + u^8. \quad (\text{III.3.18})$$

For $0 < t \leq \min(\delta, 1 - \delta)$ this is a weight in $[0, 1]$.

Proof. The Fourier support is $\{1, -1\}$, with coefficients $t/2$. Odd-degree terms vanish, since an odd number of signs cannot sum to zero and $p > 8$ prevents modular aliasing. A six-set omits two distinct vertices. In a coordinate where those vertices differ, the selected set has exactly three ones, so no signed zero sum is possible there either.

In the full eight-vertex term, the positive-sign four-set must have two ones in each coordinate. There are exactly eight choices: six unions of two opposite-vertex pairs, and the two parity tetrahedra. To see completeness, if one opposite pair occurs, the remaining two vertices must also be opposite; otherwise, reflecting a selected vertex to 000 forces the other three to be 110, 101, 011. Thus the full term is $8(t/2)^8 = t^8/32$. The quartic term follows from Proposition III.3.2. $\square$

This proves that both the fourth power of u and its coefficient $6\sqrt{2}\delta^4$ are optimal. Moreover, a family attaining this leading coefficient as $u \rightarrow 0$ at fixed positive density must approach equality in Theorem III.3.4. Corollary III.3.5 then concentrates its Fourier fourth-power mass on one conjugate pair.

The next coefficient in (III.3.15) is also optimal over odd-order groups, but this assertion uses 3-torsion. On $\mathbb{Z}/3\mathbb{Z}$,

$$Q_3(\delta + t \cos(2\pi x/3)) = \delta^8 + \frac{3}{2}\delta^4 t^4 + \frac{1}{2}\delta^3 t^5 + \frac{1}{2}\delta^2 t^6 + t^8/32. \quad (\text{III.3.19})$$

For a direct verification, put $A = \delta + t$, $B = \delta - t/2$. Among the 81 cube parameters, the numbers with k vertices equal to zero are

k	0	2	3	4	8
number	8	32	16	24	1.

These counts follow by separating the cases of zero, one, two, or three nonzero increments. The cube count is therefore $(8B^8 + 32A^2B^6 + 16A^3B^5 + 24A^4B^4 + A^8)/81$; expansion gives (III.3.19). Since $u^8 = t^8/32$, its quintic term is exactly $2^{17/8}\delta^3 u^5$. This optimality is not asserted for large prime cyclic groups, where there is no 3-torsion.

[write] **6 October 2026.** (III.3.19) is identical to source 03's (III.2.28), computed there by grouping difference triples; credited to both.

III.3.4 Without 3-torsion: a sharp fractional correction exponent

The distinction just observed leads to a further refinement. The fifth-order correlation requires a frequency and its double. A function near equality in the sharp norm gap concentrates on a pair; without 3-torsion, doubling leaves that pair. Balancing the resulting loss and gain produces a fractional power.

Theorem III.3.8 (A correction of order $u^{16/3}$). *Suppose $|G|$ is coprime to 6, $\mathbb{E}f = 0$, f is real, and $\delta > 0$. With $u = \|f\|_{U^3}$,*

$$Q_3(\delta + f) \leq \delta^8 + 6\sqrt{2}\delta^4 u^4 + 6\delta^{8/3} u^{16/3} + 28\delta^2 u^6 + 8\delta u^7 + u^8. \quad (\text{III.3.20})$$

The exponent 16/3 cannot be increased after subtracting the sharp leading term. The coefficient 6 is an explicit upper bound, not a claimed optimal constant. In the parameter $\alpha = u^8$, the correction has order $\alpha^{2/3}$.

Proof. The zero function is immediate. Otherwise put $S = \|f\|_{U^2}^4$, choose a largest Fourier pair $\{\xi, -\xi\}$, and set

$$\rho = |a_\xi|, \quad z = 1 - \frac{2\rho^4}{S}, \quad D = zS = \sum_{r \notin \{\xi, -\xi\}} |a_r|^4.$$

Here $0 \leq z < 1$. Since $M = \sum_r |a_r|^8 \leq \rho^4 S = (1 - z)S^2/2$, (III.3.13) gives $u^8 \geq (2 + 3z)S^2$. The convex function $g(z) = (1 + 3z/2)^{-1/2}$ lies below its chord on $[0, 1]$, so

$$g(z) \leq 1 - (1 - \sqrt{2/5})z \leq 1 - z/3.$$

Consequently,

$$12\delta^4 S \leq 6\sqrt{2}\delta^4 u^4 - 2\sqrt{2}\delta^4 u^4 z. \quad (\text{III.3.21})$$

There is no 3-torsion, so 2ξ and -2ξ are outside the selected pair. The two selected terms of (III.3.8) contribute at most $2\rho^4(D/2)^{1/4}$ in absolute value; the other terms contribute at most ρD . Thus

$$\begin{aligned} |B_5(f)| &\leq 2^{-1/4} S^{5/4} ((1 - z)z^{1/4} + (1 - z)^{1/4} z) \\ &\leq 2^{3/4} S^{5/4} z^{1/4} \leq 2^{1/8} u^5 z^{1/4}. \end{aligned}$$

Combine this with (III.3.21). For $A, K > 0$,

$$\sup_{z \geq 0} (Kz^{1/4} - Az) = \frac{3K^{4/3}}{4^{4/3} A^{1/3}}.$$

Taking $A = 2\sqrt{2}\delta^4 u^4$ and $K = 2^{25/8}\delta^3 u^5$ makes the right side $6\delta^{8/3}u^{16/3}$. Inserting the remainder estimates from (III.3.7) proves (III.3.20). $\square$

Proposition III.3.9 (A two-frequency obstruction). *Fix $0 < \delta < 1$ and a prime $p > 16$. There are weights W_u on $\mathbb{Z}/p\mathbb{Z}$, with mean δ and $\|W_u - \delta\|_{U^3} = u$, such that, as $u \downarrow 0$,*

$$Q_3(W_u) - \delta^8 = 6\sqrt{2}\delta^4 u^4 + (9/4)^{1/3}\delta^{8/3}u^{16/3} + o_\delta(u^{16/3}). \quad (\text{III.3.22})$$

Proof. For $f(x) = a \cos(2\pi x/p) + b \cos(4\pi x/p)$, with $a, b > 0$, Fourier inversion gives

$$\|f\|_{U^3}^8 = \frac{a^8 + 6a^4 b^4 + b^8}{32}, \quad \|f\|_{U^2}^4 = \frac{a^4 + b^4}{8}, \quad B_5(f) = \frac{a^4 b}{16}. \quad (\text{III.3.23})$$

In fact there is the complete identity

$$\begin{aligned} Q_3(\delta + f) &= \delta^8 + \frac{3}{2}\delta^4(a^4 + b^4) + \frac{1}{2}\delta^3 a^4 b + \frac{3}{2}\delta^2 a^4 b^2 \\ &\quad + \frac{a^8 + 6a^4 b^4 + b^8}{32}. \end{aligned} \quad (\text{III.3.24})$$

Here is a finite counting proof of both this identity and the first formula in (III.3.23). Apply the Fourier cube identity (III.3.11) to $\delta + f$. Its frequency support is contained in $\{-2, -1, 0, 1, 2\}$, with coefficients $\delta, a/2, b/2$ at frequencies of absolute value 0, 1, 2, respectively. Since $p > 16$, the orthogonality equations have no modular aliasing, so the frequency variables are integer affine cubes in this five-point interval.

Reflecting directions with negative increments makes all increments nonnegative; their sum is at most four. Enumerate their nonzero magnitudes, choose their coordinate positions and signs, and

then choose the initial vertex between -2 and 2 minus their sum. The possibilities are the empty list, the singletons $(1), (2), (3), (4)$, the pairs $(1, 1), (1, 2), (1, 3), (2, 2)$, and the triples $(1, 1, 1), (1, 1, 2)$. If n_j is the number of vertices with frequency of absolute value j , this gives

(n_0, n_1, n_2)	number of frequency cubes
$(8, 0, 0)$	1
$(4, 4, 0)$	24
$(4, 0, 4)$	24
$(3, 4, 1)$	16
$(2, 4, 2)$	96
$(0, 8, 0)$	8
$(0, 4, 4)$	48
$(0, 0, 8)$	8

Each row contributes its count times $\delta^{n_0}(a/2)^{n_1}(b/2)^{n_2}$, proving (III.3.24). Setting $\delta = 0$ proves the stated U^3 formula. The remaining two formulas in (III.3.23) follow from the Fourier fourth moment and (III.3.8).

Let $c = (\sqrt{2}/6)^{1/3}$ and choose

$$b = c\delta^{-1/3}u^{4/3}, \quad a^4 = -3b^4 + \sqrt{32u^8 + 8b^8}.$$

For small u this is positive, $\delta + f$ takes values in $[0, 1]$, and (III.3.23) gives $\|f\|_{U^3} = u$ exactly. Since

$$a^4 = 4\sqrt{2}u^4 - 3b^4 + O(b^8/u^4),$$

equation (III.3.24) gives

$$Q_3(\delta + f) - \delta^8 = 6\sqrt{2}\delta^4u^4 - 3\delta^4b^4 + 2\sqrt{2}\delta^3u^4b + O_\delta(u^6).$$

Substitution of b produces the coefficient $-3c^4 + 2\sqrt{2}c = (9/4)^{1/3}$, proving (III.3.22). $\square$

For the local extremal problem over groups of order coprime to 6, these results determine the first coefficient and the next exponent. More precisely, subtract $6\sqrt{2}\delta^4u^4$ from the supremum of the cube excess over weights of mean δ with centered U^3 norm at most u , and divide by $\delta^{8/3}u^{16/3}$. The liminf of this normalized correction is at least $(9/4)^{1/3}$, and its limsup is at most 6. Proving convergence and determining the limit remain focused open questions; existence of an asymptotic second coefficient is not asserted here.

[write] 6 October 2026; sources 11–14. *Settled by source 14.* The limit exists and equals $(9/4)^{1/3}$, uniformly over groups of order coprime to 6 (Theorem III.34.1; Remark W4 for this normalization). The two-frequency family of Proposition III.3.9 is therefore asymptotically extremal; the 6 of Theorem III.3.8 stays an explicit, now superseded, upper bound.

III.3.5 Sharpness for indicator sets

Proposition III.3.10 (Rounding the sharpness examples). *For every fixed $0 < \delta < 1$, there are subsets A_j of prime cyclic groups, with densities $\delta_j \rightarrow \delta$ and $\alpha_j = \|1_{A_j} - \delta_j\|_{U^3}^8 \rightarrow 0$, such that*

$$Q_3(1_{A_j}) - \delta_j^8 \sim 6\sqrt{2}\delta^4\alpha_j^{1/2}. \quad (\text{III.3.25})$$

The obstruction to improving the exponent $16/3$ also persists for indicator sets on growing prime cyclic groups.

Proof. Independently include each $x \in \mathbb{Z}/p\mathbb{Z}$ with probability $w(x)$, where w is a prescribed weight of mean δ . At most $\binom{2^d}{2}/p$ of the normalized cube parameters identify two distinct vertices: each equality is one nontrivial linear equation with probability $1/p$. Away from these parameters, independence makes the expected product of indicators equal the product of their probabilities. The same argument applies to the centered variables $1_A(x) - \delta$. Thus the expectation error in the centered cube polynomial is at most $2\binom{2^d}{2}/p$.

Changing one inclusion decision changes a normalized cube polynomial by at most $2^d/p$. Indeed, telescope the product over its vertex occurrences; each occurrence has p^d possible remaining parameters, and the other factors are bounded by one. The bounded-difference variance inequality therefore gives variance $O_d(1/p)$. The empirical density has variance at most $1/(4p)$. Replacing δ by the empirical density δ_A changes the centered cube polynomial by at most $2^d|\delta_A - \delta|$. Consequently, for sufficiently large p there is a realization simultaneously approximating the prescribed density, cube count, and centered cube power to any specified positive error.

Apply this to the cosine weights of Proposition III.3.7, with $t_j \rightarrow 0$, and choose primes p_j sufficiently large that all errors are $o(t_j^8)$. Then

$$\alpha_j = t_j^8/32 + o(t_j^8), \quad Q_3(1_{A_j}) - \delta_j^8 = \frac{3}{2}\delta_j^4 t_j^4 + o(t_j^4),$$

which proves (III.3.25).

For the two-frequency example, choose approximation errors $o(u^{28/3})$. The error in replacing its prescribed u^4 by the rounded value is then $o(u^{16/3})$, since u^4 is the square root of the centered eighth power. The density and cube-count errors are smaller as well. Thus (III.3.22) transfers with its nonzero $u^{16/3}$ term. The 3-torsion quintic example can instead be rounded on $\mathbb{Z}/3\mathbb{Z} \times \mathbb{Z}/p\mathbb{Z}$; it does not give quintic sharpness on prime cyclic groups. $\square$

III.4 Density-weighted progression counting

Source 04, delivered Section 7.

The expansion in Gowers's Corollary 3.3 uses every subset of the set of positions, producing a factor bounded by 2^k . An ordered telescoping expansion gives a smaller bound and keeps the density factors. This section first states the precise group hypothesis needed for the Cauchy–Schwarz argument.

Definition III.4.1. Integers $c_1, \dots, c_m$ are *admissible on G* if the map $x \mapsto (c_i - c_j)x$ is an automorphism of G for every $i \neq j$. For functions $a_i : G \rightarrow \mathbb{C}$, write

$$\Lambda_{\mathbf{c}}(a_1, \dots, a_m) = \mathbb{E}_{x,y} \prod_{i=1}^m a_i(x + c_i y).$$

For $G = \mathbb{Z}/N\mathbb{Z}$, admissibility is equivalent to $\gcd(c_i - c_j, N) = 1$ for all pairs. Consecutive slopes $0, 1, \dots, k-1$ are therefore admissible whenever $\gcd(N, (k-1)!) = 1$. Primality is sufficient but unnecessary.

Lemma III.4.2 (Generalized von Neumann bound). *Suppose $m \geq 2$, the slopes are admissible, and $|a_i| \leq 1$. For every j ,*

$$|\Lambda_{\mathbf{c}}(a_1, \dots, a_m)| \leq \|a_j\|_{U^{m-1}}.$$

Proof. Relabel so that the target is a_m . For $m = 2$, the map $(x, y) \mapsto (x + c_1 y, x + c_2 y)$ is a bijection: its inverse uses the automorphism $c_2 - c_1$. The average factors as $(\mathbb{E}a_1)(\mathbb{E}a_2)$, giving the assertion.

Assume $m > 2$ and the result for $m - 1$. Replace x by $x - c_1 y$, and apply Cauchy–Schwarz in x , using $|a_1| \leq 1$. Writing $d_i = c_i - c_1$, this gives

$$|\Lambda_{\mathbf{c}}|^2 \leq \mathbb{E}_x \left| \mathbb{E}_y \prod_{i=2}^m a_i(x + d_i y) \right|^2 = \mathbb{E}_h \mathbb{E}_{x,y} \prod_{i=2}^m a_i(x + d_i y) \overline{a_i(x + d_i y + d_i h)}.$$

For each h , apply the inductive assertion to the $m - 1$ derivative functions. Differences of the new slopes are still automorphisms. The triangle inequality bounds the last expression by

$$\mathbb{E}_h \|\Delta_{d_m h} a_m\|_{U^{m-2}}, \quad \Delta_t a(x) = a(x) \overline{a(x + t)}.$$

The map $h \mapsto d_m h$ is a bijection. Hölder’s inequality and the derivative identity for Gowers norms give

$$\mathbb{E}_h \|\Delta_{d_m h} a_m\|_{U^{m-2}} \leq \left(\mathbb{E}_t \|\Delta_t a_m\|_{U^{m-2}}^{2^{m-2}} \right)^{1/2^{m-2}} = \|a_m\|_{U^{m-1}}^2.$$

Taking square roots completes the induction. $\square$

Theorem III.4.3 (Telescoping with the density factors retained). *Let $k \geq 3$, let the slopes be admissible on G , and let $a_i : G \rightarrow [0, 1]$ have means δ_i . Put $b_i = a_i - \delta_i$ and $u_i = \|b_i\|_{U^{i-1}}$ for $i \geq 3$. Then*

$$\left| \Lambda_{\mathbf{c}}(a_1, \dots, a_k) - \prod_{i=1}^k \delta_i \right| \leq \sum_{j=3}^k \left(\prod_{i=j+1}^k \delta_i \right) u_j. \quad (*)$$

Every permutation of the positions gives a valid version, with the appropriate Gowers norm of the function in the j -th position.

Proof. Successively write $a_j = \delta_j + b_j$, starting with $j = k$ and ending with $j = 3$. Multilinearity gives the exact identity

$$\Lambda_{\mathbf{c}}(a_1, \dots, a_k) - \prod_i \delta_i = \sum_{j=3}^k \left(\prod_{i=j+1}^k \delta_i \right) \Lambda_{c_1, \dots, c_j}(a_1, \dots, a_{j-1}, b_j).$$

The remaining two-function average is exactly $\delta_1 \delta_2$ by pairwise admissibility. Each term is bounded by u_j , by Lemma III.4.2; all other functions in that term are 1-bounded. Taking absolute values proves the result. Relabeling preserves admissibility, proving the last assertion. $\square$

Under the source’s hypotheses $u_j \leq \varepsilon$, the new error is

$$\varepsilon \sum_{j=3}^k \prod_{i=j+1}^k \delta_i \leq (k - 2)\varepsilon.$$

This is a direct replacement for $2^k \varepsilon$, in the same normalization. When all densities equal δ , the factor is

$$S_{k-2}(\delta) := \sum_{r=0}^{k-3} \delta^r = \begin{cases} (1 - \delta^{k-2})/(1 - \delta), & \delta \neq 1, \\ k - 2, & \delta = 1. \end{cases}$$

In particular it is at most $1/(1 - \delta)$ for $0 \leq \delta < 1$, independently of k , and the inequality is strict when $0 < \delta < 1$.

[write] **6 October 2026.** Source 03's Section III.1 proves the same generalized von Neumann bound (Lemma III.1.1; "slopes with invertible differences" there are "admissible slopes" here) and the same telescoping bound (Theorem III.1.2), by the same induction and expansion. Its order-optimization recursion $B(S)$ is $D(S)$ below. The two texts were written independently (the intake measured under 0.8% shared text); both are kept and credited. The first display of Corollary III.4.4 is source 03's (III.1.2). Source 03 concludes at least $\delta^k N^2/4$ progressions under $N \geq 4\delta^{1-k}$ (Corollary III.1.3), while source 04 concludes positivity under $N > 2\delta^{1-k}$. Source 04's exchange rule and source 03's real-character torsion example are each one source's alone. Source 04's $\mathbb{Z}/2$ example below has a complex a_3 and shows that the generalized von Neumann inequality itself fails.

III.4.1 Choosing the order of elimination

The preceding result has a small useful optimization principle. Suppose one has upper bounds $u_i(s) \geq \|b_i\|_{U^s}$, for all $2 \leq s \leq k-1$. For a subset S of positions define

$$D(S) = 0 \quad (|S| \leq 2), \quad D(S) = \min_{i \in S} (u_i(|S| - 1) + \delta_i D(S \setminus \{i\})) \quad (|S| \geq 3).$$

Induction on $|S|$ shows that $D(S)$ bounds the counting error for the subsystem indexed by S . Moreover it is precisely the smallest bound obtained by this family of telescoping estimates. Computing the recurrence requires at most $k2^k$ elementary comparisons, once the norm bounds have been supplied.

If a single upper bound v_i is used for each function at every remaining order, there is also a simple exchange rule. For two successive eliminations i, j , their contribution before the common later tail is either $v_i + \delta_i v_j$ or $v_j + \delta_j v_i$. Thus i should precede j exactly when

$$v_i(1 - \delta_j) \leq v_j(1 - \delta_i).$$

For a fixed pair of positions to retain, sort the other positions by $v_i/(1 - \delta_i)$, with the degenerate cases interpreted through the displayed inequality. One can compare the $\binom{k}{2}$ possible retained pairs. This optimizes the stated bound, and is not a claim of an optimal counting inequality among all methods.

III.4.2 An explicit supersaturation consequence

Corollary III.4.4 (A sharper uniformity threshold). *Let $A \subset G$ have density $0 < \delta \leq 1$, and suppose that the consecutive slopes $0, \dots, k-1$ are admissible, with $k \geq 3$. Put $u = \|1_A - \delta\|_{U^{k-1}}$. The number $T_k^*(A)$ of ordered k -term progressions with nonzero difference satisfies*

$$T_k^*(A) \geq N^2(\delta^k - u S_{k-2}(\delta)) - \delta N. \quad (\text{III.4.1})$$

In particular, if

$$u \leq \frac{\delta^k}{2S_{k-2}(\delta)} \quad \text{and} \quad N > 2\delta^{1-k},$$

then $T_k^(A) > 0$.*

Proof. Norm monotonicity bounds every U^{j-1} -norm in Theorem III.4.3 by u . There are N^2 ordered choices of start and difference. Exactly $|A| = \delta N$ of the counted progressions have difference zero, so subtracting them gives the asserted bound. The two displayed assumptions make its right-hand side positive. $\square$

Admissibility also ensures that a progression with nonzero difference has k distinct entries: a repetition would give $(i - j)y = 0$ with $0 < |i - j| < k$, contrary to the automorphism hypothesis.

[write] **6 October 2026; sources 06–10.** *Two further counting refinements (sources 06 and 10).* Source 10’s Corollary III.29.2 has error $\delta S_k(\delta)u$, a factor δ below the error $uS_{k-2}(\delta)$ of Corollary III.4.4 (the polynomials are equal: $S_k(\delta)$ there is $1 + \delta + \dots + \delta^{k-3}$), because its mixed L^p norms of indicators equal δ ; its Corollary III.29.3 needs $u \leq \delta^{k-1}/(2S_k(\delta))$ in place of $u \leq \delta^k/(2S_{k-2}(\delta))$. Source 06’s Corollary III.5.5 is quadratic in u : error $\sqrt{\delta} B_k(\delta)u^2$ with $B_k(\delta) = \sum_{t \leq k-3} (t+1)\delta^t$, and its Corollary III.5.7 needs $u^2 \leq \delta^{k-1/2}/(2B_k(\delta))$ (corrected after the independent check of 6 October 2026; the first wording, “its criterion”, read as a reference to Corollary III.5.5). In the paper’s α (with $u^{2^{k-1}} \leq \alpha$) the sufficient conditions become $\alpha \leq (\delta^k/2S_{k-2})^{2^{k-1}}$ here, $\alpha \leq (\delta^{k-1}/2S_k)^{2^{k-1}}$ (source 10) and $\alpha \leq (\delta^{k-1/2}/2B_k)^{2^{k-2}}$ (source 06), against the formal `corollary_3_6`’s $(\delta/2)^{k2^k}$. The powers of δ are $k2^{k-1}$, $(k-1)2^{k-1}$, $(k-\frac{1}{2})2^{k-2}$ and $k2^k$; source 06’s is the smallest for every $k \geq 3$, since $(k-\frac{1}{2})2^{k-2} < (k-1)2^{k-1}$ is $k > \frac{3}{2}$ (the constants $2S_{k-2} \leq 2(k-2)$ and $2B_k \leq (k-1)(k-2)$ differ). All need invertibility of $1, \dots, k-1$; source 10’s Theorem III.28.2 and its criterion (III.29.6) work without it, with explicit kernel factors.

In the paper’s uniformity parameter, the sufficient condition becomes

$$\alpha \leq \left(\frac{\delta^k}{2S_{k-2}(\delta)} \right)^{2^{k-1}}.$$

For fixed k and small δ , its density exponent is $k2^{k-1}$, compared with $k2^k$ in the sufficient condition $(\delta/2)^{k2^k}$ displayed in the inspected version of Corollary 3.6. This comparison concerns the modular progression step.

Lemma III.4.5 (Lifting from a short interval). *Let $A \subset \{0, \dots, n-1\}$ be viewed in $\mathbb{Z}/N\mathbb{Z}$, with $2(n-1) < N$. If A contains a nonconstant modular progression of length $k \geq 3$, then it contains an ordinary integer progression of length k and positive difference.*

Proof. Let $x_0, \dots, x_{k-1} \in \{0, \dots, n-1\}$ be the representatives. Each integer $x_i + x_{i+2} - 2x_{i+1}$ is divisible by N and has absolute value at most $2(n-1) < N$; it is therefore zero. Successive integer differences are equal. The common difference is nonzero because the modular progression is nonconstant. Reverse the sequence if that integer difference is negative. $\square$

The lemma specifies the extra hypothesis needed to draw an integer conclusion. A modular progression in an unrestricted subset of $\mathbb{Z}/N\mathbb{Z}$ can wrap around, so that conclusion should not be silently inserted into Corollary III.4.4.

[write] **6 October 2026.** *Already formalized.* This lemma is proved in Lean as `hasNatAP_of_short_modular_sequence` (`Proofs18IntervalTransfer.lean`, line 22), with the set form `hasNatAP_of_hasModAP_image` (line 92); both were added in commit 327773149, source 04’s own pin. The Lean statement takes representatives $f(i) \leq n$ with $2n < N$ and a nonzero modular difference, for every length k : after $n-1 \mapsto n$ it is this lemma, and it also covers $k < 3$. Source 04 does not mention the formal version. It is the only statement of sources 01–05 that is formalized; source 03’s rectification remark (Remark III.1.4) is the same argument.

Remark III.4.6 (Why invertibility cannot simply be omitted). For $G = \mathbb{Z}/2\mathbb{Z}$, take slopes 0, 1, 2, $a_3(0) = 1$, $a_3(1) = i$, $a_1 = \overline{a_3}$, and $a_2 = 1$. The forms at positions 0 and 2 coincide, so $\Lambda = 1$. Both normalized Fourier coefficients of a_3 have modulus $2^{-1/2}$, whence $\|a_3\|_{U^2} = 2^{-1/4} < 1$. Thus the stated generalized von Neumann inequality itself fails without an algebraic hypothesis. The obstruction is an algebraic dependence, and the admissibility condition states exactly what the present proof uses.

III.5 Quadratic discrepancy bounds for arithmetic progressions

Source 06, delivered Section 3.

The proof of Gowers's Theorem 3.2 is a repeated Cauchy–Schwarz argument. Keeping two functions in that argument, rather than discarding all but one of their norms, produces a quadratic error estimate. A second telescoping identity then exploits the exact disappearance of one- and two-function balanced correlations. This refines the displayed counting estimates in Section 3 of the paper and its repository transcription [1, 41].

III.5.1 Normalization and the precise hypothesis on the modulus

Let G be a finite abelian group of order N , with normalized averages. For an integer a , let $[a]: G \rightarrow G$ denote multiplication by a . For slopes $a_1, \dots, a_k$, define

$$\Lambda_a(F_1, \dots, F_k) = \mathbb{E}_{x,d \in G} \prod_{i=1}^k F_i(x + a_i d).$$

Throughout this section, assume that

$$[a_i - a_j] \text{ is an automorphism of } G \text{ whenever } i \neq j. \quad (\text{III.5.1})$$

This assumption is inherited by every subset of the slopes. It makes the map

$$(x, d) \mapsto (x + a_i d, x + a_j d)$$

a bijection of G^2 . In particular,

$$\mathbb{E}_{x,d} F_i(x + a_i d) F_j(x + a_j d) = (\mathbb{E} F_i)(\mathbb{E} F_j). \quad (\text{III.5.2})$$

For consecutive slopes $0, 1, \dots, k-1$, condition (III.5.1) means that multiplication by each of $1, \dots, k-1$ is invertible. For $G = \mathbb{Z}/N\mathbb{Z}$ it is equivalent to

$$\gcd(N, (k-1)!) = 1. \quad (\text{III.5.3})$$

Thus the counting results below apply to many composite moduli. For example, $N = 25$ is admissible for every $k \leq 5$. If $N \geq 2$ and the slopes are consecutive, every progression with $d \neq 0$ has k distinct terms: an equality between two terms would put d in the kernel of one of the automorphisms in (III.5.1).

For $s \geq 1$, use the normalized uniformity quantity

$$\|f\|_{U^s(G)}^{2^s} = \mathbb{E}_{x, h_1, \dots, h_s \in G} \prod_{\omega \in \{0,1\}^s} \mathcal{C}^{|\omega|} f(x + \omega \cdot h),$$

where $\mathcal{C}$ is complex conjugation. Thus $\|f\|_{U^1} = |\mathbb{E} f|$. The standard derivative identity is

$$\|f\|_{U^s}^{2^s} = \mathbb{E}_h \|\Delta_h f\|_{U^{s-1}}^{2^{s-1}}, \quad \Delta_h f(x) = f(x) \overline{f(x+h)} \quad (s \geq 2). \quad (\text{III.5.4})$$

We use the usual inequalities $\|f\|_{U^s} \leq \|f\|_{U^{s+1}}$ and $\|f\|_{U^s} \leq \|f\|_\infty$; they follow from the same Cauchy–Schwarz argument used in Section 3 of [1]. In the paper's convention, degree- d α -uniformity is precisely

$$\|f\|_{U^{d+1}}^{2^{d+1}} \leq \alpha. \quad (\text{III.5.5})$$

III.5.2 Two distinguished functions

Theorem III.5.1 (Two-function uniformity estimate). *Assume (III.5.1) and $k \geq 2$. For distinct indices p, q and arbitrary complex functions $F_1, \dots, F_k$ on G ,*

$$|\Lambda_a(F_1, \dots, F_k)| \leq \|F_p\|_{U^{k-1}} \|F_q\|_{U^{k-1}} \prod_{i \notin \{p, q\}} \|F_i\|_\infty. \quad (\text{III.5.6})$$

If $k \geq 3$ and $r \notin \{p, q\}$, then the stronger estimate

$$|\Lambda_a(F_1, \dots, F_k)| \leq \|F_r\|_2 \|F_p\|_{U^{k-1}} \|F_q\|_{U^{k-1}} \prod_{i \notin \{p, q, r\}} \|F_i\|_\infty \quad (\text{III.5.7})$$

also holds. The coefficient 1 in (III.5.6) is sharp.

Proof. By homogeneity, it is enough to suppose that the functions other than F_p, F_q have supremum norm at most one. If any normalizing norm is zero, the corresponding function vanishes and there is nothing to prove. For $k = 2$, equation (III.5.2) gives the identity

$$|\Lambda_{(a_p, a_q)}(F_p, F_q)| = |\mathbb{E} F_p| |\mathbb{E} F_q| = \|F_p\|_{U^1} \|F_q\|_{U^1}.$$

Suppose (III.5.6) has been proved for $k - 1$ functions. Choose $r \notin \{p, q\}$ and change x to $x - a_r d$ so that the r th slope becomes zero. Put $b_i = a_i - a_r$. Cauchy–Schwarz in x gives

$$\begin{aligned} |\Lambda_a(F_1, \dots, F_k)|^2 &\leq \|F_r\|_2^2 \mathbb{E}_x \left| \mathbb{E}_d \prod_{i \neq r} F_i(x + b_i d) \right|^2 \\ &= \|F_r\|_2^2 \mathbb{E}_h \Lambda_{(b_i)_{i \neq r}} ((\Delta_{b_i h} F_i)_{i \neq r}). \end{aligned}$$

The last average is real and nonnegative, as is apparent from the preceding line. Applying the triangle inequality and the induction hypothesis bounds it by

$$\mathbb{E}_h B(h) C(h), \quad B(h) = \|\Delta_{b_p h} F_p\|_{U^{k-2}}, \quad C(h) = \|\Delta_{b_q h} F_q\|_{U^{k-2}}.$$

All remaining differentiated functions have supremum norm at most one. Set $Q = 2^{k-2} \geq 2$. Hölder’s inequality on the probability space G gives

$$\mathbb{E}_h B(h) C(h) \leq (\mathbb{E}_h B(h)^Q)^{1/Q} (\mathbb{E}_h C(h)^Q)^{1/Q}.$$

For $Q > 2$, this is Hölder with a third factor 1 and exponent $Q/(Q - 2)$; for $Q = 2$, it is Cauchy–Schwarz. Both $[b_p]$ and $[b_q]$ are automorphisms. Therefore (III.5.4) yields

$$\mathbb{E}_h B(h)^Q = \|F_p\|_{U^{k-1}}^{2^{k-1}}, \quad \mathbb{E}_h C(h)^Q = \|F_q\|_{U^{k-1}}^{2^{k-1}}.$$

Taking square roots proves (III.5.7). Using $\|F_r\|_2 \leq \|F_r\|_\infty$ proves (III.5.6) and completes the induction. Restoring the supremum norms gives the homogeneous statements. Constant functions show that the coefficient in (III.5.6) cannot be decreased. $\square$

[write] **6 October 2026; sources 15–20.** Source 20’s Theorem III.43.3 proves (III.5.7) for arbitrary surjective homomorphisms with directional seminorms, independently (source 20 could not see this manuscript).

Bounding one of the two distinguished uniformity quantities by the supremum norm recovers the ordinary generalized von Neumann estimate. The gain in Theorem III.5.1 is useful when both distinguished functions are balanced and have small uniformity norm.

[write] **6 October 2026; sources 06–10.** The one-function case is the generalized von Neumann bound of sources 03 and 04 (Lemmas III.1.1 and III.4.2), with the same slope hypothesis (III.5.1). Source 10's Theorem III.28.2 replaces the L^∞ norms by mixed L^p norms and drops the invertibility of all differences except one, at the price of an explicit kernel factor. Keeping two distinguished functions is specific to this source.

III.5.3 First and second telescoping

Let $0 \leq F_i \leq 1$, let $\delta_i = \mathbb{E}F_i$, and put $f_i = F_i - \delta_i$.

Theorem III.5.2 (Indexed first-order estimate). *Suppose $k \geq 2$, assume (III.5.1), and suppose $\|f_j\|_{U^{j-1}} \leq \varepsilon_j$ for $3 \leq j \leq k$. Then*

$$\left| \Lambda_a(F_1, \dots, F_k) - \prod_{i=1}^k \delta_i \right| \leq \sum_{j=3}^k \varepsilon_j \prod_{h=j+1}^k \delta_h. \quad (\text{III.5.8})$$

For $k = 2$, the empty sum is zero and the count is exact.

Proof. The pointwise telescoping identity is

$$\prod_{i=1}^k F_i - \prod_{i=1}^k \delta_i = \sum_{j=1}^k f_j \prod_{i < j} F_i \prod_{h > j} \delta_h.$$

Evaluate the i th function at $x + a_i d$ and average. The $j = 1$ summand vanishes because $\mathbb{E}f_1 = 0$. The $j = 2$ summand vanishes by (III.5.2). For $j \geq 3$, apply the one-function consequence of Theorem III.5.1 to the j slopes $a_1, \dots, a_j$. This bounds that summand by $\varepsilon_j \prod_{h > j} \delta_h$. $\square$

Under the indexed hypotheses of Gowers's Corollary 3.3, the right side of (III.5.8) is at most $(k-2)\alpha$, in the notation of that corollary, replacing its displayed $2^k\alpha$ bound. The symbol α there is a norm-scale parameter; conversion to the paper's degree-uniformity energy must use (III.5.5).

Theorem III.5.3 (Second-order estimate). *Suppose $k \geq 3$, assume (III.5.1), and suppose $\|f_i\|_{U^{k-1}} \leq \varepsilon_i$ for all i . For $2 \leq i < j \leq k$, set*

$$w_{ij} = \prod_{i < h < j} \delta_h \prod_{h > j} \delta_h, \quad \mu_i = \min_{r < i} \|F_r\|_2.$$

Then

$$\left| \Lambda_a(F_1, \dots, F_k) - \prod_{i=1}^k \delta_i \right| \leq \sum_{2 \leq i < j \leq k} w_{ij} \mu_i \varepsilon_i \varepsilon_j. \quad (\text{III.5.9})$$

One may replace every μ_i by 1. For indicator functions, $\mu_i = \min_{r < i} \sqrt{\delta_r}$.

Proof. In the proof of Theorem III.5.2, telescope each prefix a second time:

$$\prod_{h < j} F_h = \prod_{h < j} \delta_h + \sum_{i < j} f_i \prod_{r < i} F_r \prod_{i < h < j} \delta_h.$$

The constant-prefix contribution vanishes after multiplication by $f_j(x + a_j d)$ and averaging. The $i = 1$ contribution vanishes by (III.5.2). The exact surviving expression for the discrepancy is consequently

$$\sum_{2 \leq i < j \leq k} w_{ij} \Lambda_{(a_1, \dots, a_i, a_j)}(F_1, \dots, F_{i-1}, f_i, f_j).$$

There are $i + 1$ functions in each average. Apply (III.5.7) with f_i, f_j distinguished and any F_r , $r < i$, supplying the L^2 factor. Norm monotonicity gives $\|f_i\|_{U^i} \leq \|f_i\|_{U^{k-1}}$ and the corresponding inequality for f_j . Minimizing over $r < i$ and summing proves the claim. $\square$

Remark III.5.4 (Ordering the inputs). If all balanced functions satisfy the common bound $\|f_i\|_{U^{k-1}} \leq \varepsilon$, the slope–function pairs may be reordered before either telescoping argument. A nonincreasing order of the densities minimizes the coefficient in (III.5.8), and also minimizes the coefficient in (III.5.9) when the μ_i are replaced by 1. For the first assertion, the coefficient is a sum of products of final segments. In an adjacent swap, the only changed final-segment term is a nonnegative common product times the later density; placing the smaller density later cannot increase it. For the second assertion, the coefficient is

$$\sum_{i=2}^{k-1} e_{k-i-1}(\delta_{i+1}, \dots, \delta_k),$$

where e_j is the elementary symmetric polynomial. Again, an adjacent swap changes only one final-segment summand, whose dependence on the changed endpoint is affine with a nonnegative coefficient. This is an optimization of these bounds among orders; it does not assert that their coefficients are universally sharp discrepancy constants.

III.5.4 One set and explicit coefficients

For $k \geq 3$, define the polynomials

$$S_k(\delta) = \sum_{t=0}^{k-3} \delta^t, \quad B_k(\delta) = \sum_{t=0}^{k-3} (t+1) \delta^t. \quad (\text{III.5.10})$$

Corollary III.5.5 (Quadratic progression discrepancy). *Let $A \subseteq G$ have density δ , let $\varepsilon = \|1_A - \delta\|_{U^{k-1}}$, and suppose $k \geq 3$ and (III.5.1). Then*

$$\left| \Lambda_a(1_A, \dots, 1_A) - \delta^k \right| \leq \min \left\{ S_k(\delta) \varepsilon, \sqrt{\delta} B_k(\delta) \varepsilon^2 \right\}. \quad (\text{III.5.11})$$

Proof. Apply Theorems III.5.2 and III.5.3, using norm monotonicity for the first. In the second theorem, $\mu_i = \sqrt{\delta}$ and $w_{ij} = \delta^{k-i-1}$. For fixed i there are $k - i$ choices of j , so its coefficient is

$$\sum_{i=2}^{k-1} (k-i) \delta^{k-i-1} = \sum_{t=0}^{k-3} (t+1) \delta^t = B_k(\delta).$$

$\square$

[write] **6 October 2026; sources 15–20.** Source 20’s Corollary III.45.4 has a coefficient (its own $B_k(\delta)$, a different polynomial) at most $\sqrt{\delta} B_k(\delta)$ with the B_k here, and strictly smaller for every $k \geq 3$ and $0 < \delta < 1$ (proved in the note there); the quadratic power itself is proved here first, and source 20’s Theorem III.48.3 shows it cannot be raised for three-term counts of indicator sets at density near $1/2$.

For $0 \leq \delta < 1$, the closed forms are

$$S_k(\delta) = \frac{1 - \delta^{k-2}}{1 - \delta}, \quad B_k(\delta) = \frac{1 - (k-1)\delta^{k-2} + (k-2)\delta^{k-1}}{(1 - \delta)^2}.$$

At $\delta = 1$, the polynomial values are $k - 2$ and $(k - 1)(k - 2)/2$. In particular,

$$B_k(\delta) \leq \frac{(k-1)(k-2)}{2}, \quad B_k(\delta) \leq \frac{1}{(1-\delta)^2} \quad (\delta < 1).$$

For fixed $\delta < 1$, this latter bound remains bounded as k grows. The quadratic dependence on ε strengthens the usual linear discrepancy estimate independently of the improvement in the coefficient.

Proposition III.5.6 (A sharp three-term variance factor). *Under the three-slope case of (III.5.1),*

$$\left| \Lambda_a(1_A, 1_A, 1_A) - \delta^3 \right| \leq \sqrt{\delta(1-\delta)} \|1_A - \delta\|_{U^2}^2. \quad (\text{III.5.12})$$

The coefficient 1 is sharp, even for consecutive slopes in cyclic groups of odd order.

Proof. Set $f = 1_A - \delta$. Every expansion term with one or two factors f vanishes by mean zero and (III.5.2). Thus the discrepancy equals $\Lambda_a(f, f, f)$. Apply (III.5.7) and use $\|f\|_2^2 = \delta(1 - \delta)$.

For sharpness, take A to be a singleton in a cyclic group of odd order $N \geq 3$. Then $\delta = 1/N$, and its normalized three-term count is $1/N^2$. With normalized Fourier coefficients, the balanced singleton has coefficient 0 at the trivial character and modulus $1/N$ at each of the other $N - 1$ characters. Therefore

$$\|f\|_{U^2}^4 = \frac{N-1}{N^4}, \quad \sqrt{\delta(1-\delta)} \|f\|_{U^2}^2 = \frac{N-1}{N^3} = \frac{1}{N^2} - \frac{1}{N^3}.$$

Equality holds in (III.5.12). □

[write] **6 October 2026; sources 15–20.** This coefficient is source 20's $B_3(\delta)$. Its sharpness here is at singletons ($\delta = 1/N$); at fixed density source 20 shows that the exponent 2 cannot be raised (Theorem III.48.3), while the best coefficient stays open (item III.8).

III.5.5 An explicit modular existence criterion

Corollary III.5.7 (Exact subtraction of constant progressions). *Let $N \geq 2$, $k \geq 3$, and let $A \subseteq G$ have density $0 < \delta \leq 1$. Assume that multiplication by $1, \dots, k-1$ is invertible on G . Put*

$$E_k = \min \left\{ S_k(\delta)\varepsilon, \sqrt{\delta} B_k(\delta)\varepsilon^2 \right\}, \quad \varepsilon = \|1_A - \delta\|_{U^{k-1}}.$$

The number of nonconstant ordered k -term progressions in A is at least

$$N^2(\delta^k - E_k) - \delta N. \quad (\text{III.5.13})$$

In particular, such a progression exists whenever

$$\delta^k - E_k > \frac{\delta}{N}. \quad (\text{III.5.14})$$

A convenient sufficient condition is

$$N > 2\delta^{1-k}, \quad \varepsilon^2 \leq \frac{\delta^{k-1/2}}{2B_k(\delta)}. \quad (\text{III.5.15})$$

Consequently, if A is α -uniform of degree $k-2$ in the paper's convention, it is sufficient that

$$N > 2\delta^{1-k}, \quad \alpha \leq \left(\frac{\delta^{k-1/2}}{2B_k(\delta)} \right)^{2^{k-2}}. \quad (\text{III.5.16})$$

Proof. Corollary III.5.5 gives at least $N^2(\delta^k - E_k)$ ordered progressions. Exactly $|A| = \delta N$ of them have $d = 0$. Subtracting these proves (III.5.13); every remaining progression has distinct terms by (III.5.1). Under (III.5.15), $E_k \leq \delta^k/2$ and $\delta/N < \delta^k/2$, proving (III.5.14). Finally, (III.5.5) implies $\varepsilon^2 \leq \alpha^{1/2^{k-2}}$, giving (III.5.16). $\square$

For $k = 2$, no uniformity assumption is necessary: the number of nonconstant progressions is exactly $|A|(|A| - 1)$, so existence is equivalent to $|A| \geq 2$. For $\delta = 1$ and $N \geq 2$, a nonzero difference gives a progression immediately. For $N = 1$, no nonconstant progression exists. Empty and full sets have zero balanced function, so their progression counts are exact.

The conclusions of Corollary III.5.7 concern modular progressions. Transferring them to integer intervals requires a separate embedding without wraparound or a rectification argument. The improved uniformity threshold is a local improvement in the counting part of the proof; a stronger final quantitative Szemerédi theorem would also require corresponding control of the subsequent inverse and density-increment steps.

[write] **6 October 2026; sources 06–10.** Theorem III.5.2 is the telescope of sources 03 and 04 (Theorems III.1.2 and III.4.3); Remark III.5.4 is their optimal-order observation. The criteria of Corollary III.5.7 are compared with those of sources 03, 04 and 10 in the note after Corollary III.4.4: in the paper's α , (III.5.16) has the smallest power of δ . Not formalized; `corollary_3_3_holds` and `corollary_3_6_holds` keep the printed constants.

III.6 Normalization and the basic analytic tools

Source 08, delivered Section 2.

Let G be a finite abelian group, written additively, and let all expectations be normalized counting averages. Put

$$V_d = \{0, 1\}^d, \quad p = 2^d, \quad L_v(x, h) = x + \sum_{i=1}^d v_i h_i.$$

The variables $(x, h_1, \dots, h_d)$ are independent and uniform in G . Define the real multilinear cube average by

$$\Lambda_d((F_v)_{v \in V_d}) = \mathbb{E}_{x, h} \prod_{v \in V_d} F_v(L_v(x, h)), \quad \mathcal{C}_d(F) = \Lambda_d((F)_{v \in V_d}). \quad (\text{III.6.1})$$

For a set $A \subseteq G$, the unnormalized number of parameterized cubes in A is $|G|^{d+1} \mathcal{C}_d(\mathbf{1}_A)$. Degenerate cubes are included. Thus no assumption that the sampled vertices are distinct is hidden in the notation.

For a complex function g , the normalized Gowers norm is

$$\|g\|_{U^d(G)}^p = \mathbb{E}_{x,h} \prod_{v \in V_d} \mathcal{K}^{|v|} g(L_v(x, h)), \quad (\text{III.6.2})$$

where $\mathcal{K}$ is complex conjugation. For real functions,

$$\mathcal{C}_d(g) = \|g\|_{U^d(G)}^p. \quad (\text{III.6.3})$$

For $d = 1$ this is a seminorm, $\|g\|_{U^1} = |\mathbb{E}g|$; for $d \geq 2$ it is a norm.

We use the normalized Gowers–Cauchy–Schwarz inequality

$$\left| \mathbb{E}_{x,h} \prod_{v \in V_d} \mathcal{K}^{|v|} g_v(L_v) \right| \leq \prod_{v \in V_d} \|g_v\|_{U^d(G)}. \quad (\text{III.6.4})$$

This is the normalized form of the cube inequality in [1, Lemma 3.8]. Its repeated Cauchy–Schwarz proof uses only translation invariance of the uniform measure, so it applies to every finite abelian group. Real inputs allow us to omit the conjugations. Complex unconjugated inputs can be treated by replacing g_v with $\mathcal{K}^{|v|} g_v$.

Here are the consequences needed later. Padding one face of a $(d+1)$ -cube with the constant function 1, and the other face with g , gives from (III.6.4)

$$\|g\|_{U^d}^{2^d} \leq \|g\|_{U^{d+1}}^{2^d}.$$

Together with the U^1 identity this proves

$$|\mathbb{E}g| \leq \|g\|_{U^2} \leq \cdots \leq \|g\|_{U^d} \leq \|g\|_{\infty}. \quad (\text{III.6.5})$$

Expanding the cube of $g + h$ and applying (III.6.4) term by term proves Minkowski’s inequality. These facts require no condition on the torsion of G .

Fix now a real function F with nonnegative mean, and write

$$\delta = \mathbb{E}F \geq 0, \quad f = F - \delta, \quad t = \|f\|_{U^d(G)}, \quad \mathcal{D}_d(F) = \mathcal{C}_d(F) - \delta^p. \quad (\text{III.6.6})$$

Most applications use $0 \leq F \leq 1$, but the polynomial identities hold for arbitrary real f of mean zero and arbitrary $\delta \geq 0$. By (III.6.5), $\mathcal{D}_d(F) \geq 0$ even without pointwise positivity of F .

For $S \subseteq V_d$, set

$$\Lambda_S(f) = \mathbb{E}_{x,h} \prod_{v \in S} f(L_v(x, h)), \quad \Lambda_{\emptyset}(f) = 1. \quad (\text{III.6.7})$$

Padding the other vertices with 1 in (III.6.4) gives the useful homogeneous estimate

$$|\Lambda_S(f)| \leq t^{|S|}. \quad (\text{III.6.8})$$

Unlike the estimate of every error term by t , this remembers the number of balanced factors.

III.7 Three exact cancellations and the fourth-order bound

Source 08, delivered Section 3.

Lemma III.7.1 (Three-vertex independence). *Let $1 \leq r \leq 3$, and let $v_1, \dots, v_r$ be distinct vertices of V_d . Then $(L_{v_1}, \dots, L_{v_r})$ is uniformly distributed on G^r . Consequently, for functions $g_1, \dots, g_r : G \rightarrow \mathbb{C}$,*

$$\mathbb{E}_{x,h} \prod_{j=1}^r g_j(L_{v_j}) = \prod_{j=1}^r \mathbb{E} g_j.$$

Proof. Reflecting coordinate i of a cube is implemented by $x' = x + h_i$, $h'_i = -h_i$, leaving the other increments unchanged. This is a bijection of G^{d+1} preserving its uniform distribution. Reflect enough coordinates to send v_1 to 0.

For two vertices the other vertex is a nonzero binary vector u . At least one coefficient of $u \cdot h$ is 1, so this linear form is uniform and independent of x .

For three vertices write them as 0, u, v , with u, v distinct and nonzero. There are two coordinates i, j for which

$$\det \begin{pmatrix} u_i & u_j \\ v_i & v_j \end{pmatrix} = \pm 1.$$

Indeed, distinct nonzero binary vectors are linearly independent over $\mathbb{F}_2$; an invertible 2×2 binary minor has integer determinant ± 1 . After fixing all other increments, the map $(h_i, h_j) \mapsto (u \cdot h, v \cdot h)$ is therefore a bijection of G^2 : its inverse has integer coefficients. Together with the independent variable x , this makes $(x, x + u \cdot h, x + v \cdot h)$ uniform on G^3 . No division by 2 or another potentially noninvertible integer occurs. $\square$

Corollary III.7.2. *If $\mathbb{E}f = 0$ and $1 \leq |S| \leq 3$, then $\Lambda_S(f) = 0$. The same conclusion holds when the centered function at each selected vertex is allowed to be different.*

Theorem III.7.3 (Fourth-order refinement). *Let G be a finite abelian group, $d \geq 2$, $p = 2^d$, and let $F = \delta + f$ be real, where $\delta \geq 0$ and $\mathbb{E}f = 0$. With $t = \|f\|_{U^d(G)}$,*

$$0 \leq \mathcal{D}_d(F) \leq \sum_{r=4}^p \binom{p}{r} \delta^{p-r} t^r, \quad (\text{III.7.1})$$

$$\mathcal{C}_d(F) \leq (\delta + t)^p - p\delta^{p-1}t - \binom{p}{2}\delta^{p-2}t^2 - \binom{p}{3}\delta^{p-3}t^3. \quad (\text{III.7.2})$$

In dimension 2, the first estimate is an identity: $\mathcal{C}_2(F) = \delta^4 + \|f\|_{U^2}^4$.

Proof. The finite product expansion gives the exact identity

$$\mathcal{C}_d(\delta + f) = \sum_{S \subseteq V_d} \delta^{p-|S|} \Lambda_S(f). \quad (\text{III.7.3})$$

The empty subset contributes δ^p . Corollary III.7.2 removes all subsets of sizes 1, 2, 3. For each remaining subset, (III.6.8) bounds its absolute contribution by $\delta^{p-|S|} t^{|S|}$. There are $\binom{p}{r}$ subsets of size r . This proves the upper bound; the lower bound was established in (III.6.5). Expanding $(\delta + t)^p$ gives (III.7.2). When $d = 2$, the only nonempty surviving subset is the entire four-vertex cube, whose average is t^4 . $\square$

[write] **6 October 2026; sources 06–10.** The cancellation through degree three and (III.7.1) are also proved by source 03 (Lemma III.2.1, Corollary III.2.2), source 04 (Lemma III.3.1) and source 09 (Lemma III.17.1, Theorem III.17.2); four independent proofs. This t is 03's η , 04's u and 09's ε ; this $\mathcal{C}_d$ is their Q_d and $\mathcal{C}_d$. Not formalized; lemma_3_10_holds keeps the Minkowski bound.

III.7.1 Conversion to the original uniformity parameter

Define

$$K_d = \sum_{r=4}^p \binom{p}{r} = 2^p - 1 - p - \binom{p}{2} - \binom{p}{3}. \quad (\text{III.7.4})$$

For $F = \mathbf{1}_A$, $0 \leq \delta, t \leq 1$. If $t^p \leq \alpha \leq 1$, then

$$0 \leq \mathcal{C}_d(\mathbf{1}_A) - \delta^p \leq K_d \alpha^{4/p}. \quad (\text{III.7.5})$$

The original bound (F.13.1), after normalization and subtraction of δ^p , has a leading term of order $\alpha^{1/p}$ for fixed positive δ . Equation (III.7.5) replaces that exponent by $4/p$. For example, the exponents are 1, $1/2$, $1/4$, and $1/8$ in dimensions 2, 3, 4, 5, respectively. Theorem III.11.4 will show that this power cannot be increased in a bound uniform over groups and sets.

III.7.2 Density-sensitive versions

When $0 < t \leq \delta$, equation (III.7.1) gives

$$\mathcal{D}_d(F) \leq K_d \delta^{p-4} t^4. \quad (\text{III.7.6})$$

More precisely, for $\delta > 0$ put $s = t/\delta$. Then

$$\frac{\mathcal{D}_d(F)}{\delta^p} \leq B_p(s), \quad B_p(s) = \sum_{r=4}^p \binom{p}{r} s^r. \quad (\text{III.7.7})$$

This makes the relative scale t/δ , rather than t alone, explicit. For $0 < \varepsilon \leq 1$, a sufficient condition for relative error at most ε is

$$t^p \leq \delta^p \left(\frac{\varepsilon}{K_d} \right)^{p/4}. \quad (\text{III.7.8})$$

The condition implies $t \leq \delta$ because $K_d \geq 1$.

A useful closed bound, valid without $t \leq \delta$, is

$$\mathcal{D}_d(F) \leq \binom{p}{4} t^4 (\delta + t)^{p-4}. \quad (\text{III.7.9})$$

To verify it, compare coefficients using $\binom{p}{4} \binom{p-4}{r-4} = \binom{p}{r} \binom{r}{4} \geq \binom{p}{r}$. These convenient constants are not claimed to be optimal. The next section substantially reduces the fourth-order coefficient itself.

III.8 The exact quartic term and the role of two-torsion

Source 08, delivered Section 4.

III.8.1 Fourier notation

Write $\widehat{G}$ additively for the character group, and use $e_\chi(x)$ for the character corresponding to $\chi \in \widehat{G}$. Set

$$\begin{aligned}\widehat{f}(\chi) &= \mathbb{E}_x f(x) \overline{e_\chi(x)}, & E_4(f) &= \sum_{\chi \in \widehat{G}} |\widehat{f}(\chi)|^4, \\ E_{\langle 2 \rangle}(f) &= \sum_{\substack{\chi \in \widehat{G} \setminus \{0\} \\ 2\chi=0}} |\widehat{f}(\chi)|^4.\end{aligned}\tag{III.8.1}$$

For real f , $\widehat{f}(-\chi) = \overline{\widehat{f}(\chi)}$. Character orthogonality on a two-cube gives

$$E_4(f) = \|f\|_{U^2(G)}^4, \quad 0 \leq E_{\langle 2 \rangle}(f) \leq E_4(f) \leq t^4.\tag{III.8.2}$$

If G has odd order, $E_{\langle 2 \rangle}(f) = 0$. If G has exponent 2 and f has mean zero, $E_{\langle 2 \rangle}(f) = E_4(f)$.

For any $S \subseteq V_d$, expanding every factor by Fourier inversion yields

$$\Lambda_S(f) = \sum_{\substack{(\chi_v)_{v \in S} \in \widehat{G}^S \\ \sum_v \chi_v = 0, \sum_v v_i \chi_v = 0 \ (1 \leq i \leq d)}} \prod_{v \in S} \widehat{f}(\chi_v).\tag{III.8.3}$$

This formula is exact over every finite abelian group. In particular, one must solve the equations in $\widehat{G}$, not merely compute a rank over $\mathbb{Q}$.

III.8.2 Classification of four-vertex subsets

A set of four distinct binary vertices is an *ordinary parallelogram* if it can be labeled a, b, c, e with $a + b = c + e$ as an equality in $\mathbb{Z}^d$. It is a *binary affine plane* if its four vertices sum to 0 in $\mathbb{F}_2^d$. Every ordinary parallelogram is a binary affine plane, but the converse fails in dimension at least 3.

Lemma III.8.1 (Quartic classification). *Suppose $f : G \rightarrow \mathbb{R}$ has mean zero and $|S| = 4$. Then*

$$\Lambda_S(f) = \begin{cases} E_4(f), & S \text{ is an ordinary parallelogram,} \\ E_{\langle 2 \rangle}(f), & S \text{ is a binary affine plane but not an ordinary parallelogram,} \\ 0, & S \text{ is not a binary affine plane.} \end{cases}$$

Proof. Use cube reflections to write $S = \{0, u, v, w\}$ with distinct nonzero binary vectors u, v, w . Let the corresponding Fourier frequencies be $\lambda_0, \lambda_1, \lambda_2, \lambda_3$. The constraints in (III.8.3) are

$$\lambda_0 + \lambda_1 + \lambda_2 + \lambda_3 = 0, \quad u_i \lambda_1 + v_i \lambda_2 + w_i \lambda_3 = 0 \quad (1 \leq i \leq d).\tag{III.8.4}$$

First suppose the matrix with columns u, v, w has rank 2 over $\mathbb{Q}$. The vectors u, v have a unit 2×2 minor, and $w = au + bv$ for some rational a, b . Among the coordinate patterns (u_i, v_i) , at least two of 10, 01, 11 occur. If all three occur, the constraints that $a, b, a + b$ lie in $\{0, 1\}$ would force w to be 0, u , or v , which is excluded. If only 10, 01 occur, then $w = u + v$; if the two patterns are 10, 11 or 01, 11, then one of u, v, w is the sum of the other two. In every case the four points form a parallelogram. The unit minor shows that all solutions of (III.8.4) are the primitive parallelogram relation multiplied by a single character χ . The product of the four Fourier coefficients is $|\widehat{f}(\chi)|^4$.

Next suppose the matrix has rank 3 over $\mathbb{F}_2$. It has an odd 3×3 binary minor. Every 3×3 binary determinant has absolute value at most 2, so this minor is ± 1 and is invertible over every abelian group. Thus all four frequencies vanish, and the contribution is zero because $\hat{f}(0) = 0$. For completeness, the determinant bound follows by adjoining an all-one first row and column and replacing the binary block A by $1 - 2A$. The resulting 4×4 sign matrix has determinant $-8 \det A$ and absolute determinant at most 16 by Hadamard's inequality.

The remaining case has rank 3 over $\mathbb{Q}$ and rank 2 over $\mathbb{F}_2$. Since u, v, w are distinct and nonzero, their binary relation is $u + v + w = 0$. The only nonzero coordinate patterns (u_i, v_i, w_i) are 110, 101, 011. All three patterns must occur, since otherwise the rational rank would be at most 2. Equations (III.8.4) now give

$$\lambda_1 + \lambda_2 = \lambda_1 + \lambda_3 = \lambda_2 + \lambda_3 = 0.$$

Hence $\lambda_1 = \lambda_2 = \lambda_3 = \chi$, $2\chi = 0$, and $\lambda_0 = \chi$. The Fourier coefficient of an order-two character is real, and the trivial character contributes zero. The sum is precisely $E_{\langle 2 \rangle}(f)$. These cases exhaust all possibilities. $\square$

III.8.3 Counting the two types

Define

$$R_d = \frac{6^d - 2 \cdot 4^d + 2^d}{8}, \quad (\text{III.8.5})$$

$$F_d = \frac{2^d(2^d - 1)(2^d - 2)}{24}, \quad (\text{III.8.6})$$

$$T_d = F_d - R_d = \frac{8^d - 3 \cdot 6^d + 3 \cdot 4^d - 2^d}{24}. \quad (\text{III.8.7})$$

Here F_d is a combinatorial count and should not be confused with the function F .

Lemma III.8.2. *The numbers of ordinary parallelograms and binary affine planes in V_d are R_d and F_d , respectively. The number of non-parallelogram binary planes is T_d .*

Proof. For one binary coordinate, there are six ordered solutions of $a + b = c + e$: one with sum 0, four with sum 1, and one with sum 2. Thus there are 6^d ordered solutions in V_d . The repeated-vertex solutions are exactly those with $(a, b) = (c, e)$ or $(a, b) = (e, c)$, numbering $2 \cdot 4^d - 2^d$. Every remaining four-element parallelogram is counted eight times, corresponding to the orderings of its two diagonals and their interchange. This proves (III.8.5).

A binary affine plane has four possible origins and six ordered bases for its two-dimensional direction space. Choosing an origin and two independent directions in $\mathbb{F}_2^d$ gives $2^d(2^d - 1)(2^d - 2)$ choices, each plane occurring 24 times. This proves (III.8.6); subtraction gives (III.8.7). $\square$

d	$\binom{2^d}{4}$	R_d	T_d	F_d
2	1	1	0	1
3	70	12	2	14
4	1,820	100	40	140
5	35,960	720	520	1,240
6	635,376	4,816	5,600	10,416

The middle columns count all parallelograms, not just coordinate square faces. In particular, a three-dimensional Boolean cube contains twelve ordinary parallelograms, not six.

Theorem III.8.3 (Exact torsion-sensitive quartic expansion). *Under the hypotheses of Theorem III.7.3, put*

$$Q_d(f) = R_d E_4(f) + T_d E_{\langle 2 \rangle}(f).$$

Then

$$\mathcal{C}_d(\delta + f) = \delta^p + \delta^{p-4} Q_d(f) + \mathcal{R}_{\geq 5}, \quad (\text{III.8.8})$$

where

$$|\mathcal{R}_{\geq 5}| \leq \sum_{r=5}^p \binom{p}{r} \delta^{p-r} t^r. \quad (\text{III.8.9})$$

In particular,

$$\mathcal{D}_d(F) \leq F_d \delta^{p-4} t^4 + \sum_{r=5}^p \binom{p}{r} \delta^{p-r} t^r. \quad (\text{III.8.10})$$

If $|G|$ is odd, F_d in this upper bound can be replaced by R_d .

Proof. In (III.7.3), group the four-element subsets according to Lemma III.8.1 and use Lemma III.8.2. The remaining subsets have size at least five, so (III.6.8) gives (III.8.9). Finally, $E_{\langle 2 \rangle}(f) \leq E_4(f) \leq t^4$, with $E_{\langle 2 \rangle}(f) = 0$ in odd order. $\square$

Remark III.8.4 (What the torsion correction measures). For a group of exponent 2, the quartic coefficient is $F_d E_4(f)$. For an odd-order group it is $R_d E_4(f)$. In a general group, the additional contribution sees only the part of the Fourier spectrum lying on characters of order two. It is not a correction proportional to the total size of the two-torsion subgroup.

Remark III.8.5 (A sharp coefficient and a potentially non-sharp one). The universal leading coefficient F_d in (III.8.10) is sharp; a real order-two character attains it to fourth order (Proposition III.11.1). The coefficient R_d in the odd-order upper bound is the exact multiplier of $E_4(f)$, but its optimality as a multiplier of t^4 is a different question. We do not identify those two optimization problems.

[write] **6 October 2026; sources 06–10.** Theorem III.8.3 is source 03's Theorem III.2.6 (same R_d , T_d , and $E_{\langle 2 \rangle} = \mathcal{E}_{\langle 2 \rangle}$) and the quartic part of source 09's Theorem III.21.1 ($P_d = R_d$); three independent proofs, by Fourier kernels with binary minors here, by an XOR classification in source 03 and by lattice indices in source 09. The odd-order question in the last remark is source 03's Research question V.14.1 and this source's Question V.34.1; it is settled for $d = 3$ by source 04 (note there).

III.9 The complete three-cube expansion in odd order

Source 08, delivered Section 5.

In this section $d = 3$, $p = 8$, and G has odd order. Define

$$S_5(f) = \sum_{\chi \in \widehat{G}} |\widehat{f}(\chi)|^2 \widehat{f}(\chi)^2 \overline{\widehat{f}(2\chi)}. \quad (\text{III.9.1})$$

The sum is real: the summand at $-\chi$ is the complex conjugate of the summand at χ . Set

$$\begin{aligned} A_6(f) &= \Lambda_{V_3 \setminus \{000, 001\}}(f), \\ B_6(f) &= \Lambda_{V_3 \setminus \{000, 011\}}(f), \\ C_6(f) &= \Lambda_{V_3 \setminus \{000, 111\}}(f), \\ A_7(f) &= \Lambda_{V_3 \setminus \{000\}}(f). \end{aligned}$$

Binary strings denote vertices, and Λ_S is still averaged over all four cube parameters.

Lemma III.9.1 (Five-vertex terms). *For a real mean-zero f on an odd-order group,*

$$\sum_{\substack{S \subseteq V_3 \\ |S|=5}} \Lambda_S(f) = 8S_5(f).$$

Proof. There are $\binom{8}{5} = 56$ five-element subsets. Exactly 48 contain an ordinary parallelogram: there are 12 parallelograms, each with four choices of an additional vertex, and no five-element set contains two different parallelograms. To justify the last claim, two parallelograms sharing three vertices lie in the same affine plane; an affine two-plane contains at most four vertices of a Boolean cube. One way to see the latter fact is to choose two coordinate projections that are injective on its two-dimensional direction space; they map its binary vertices injectively into $\{0, 1\}^2$.

A parallelogram together with a fifth vertex has just its parallelogram relation as a rational dependence. More importantly, this remains the only dependence over $\hat{G}$. Choose three affinely independent vertices of the parallelogram and the fifth vertex. Their 4×4 affine matrix has determinant ± 1 or ± 2 : reflect one chosen vertex to zero and use the binary 3×3 determinant bound from the proof of Lemma III.8.1. Multiplication by either determinant is invertible on an odd-order group. Subtracting a suitable multiple of the primitive parallelogram relation from any Fourier solution kills one parallelogram frequency, after which this invertible matrix kills all remaining frequencies. In particular, the fifth frequency is zero. Its factor $\hat{f}(0)$ makes the average vanish.

The other eight five-element sets are the cube symmetries of

$$S_* = \{000, 110, 101, 011, 111\}.$$

Indeed, for each of the eight vertices w , delete the three neighbors of w . These give eight distinct sets with no parallelogram. To check the latter property for S_* , its unique rational dependence, in the displayed order, is

$$(-1, 1, 1, 1, -2), \tag{III.9.2}$$

which has full support. A parallelogram would give a relation with one zero coefficient. The count $56 - 48 = 8$ proves exhaustion.

For S_* , the three coordinate equations show directly, over any character group, that the frequencies at 110, 101, 011 coincide, say at χ . The frequencies at 111 and 000 are -2χ and $-\chi$, respectively. Thus

$$\Lambda_{S_*}(f) = \sum_{\chi} \hat{f}(-\chi) \hat{f}(\chi)^3 \hat{f}(-2\chi) = S_5(f).$$

Cube reflections and coordinate permutations preserve the average, proving the asserted factor of eight. $\square$

Theorem III.9.2 (Exact three-cube polynomial). *Let G have odd order and $f : G \rightarrow \mathbb{R}$ have mean zero. For $\delta \geq 0$,*

$$\begin{aligned} \mathcal{C}_3(\delta + f) &= \delta^8 + 12\delta^4 E_4(f) + 8\delta^3 S_5(f) \\ &\quad + \delta^2(12A_6(f) + 12B_6(f) + 4C_6(f)) \\ &\quad + 8\delta A_7(f) + \mathcal{C}_3(f). \end{aligned} \tag{III.9.3}$$

Consequently, with $t = \|f\|_{U^3(G)}$,

$$0 \leq \mathcal{D}_3(\delta + f) \leq 12\delta^4 t^4 + 8\delta^3 t^5 + 28\delta^2 t^6 + 8\delta t^7 + t^8. \tag{III.9.4}$$

Proof. The constant and degree-four terms follow from Theorem III.8.3, since $R_3 = 12$ and there is no order-two Fourier contribution. Lemma III.9.1 gives the fifth-degree term. A six-element subset is determined by its missing pair of vertices. Pairs at Hamming distances 1, 2, 3 form three symmetry classes of sizes 12, 12, 4, respectively. These give the three degree-six averages displayed above. The eight seven-element subsets are all equivalent under cube reflections, and the eighth-degree term is the full cube of f . This proves the identity. Apply (III.6.8) to each average, and use $E_4(f) \leq t^4$. $\square$

[write] **6 October 2026; sources 11–14.** Source 13’s Theorem III.31.5 is this identity over $\mathbb{F}_p^n$, p odd, written with the orbit moments T_5, B_1, B_2, B_3, T_7 , which it bounds (including a spectral deficit); source 14’s Appendix A (Section III.38) certifies the same support counts.

The naive fourth-order estimate in dimension three has coefficients 70, 56, 28, 8, 1 in degrees 4, 5, 6, 7, 8. The all-group quartic analysis changes the first coefficient to 14. In odd order the exact support analysis improves these coefficients to 12, 8, 28, 8, 1. In particular, if $t \leq \delta$,

$$\mathcal{D}_3(\delta + f) \leq 57\delta^4 t^4. \tag{III.9.5}$$

This is a convenient uniform corollary, not an assertion that 57 is the best possible constant.

[write] **6 October 2026; sources 06–10.** Theorem III.9.2 contains source 04’s Lemma III.3.3 (the same support counts 12, 8, 28, 8, 1; this S_5 is 04’s B_5) and is the $d = 3$ case of source 09’s Theorem III.21.1 in odd order. Source 04’s Theorem III.3.6 replaces the leading $12\delta^4 t^4$ by the sharp $6\sqrt{2}\delta^4 t^4$.

III.9.1 A Fourier-sensitive remainder

Let $m(f) = \max_\chi |\widehat{f}(\chi)|$. Directly from (III.9.1),

$$|S_5(f)| \leq m(f)E_4(f). \tag{III.9.6}$$

Together with the cube inequality, we also have $|S_5(f)| \leq t^5$. Thus (III.9.3) gives the two-sided estimate

$$\left| \mathcal{D}_3(\delta + f) - 12\delta^4 E_4(f) \right| \leq 8\delta^3 m(f)E_4(f) + 28\delta^2 t^6 + 8\delta t^7 + t^8. \tag{III.9.7}$$

This is useful when the fourth Fourier moment is substantially smaller than t^4 . It does not turn U^2 uniformity alone into control of the full three-cube count: the remaining t^6, t^7, t^8 terms still matter.

The formula also identifies a concrete interaction invisible in a simple norm bound. The fifth-order contribution couples frequencies χ and 2χ . Its sign depends on their relative phases. Even for real weights, that sign need not be positive.

III.10 A counterexample to the quartic global lower bound

Source 08, delivered Section 6.

The positive fourth-order term might suggest the stronger lower estimate

$$\mathcal{D}_3(F) \stackrel{?}{\geq} 12\delta^4 E_4(F - \delta) \quad (|G| \text{ odd}, \quad 0 \leq F \leq 1). \quad (\text{III.10.1})$$

It is false. This is a natural strengthening posed and settled within this memorandum, not a claim to settle a previously identified published conjecture.

Theorem III.10.1 (Negative fifth-order correction). *On $G = \mathbb{Z}/11\mathbb{Z}$, put*

$$h(x) = \cos(2\pi x/11) - \cos(4\pi x/11).$$

For every fixed $0 < \delta < 1$, the weight $F = \delta + \eta h$ belongs to $[0, 1]$ and violates (III.10.1) for all sufficiently small positive η .

Proof. The nonzero Fourier coefficients of h are

$$\hat{h}(1) = \hat{h}(-1) = \frac{1}{2}, \quad \hat{h}(2) = \hat{h}(-2) = -\frac{1}{2}.$$

Thus $\mathbb{E}h = 0$, $E_4(h) = 1/4$, and (III.9.1) gives $S_5(h) = -1/16$: only $\chi = 1, -1$ contribute, each with value $-1/32$. Applying (III.9.3) to $f = \eta h$ yields

$$\mathcal{D}_3(\delta + \eta h) - 12\delta^4 E_4(\eta h) = -\frac{1}{2}\delta^3 \eta^5 + O_\delta(\eta^6), \quad (\text{III.10.2})$$

which is negative for sufficiently small positive η . Since $|h| \leq 2$, the condition $2\eta \leq \min(\delta, 1 - \delta)$ guarantees $0 \leq F \leq 1$.

There is also a completely explicit safe range. Use $\|h\|_{U^3} \leq 2$ in the terms of degree at least six in (III.9.3). Their absolute value, divided by $\frac{1}{2}\delta^3 \eta^5$, is at most

$$3584 \frac{\eta}{\delta} + 2048 \left(\frac{\eta}{\delta}\right)^2 + 512 \left(\frac{\eta}{\delta}\right)^3.$$

This is less than 1 when $0 < \eta/\delta \leq 10^{-4}$. Combining that condition with the pointwise range condition proves the claim without any numerical evaluation of a Gowers norm. $\square$

III.10.1 An exact finite certificate and a larger explicit example

For the same function h , a finite Fourier calculation gives

$$\mathcal{C}_3(\delta + \eta h) = \delta^8 + 3\delta^4 \eta^4 - \frac{1}{2}\delta^3 \eta^5 + \frac{3}{2}\delta^2 \eta^6 + \frac{1}{4}\eta^8. \quad (\text{III.10.3})$$

Here is a compact way to reproduce and check that calculation. The four Fourier constraints on the eight cube vertices have the following complete parametrization, with arithmetic modulo 11:

v	000	001	010	100	011	101	110	111
λ_v	a	b	c	e	$-a - b - c$	$-a - b - e$	$-a - c - e$	$2a + b + c + e$.

(III.10.4)

Every frequency must lie in $D = \{0, 1, -1, 2, -2\}$. A zero frequency contributes δ ; a frequency ± 1 contributes $\eta/2$; a frequency ± 2 contributes $-\eta/2$. It therefore suffices to check $5^4 = 625$ tuples $(a, b, c, e) \in D^4$. The resulting signed counts are

Degree r	0	1	2	3	4	5	6	7	8
Positive products	1	0	0	0	48	0	96	0	64
Negative products	0	0	0	0	0	16	0	0	0

Dividing the signed count in degree r by 2^r gives (III.10.3). Appendix III.15 supplies the short exhaustive certificate; the accompanying verification program also checks it against an independent eight-frequency enumeration. The general negative-sign conclusion in Theorem III.10.1 does not depend on this enumeration.

For an explicit example with comfortable margins from 0 and 1, take $\delta = 1/2$ and $\eta = 1/12$. Then $1/3 \leq F \leq 2/3$ and

$$\frac{\mathcal{D}_3(F)}{\delta^4 E_4(F - \delta)} = 12 - 2s + 6s^2 + s^4 \Big|_{s=1/6} = \frac{15337}{1296} < 12. \quad (\text{III.10.5})$$

The distinction between a local Taylor coefficient and a global lower-bound coefficient is therefore substantive, not just a possible technical caveat.

[write] **6 October 2026; sources 06–10.** Kept on record as Remark W1 in source 03’s section, where source 03 notes the same failure on $\mathbb{Z}/3\mathbb{Z}$; source 09’s Proposition III.22.2 proves it on primes $q \geq 17$. The polynomial (III.10.3) and the ratio (III.10.5) were recomputed independently at the second write (all 11^4 frequency choices, exact arithmetic).

III.11 Sharpness of the fourth-order exponent

Source 08, delivered Section 7.

III.11.1 An exact order-two model

Proposition III.11.1. *Suppose G has a nontrivial character $\chi : G \rightarrow \{1, -1\}$. For $p = 2^d$, $d \geq 2$,*

$$\mathcal{C}_d(\delta + \eta\chi) = \frac{(\delta + \eta)^p + (\delta - \eta)^p + 2(p-1)(\delta^2 - \eta^2)^{p/2}}{2p}. \quad (\text{III.11.1})$$

Moreover, $\|\eta\chi\|_{U^d} = |\eta|$, and for fixed $\delta > 0$,

$$\mathcal{D}_d(\delta + \eta\chi) = F_d \delta^{p-4} \eta^4 + O_{d,\delta}(\eta^6).$$

Thus the leading constant F_d in the all-group bound (III.8.10) is sharp.

Proof. The $d+1$ signs $\chi(x), \chi(h_1), \dots, \chi(h_d)$ are independent and uniform. If every increment sign is 1, all cube values have the same character sign; the two choices of $\chi(x)$ give the first two terms in the numerator. There are $p-1$ other increment-sign patterns. For each, exactly $p/2$ vertices have each sign, so either base sign gives the product $(\delta^2 - \eta^2)^{p/2}$. This proves the exact formula.

A character has Gowers norm 1 in every dimension at least two. The coefficient of η^4 in (III.11.1) is

$$\frac{2\binom{p}{4} + 2(p-1)\binom{p/2}{2}}{2p} = \frac{p(p-1)(p-2)}{24} = F_d.$$

The coefficient of η^2 cancels and all odd coefficients vanish. The remainder is of degree at least six, with the zero remainder understood when $p = 4$. $\square$

[write] **6 October 2026; sources 06–10.** (III.11.1) is source 09’s (III.22.1) (the two closed forms were expanded and compared at the second write for $d = 2, \dots, 5$). Its consequence, that the universal coefficient F_d is attained, is also source 03’s optimality of K_d over all groups and source 09’s Proposition III.22.1.

III.11.2 Odd cyclic groups and real cosine perturbations

To show that the exponent does not rely on two-torsion, let $N > p$ be an odd prime and put

$$h_N(x) = \cos(2\pi x/N), \quad x \in \mathbb{Z}/N\mathbb{Z}.$$

Then $\mathbb{E}h_N = 0$ and $E_4(h_N) = 1/8$. There is a positive constant c_d , depending only on d , such that

$$\|h_N\|_{U^d} = c_d \quad (N > p). \quad (\text{III.11.2})$$

Indeed, in the Fourier expansion of its full cube, every frequency is 1 or -1 . Every constraint is an integer of absolute value at most p ; since $N > p$, vanishing modulo N is equivalent to integer vanishing. The number of admissible frequency assignments is therefore independent of N . There is at least one assignment, namely the alternating cube assignment $\lambda_v = (-1)^{|v|}$, and every summand is positive. This proves (III.11.2) and $c_d > 0$.

For fixed $0 < \delta < 1$ and sufficiently small $\eta > 0$, the weight $F_N = \delta + \eta h_N$ takes values in $[0, 1]$. By Theorem III.8.3, uniformly for $N > p$,

$$\mathcal{D}_d(F_N) = \frac{R_d}{8} \delta^{p-4} \eta^4 + O_{d,\delta}(\eta^5), \quad \|F_N - \delta\|_{U^d}^p = c_d^p \eta^p. \quad (\text{III.11.3})$$

Since $R_d > 0$, no exponent larger than $4/p$ can replace $4/p$ in a uniform bound for these bounded real weights. The remainder could be improved in this particular example, but degree five already suffices for sharpness.

III.11.3 A rounding lemma in the Gowers norm

Weighted sharpness does not automatically imply sharpness for sets, so a separate argument is needed.

Lemma III.11.2 (Independent rounding). *Let $F : G \rightarrow [0, 1]$, $|G| = N$, and $d \geq 2$, $p = 2^d$. There exists a set $A \subseteq G$ such that*

$$\|\mathbf{1}_A - F\|_{U^d(G)} \leq \left(\frac{2\binom{p}{2}}{N} \right)^{1/p}. \quad (\text{III.11.4})$$

Proof. Choose the random variables $\mathbf{1}_A(y)$ independently, with success probabilities $F(y)$, and set $X(y) = \mathbf{1}_A(y) - F(y)$. They have mean zero under this random choice and satisfy $|X(y)| \leq 1$. For a fixed cube whose p sampled vertices are distinct, independence implies

$$\mathbb{E}_{\text{rand}} \prod_{v \in V_d} X(L_v) = 0.$$

For any pair of distinct Boolean vertices v, w , the difference $L_v - L_w$ is a linear form in the increments with at least one coefficient 1 or -1 . It is uniform in G , so $\Pr_{x,h}(L_v = L_w) = 1/N$. By the union bound, the probability that the sampled cube has any collision is at most $\binom{p}{2}/N$.

The product is bounded in absolute value by 1 in all cases. Interchanging the two finite averages therefore gives

$$0 \leq \mathbb{E}_{\text{rand}} \|X\|_{U^d}^p \leq \frac{\binom{p}{2}}{N}.$$

Markov's inequality shows that some realization has the moment at most twice this bound, which is (III.11.4). The random centering used here is pointwise in the probability space; it need not give $\mathbb{E}_{y \in G} X(y) = 0$ for an individual realization. $\square$

[write] **6 October 2026; sources 06–10.** Source 09's Lemma III.22.4 is the same random-rounding lemma with the constant $(\binom{p}{2}/|G|)^{1/p}$ (without the factor two of the Markov step); source 03 rounds on $(\mathbb{Z}/2\mathbb{Z})^n$ and $(\mathbb{Z}/3\mathbb{Z})^n$ with an exact density and source 04 on prime cyclic groups by variance. Four routes to sharpness for sets.

Lemma III.11.3 (Continuity of cube excess). *If $A \subseteq G$, $F : G \rightarrow [0, 1]$, $\delta = \mathbb{E}F$, $\delta_A = |A|/|G|$, and $q = \|\mathbf{1}_A - F\|_{U^d}$, then*

$$|\delta_A - \delta| \leq q, \quad (\text{III.11.5})$$

$$|\mathcal{D}_d(\mathbf{1}_A) - \mathcal{D}_d(F)| \leq 2pq, \quad (\text{III.11.6})$$

$$\| \|\mathbf{1}_A - \delta_A\|_{U^d} - \|F - \delta\|_{U^d} \| \leq 2q. \quad (\text{III.11.7})$$

Proof. The first assertion is (III.6.5) applied to $X = \mathbf{1}_A - F$. Telescope the difference between the two p -factor cube products. Each of the p terms has one factor X , while all other factors are F or $\mathbf{1}_A$, whose U^d norms are at most 1. Equation (III.6.4) gives $|\mathcal{C}_d(\mathbf{1}_A) - \mathcal{C}_d(F)| \leq pq$. Since $\delta, \delta_A \in [0, 1]$, $|\delta_A^p - \delta^p| \leq p|\delta_A - \delta| \leq pq$. This proves the excess estimate. Finally the difference of the centered functions is $X - (\delta_A - \delta)$, whose norm is at most $2q$ by Minkowski and the constant-function norm. The reverse triangle inequality proves the last claim. $\square$

Theorem III.11.4 (Sharpness for genuine sets in odd prime order). *Fix $d \geq 2$, $p = 2^d$, and $0 < \delta < 1$. There are primes $N_j \rightarrow \infty$ and sets $A_j \subseteq \mathbb{Z}/N_j\mathbb{Z}$ such that, with $\delta_j = |A_j|/N_j$ and $\alpha_j = \|\mathbf{1}_{A_j} - \delta_j\|_{U^d}^p$,*

$$\delta_j \rightarrow \delta, \quad \alpha_j \rightarrow 0, \quad \frac{\mathcal{D}_d(\mathbf{1}_{A_j})}{\alpha_j^{4/p}} \rightarrow \frac{R_d \delta^{p-4}}{8c_d^4} > 0.$$

For every $\beta > 4/p$, $\mathcal{D}_d(\mathbf{1}_{A_j})/\alpha_j^\beta \rightarrow \infty$. Thus a bound uniform over such sets, even with density restricted to any fixed neighborhood of δ , cannot have exponent larger than $4/p$.

Proof. Choose $\eta_j = c/j$ with $0 < c < \min(\delta, 1 - \delta)$. Choose a prime $N_j > \max(p, j^{8p})$ and set $F_j = \delta + \eta_j h_{N_j}$. Apply Lemma III.11.2 to obtain A_j with rounding error $q_j = O_d(j^{-8}) = o(\eta_j^4)$. By Lemma III.11.3 and (III.11.3),

$$\begin{aligned} \delta_j &= \delta + o(1), \\ \|\mathbf{1}_{A_j} - \delta_j\|_{U^d} &= c_d \eta_j + o(\eta_j), \\ \mathcal{D}_d(\mathbf{1}_{A_j}) &= \frac{R_d}{8} \delta^{p-4} \eta_j^4 + o(\eta_j^4). \end{aligned}$$

Divide the last relation by the fourth power of the norm in the second. For $\beta > 4/p$, the additional factor $\alpha_j^{4/p-\beta}$ tends to infinity. $\square$

Remark III.11.5 (The density statement is intentionally asymptotic). The sets in this theorem have densities tending to the prescribed δ ; we do not assert exact density δ in every prime cyclic group. For instance, density $1/2$ is impossible in an odd-order group. This does not weaken sharpness for a uniform bound such as (III.7.5).

III.12 Lower bounds and Fourier stability

Source 08, delivered Section 8.

The preceding upper estimates can be paired with a strengthened form of the basic lower cube count. This section records consequences of norm monotonicity and Parseval, rather than attributing a new general norm theorem to the present calculation.

Theorem III.12.1 (Fourier-moment lower bound). *For a real function $F = \delta + f$ on a finite abelian group, where $\delta \geq 0$ and $\mathbb{E}f = 0$, and for $d \geq 2$, $p = 2^d$,*

$$\mathcal{C}_d(F) \geq (\delta^4 + E_4(f))^{p/4}. \quad (\text{III.12.1})$$

In particular,

$$\mathcal{D}_d(F) \geq \frac{p}{4} \delta^{p-4} E_4(f). \quad (\text{III.12.2})$$

For $\delta > 0$, if $D = \mathcal{D}_d(F)$, then

$$E_4(f) \leq (\delta^p + D)^{4/p} - \delta^4 \leq \frac{4}{p} \delta^{4-p} D. \quad (\text{III.12.3})$$

Equality in $\mathcal{C}_d(F) \geq \delta^p$ holds if and only if F is constant.

Proof. The constant frequency of F is δ , while all other Fourier coefficients are those of f . Thus $\|F\|_{U^2}^4 = \delta^4 + E_4(f)$. Now $\|F\|_{U^d} \geq \|F\|_{U^2}$, giving (III.12.1). The binomial theorem, since $p/4$ is a positive integer, implies (III.12.2). Rearrange (III.12.1) to obtain the first inequality in (III.12.3). The concavity of $u \mapsto u^{4/p}$ gives the second inequality by the tangent line at $u = \delta^p$. If the cube count equals δ^p , then (III.12.1) forces $E_4(f) = 0$. Every Fourier coefficient of f is zero, so $f = 0$. The converse is immediate. $\square$

As a direct stability statement, every nontrivial Fourier coefficient obeys

$$\max_{\chi \neq 0} |\widehat{F}(\chi)| \leq \left(\frac{4}{p} \delta^{4-p} \mathcal{D}_d(F) \right)^{1/4} \quad (\delta > 0).$$

This is stability in Fourier space. It is not closeness in L^2 to a constant: for an indicator, the squared L^2 distance is exactly $\delta(1-\delta)$, even along the near-minimal sequences in Theorem III.11.4. The displayed inequality itself controls U^2 , not the balanced U^d norm; a stronger norm-geometric conclusion would require an additional argument.

Corollary III.12.2 (A finite-size correction). *Suppose $|G| = N > 1$ and write $\sigma^2 = \mathbb{E}|F - \delta|^2$. Then*

$$\mathcal{C}_d(F) \geq \left(\delta^4 + \frac{\sigma^4}{N-1} \right)^{p/4}. \quad (\text{III.12.4})$$

For $A \subseteq G$ of density δ ,

$$\mathcal{C}_d(\mathbf{1}_A) \geq \left(\delta^4 + \frac{\delta^2(1-\delta)^2}{N-1} \right)^{p/4}. \quad (\text{III.12.5})$$

Proof. Parseval and $\widehat{f}(0) = 0$ give $\sum_{\chi \neq 0} |\widehat{f}(\chi)|^2 = \sigma^2$. Cauchy–Schwarz over the $N - 1$ nontrivial characters yields $E_4(f) \geq \sigma^4/(N - 1)$. Insert this into (III.12.1). For an indicator, $\sigma^2 = \delta(1 - \delta)$. $\square$

The lower coefficient $p/4$ in (III.12.2) and the local coefficient R_d in odd order are different quantities. Theorem III.10.1 shows explicitly why one cannot simply replace the former with the latter. Determining the best global lower coefficient remains a separate optimization problem.

III.13 Different weights at different vertices

Source 08, delivered Section 9.

The centering argument is not limited to counting cubes in a single set. Suppose each vertex has a real weight

$$F_v = \delta_v + f_v, \quad \delta_v = \mathbb{E}F_v, \quad \mathbb{E}f_v = 0, \quad t_v = \|f_v\|_{U^d}.$$

The means may be different and may be negative.

Theorem III.13.1 (Inhomogeneous fourth-order estimate). *With the notation above,*

$$\left| \Lambda_d((F_v)) - \prod_{v \in V_d} \delta_v \right| \leq \sum_{\substack{S \subseteq V_d \\ |S| \geq 4}} \prod_{v \notin S} |\delta_v| \prod_{v \in S} t_v. \quad (\text{III.13.1})$$

All terms with one, two, or three centered factors vanish identically.

Proof. Expand the product by the subset of vertices at which the centered factor is chosen. Lemma III.7.1 makes every term of sizes one to three a product of zero means. Pad the remaining selected inputs with constant 1 in (III.6.4) and take absolute values. $\square$

The quartic classification is also valid with different real centered inputs. If $S = \{a, b, c, e\}$ is an ordinary parallelogram with $a + b = c + e$, the associated mixed fourth-order average is

$$\sum_{\chi} \widehat{f}_a(\chi) \widehat{f}_b(\chi) \overline{\widehat{f}_c(\chi)} \overline{\widehat{f}_e(\chi)}. \quad (\text{III.13.2})$$

For a non-parallelogram binary plane it is

$$\sum_{\substack{\chi \neq 0 \\ 2\chi=0}} \prod_{v \in S} \widehat{f}_v(\chi). \quad (\text{III.13.3})$$

For every other four-set it vanishes. These statements follow from the same character equations as Lemma III.8.1. Hölder’s inequality bounds the absolute value of either expression by

$$\prod_{v \in S} \|f_v\|_{U^2}.$$

Thus one can improve (III.13.1) further by keeping the quartic Fourier expressions and using U^d norms only from degree five onward. Unlike the common-function quartic term, a mixed quartic expression need not be nonnegative. Accordingly, no lower bound by $\prod_v \delta_v$ is asserted in this inhomogeneous setting.

This version applies, for example, when each cube vertex must belong to a different set A_v . It isolates the contribution of the densities and shows that the first possible deviation involves four of the balanced vertex conditions, rather than just one.

III.14 Which centered terms can survive?

Source 08, delivered Section 10.

The four- and five-vertex calculations are instances of a general finite linear-algebra principle. It is useful both for organizing higher coefficients and for designing checkable certificates.

III.14.1 An exact character-kernel criterion

Let $a_1, \dots, a_r \in \mathbb{Z}^m$ be coefficient columns and let $L_j(z) = a_j \cdot z$ for $z \in G^m$. Let M be the matrix with these columns. For independently chosen functions $g_j : G \rightarrow \mathbb{C}$,

$$\mathbb{E}_{z \in G^m} \prod_{j=1}^r g_j(L_j(z)) = \sum_{\lambda \in \ker_{\widehat{G}} M} \prod_{j=1}^r \widehat{g}_j(\lambda_j), \quad (\text{III.14.1})$$

where $\ker_{\widehat{G}} M$ means the solutions of $M\lambda = 0$ in $\widehat{G}^r$. A vector has *full support* if none of its coordinates is zero.

Proposition III.14.1 (Universal vanishing criterion). *The following conditions are equivalent:*

- (i) *The kernel $\ker_{\widehat{G}} M$ has no full-support vector.*
- (ii) *The average in (III.14.1) is zero for every choice of complex mean-zero functions $g_1, \dots, g_r$.*
- (iii) *The average is zero for every common real mean-zero function $g_1 = \dots = g_r = f$.*

Proof. If no kernel vector has full support, every summand in (III.14.1) contains a factor $\widehat{g}_j(0) = 0$. Thus (i) implies (ii), and (ii) implies (iii).

Conversely, suppose $\lambda \in \ker_{\widehat{G}} M$ has full support. For the independently chosen complex functions one may simply take $g_j = e_{\lambda_j}$; their product along the forms is identically 1. To obtain a common real witness as well, take

$$f = \sum_{j=1}^r (e_{\lambda_j} + e_{-\lambda_j}).$$

This function is real and has mean zero. Its Fourier coefficients are all nonnegative real numbers, and every frequency λ_j has a strictly positive coefficient. Therefore all summands in (III.14.1) are nonnegative and the summand indexed by λ is positive. This contradicts (iii), proving (iii) implies (i). Rescaling gives bounded witness functions if desired. $\square$

For a cube subset S , use the matrix with columns $(1, v)$ for $v \in S$. Let $A_{d,r}(G)$ be the number of r -element subsets whose character kernel has a full-support vector. We then have the systematic improvement

$$|\mathcal{C}_d(\delta + f) - \delta^p| \leq \sum_{r=1}^p A_{d,r}(G) \delta^{p-r} t^r \quad (\delta \geq 0, \mathbb{E}f = 0). \quad (\text{III.14.2})$$

In particular, $A_{d,1} = A_{d,2} = A_{d,3} = 0$. For a nontrivial odd-order group $A_{d,4} = R_d$, while a nontrivial elementary abelian two-group has $A_{d,4} = F_d$. The coefficients $A_{d,r}$ are exact counts of potentially nonzero supports, but the resulting norm bound is not automatically optimal: the same function need not simultaneously saturate every surviving Gowers–Cauchy–Schwarz inequality.

III.14.2 The large-prime criterion and exceptional characteristics

The column-dependence structure of an integer matrix is often called its *column matroid*. Here only a simple part of that language is needed: a column is a *coloop* if it does not lie in the span of the other columns.

Proposition III.14.2. *Fix an integer matrix M with r columns. There is a finite set of primes $\mathcal{B}_M$ such that, for every prime $q \notin \mathcal{B}_M$ with $q > r$,*

$$\ker_{\mathbb{F}_q} M \text{ has a full-support vector} \iff M \text{ has no coloop over } \mathbb{Q}.$$

Proof. For M and for each matrix obtained by deleting one column, choose a nonzero minor of size equal to its rational rank; for a rank-zero matrix, use the empty minor 1. Let $\mathcal{B}_M$ contain the prime divisors of these finitely many nonzero integers. Outside $\mathcal{B}_M$, all these ranks are preserved modulo q , since the chosen minors remain nonzero and larger minors vanish identically over the integers. Consequently, the coloop condition agrees over $\mathbb{Q}$ and $\mathbb{F}_q$.

If the j th column is a coloop, every relation has $\lambda_j = 0$, so no full-support vector exists. Conversely, suppose there is no coloop and let $K = \ker_{\mathbb{F}_q} M$ have dimension k . For every j , the coordinate map $\lambda \mapsto \lambda_j$ is a nonzero linear functional on K . Its zero set has size q^{k-1} . The union of the r coordinate zero sets has at most $rq^{k-1} < q^k$ elements. Some vector in K avoids all of them. $\square$

The restriction $q > r$ is deliberate. Even when every coordinate functional is nonzero, finitely many coordinate hyperplanes can cover a vector space over a small field. Likewise, a rank computation over $\mathbb{Q}$ alone cannot detect the order-two quartic terms found in Section III.8. For a general finite abelian group, one must solve the character-group constraints themselves; integer normal forms and prime-primary decomposition provide one way to organize that computation.

This framework is not a substitute for true-complexity theory. It decides *identical vanishing caused by centering*. True-complexity results ask which uniformity norms control the remaining nonzero configuration averages [29, 14]. The two analyses can be used consecutively: first remove terms that vanish exactly, then apply the strongest available norm estimate to the terms that remain.

III.15 A short exact certificate for the counterexample

Source 08, delivered Appendix A.

The code below implements (III.10.4) directly. Every loop variable and every comparison is an integer. Because that parametrization is a bijection between four free frequencies and the Fourier kernel, the enumeration has no omitted solutions and no multiplicities to correct. The returned coefficients are exact rational numbers.

```
from collections import Counter
from fractions import Fraction
from itertools import product

D = {0, 1, 10, 2, 9} # residues 0, +1, -1, +2, -2 mod 11
sign = {1: 1, 10: 1, 2: -1, 9: -1}
counts = Counter()
for a, b, c, e in product(D, repeat=4):
```

```

frequencies = [
    a, b, c, e,
    (-a-b-c) % 11, (-a-b-e) % 11,
    (-a-c-e) % 11, (2*a+b+c+e) % 11,
]
if not all(k in D for k in frequencies):
    continue
degree = sum(k != 0 for k in frequencies)
product_sign = 1
for k in frequencies:
    if k != 0:
        product_sign *= sign[k]
counts[degree, product_sign] += 1

coefficients = [
    Fraction(counts[r, 1] - counts[r, -1], 2**r)
    for r in range(9)
]
assert coefficients == [
    1, 0, 0, 0, 3, Fraction(-1, 2), Fraction(3, 2), 0,
    Fraction(1, 4),
]

```

The coefficient of degree r multiplies $\delta^{8-r}\eta^r$. This certificate is elementary executable arithmetic, not a Lean kernel certificate. The full verification program includes additional independent checks and records their output in `verification_results.json`.

III.16 Normalized cube forms and the analytic input

Source 09, delivered Section 2.

All groups in this paper are finite abelian groups written additively; the trivial group is allowed. Averages are normalized. The character group $\hat{G}$ is written multiplicatively, with identity character 1. The normalized Fourier transform is

$$a_\chi = \hat{f}(\chi) = \mathbb{E}_{x \in G} f(x) \overline{\chi(x)}, \quad f(x) = \sum_{\chi \in \hat{G}} a_\chi \chi(x). \quad (\text{III.16.1})$$

For real f , $a_{\chi^{-1}} = \overline{a_\chi}$, and $\mathbb{E}f = 0$ means $a_1 = 0$.

Let $V_d = \{0, 1\}^d$, and put

$$L_v(x, h) = x + \sum_{i=1}^d v_i h_i \quad (x \in G, h \in G^d, v \in V_d).$$

For real F , define

$$\mathcal{C}_d(F) = \mathbb{E}_{x, h} \prod_{v \in V_d} F(L_v(x, h)). \quad (\text{III.16.2})$$

For complex functions the Gowers form has complex conjugation at odd vertices:

$$\Lambda_d((g_v)) = \mathbb{E}_{x, h} \prod_{v \in V_d} \mathcal{C}^{|v|} g_v(L_v(x, h)), \quad \|g\|_{U^d}^{2^d} = \Lambda_d((g)_v),$$

where $\mathcal{C}$ denotes conjugation. For real functions the conjugations disappear, so (III.16.2) is $\|F\|_{U^d}^{2^d}$. For $d \geq 2$ this is a norm power. The case $d = 1$ is the seminorm $|\mathbb{E}F|$ and will not be used for the main results.

Lemma III.16.1 (Gowers–Cauchy–Schwarz). *For arbitrary complex functions $g_v : G \rightarrow \mathbb{C}$,*

$$|\Lambda_d((g_v))| \leq \prod_{v \in V_d} \|g_v\|_{U^d}.$$

Consequently, if f is real and $S \subseteq V_d$, then

$$\left| \mathbb{E}_{x,h} \prod_{v \in S} f(L_v(x, h)) \right| \leq \|f\|_{U^d}^{|S|}. \quad (\text{III.16.3})$$

The first assertion is the normalized form of Gowers’ Lemma 3.8 [1]. Its iterated Cauchy–Schwarz proof works over every finite abelian group: at each coordinate, separate the two opposite faces, apply Cauchy–Schwarz, and duplicate the averaging variable. After all coordinates have been duplicated, each vertex function has its own full cube average. If one starts with the paper’s bounded version, scaling each of the finitely many functions proves the unrestricted version. The second assertion follows by setting $g_v = f$ on S and $g_v = 1$ elsewhere.

For completeness, the auxiliary norm facts needed below follow directly from this input. Taking one vertex function to be g and all others one gives $|\mathbb{E}g| \leq \|g\|_{U^d}$. Taking g on one face and one on the opposite face gives $\|g\|_{U^{d-1}} \leq \|g\|_{U^d}$ for $d \geq 2$, interpreting U^1 as above. Expanding the cube form of $g + h$ and applying Lemma III.16.1 termwise gives the triangle inequality. Finally, Fourier orthogonality gives

$$\|f\|_{U^2}^4 = \sum_{\chi \in \widehat{G}} |a_\chi|^4. \quad (\text{III.16.4})$$

These observations also prove $\mathcal{C}_d(F) \geq (\mathbb{E}F)^m$ for real F with nonnegative mean.

Definition III.16.2 (Subset moments and binomial tails). For $S \subseteq V_d$, put

$$T_S(f) = \mathbb{E}_{x,h} \prod_{v \in S} f(L_v(x, h)), \quad T_\emptyset(f) = 1.$$

For $0 \leq r \leq m$ and $\delta, \varepsilon \geq 0$, put

$$B_{m,r}(\delta, \varepsilon) = \sum_{s=r}^m \binom{m}{s} \delta^{m-s} \varepsilon^s.$$

The elementary but useful estimate

$$B_{m,r}(\delta, \varepsilon) \leq \binom{m}{r} \varepsilon^r (\delta + \varepsilon)^{m-r} \quad (\text{III.16.5})$$

follows by comparing the coefficient of $\delta^{m-s} \varepsilon^s$ on both sides: $\binom{m}{r} \binom{m-r}{s-r} = \binom{m}{s} \binom{s}{r} \geq \binom{m}{s}$. We use the usual convention that a zeroth power is one, including at zero. No division by the density is needed in the main estimates.

III.17 Balancing removes the first three orders

Source 09, delivered Section 3.

Lemma III.17.1 (Three-vertex uniformity). *Let $S \subseteq V_d$ with $1 \leq |S| \leq 3$. If (x, h) is uniform in G^{d+1} , then $(L_v(x, h))_{v \in S}$ is uniform in G^S . In particular, $T_S(f) = 0$ whenever $\mathbb{E}f = 0$.*

Proof. Flipping an abstract cube coordinate is an invertible change of variables: replace h_i by $-h_i$ and x by $x + h_i$ for every flipped coordinate, with all replacements understood simultaneously. Thus we may move one selected vertex to 0.

For two selected vertices, the second is a nonzero binary vector. One of its coordinates is one, so the two values are controlled by x and an independent group variable with coefficient one.

For three selected vertices, write the other two as distinct nonzero binary vectors u, v . After interchanging them if necessary, there is a coordinate i with $(u_i, v_i) = (1, 0)$. There is a coordinate j with $v_j = 1$. The two rows $(1, 0)$ and $(u_j, 1)$ have determinant one. Together with the base variable, these coordinates give an integer minor of determinant ± 1 for the three value maps. Fixing all other variables, the remaining map is an automorphism of G^3 followed by a translation. Hence its output is uniform. The one-vertex case is immediate. Independence now gives $T_S(f) = (\mathbb{E}f)^{|S|} = 0$. $\square$

The determinant-one argument is important. Rational linear independence alone would not imply this statement on arbitrary finite groups.

Theorem III.17.2 (Fourth-order replacement for Lemma 3.10). *Let $d \geq 2$, $m = 2^d$, $f : G \rightarrow \mathbb{R}$ have mean zero, and $\delta \geq 0$. Put $\varepsilon = \|f\|_{U^d}$. Then*

$$0 \leq \mathcal{C}_d(\delta + f) - \delta^m \leq B_{m,4}(\delta, \varepsilon) \leq \binom{m}{4} \varepsilon^4 (\delta + \varepsilon)^{m-4}. \quad (\text{III.17.1})$$

In particular, for $A \subseteq G$ of density δ and $\|\mathbf{1}_A - \delta\|_{U^d}^m \leq \alpha$,

$$\#\{(x, h) : L_v(x, h) \in A \ \forall v\} \leq |G|^{d+1} \left[\delta^m + \sum_{s=4}^m \binom{m}{s} \delta^{m-s} \alpha^{s/m} \right]. \quad (\text{III.17.2})$$

Proof. Multilinearity gives the exact identity

$$\mathcal{C}_d(\delta + f) = \sum_{S \subseteq V_d} \delta^{m-|S|} T_S(f). \quad (\text{III.17.3})$$

The empty subset contributes δ^m . Lemma III.17.1 removes all subsets of sizes one through three. Bound the others by (III.16.3) and count subsets of each size. The final inequality is (III.16.5); the lower bound was proved after Lemma III.16.1. For an indicator, the normalized count becomes the integer count after multiplication by $|G|^{d+1}$, and the polynomial upper bound is increasing in $\varepsilon \geq 0$. $\square$

[write] **6 October 2026; sources 06–10.** Theorem III.17.2 is also proved by sources 03, 04 and 08 (note after source 08's Theorem III.7.3); (III.17.2) is source 08's proposed formal target (V.32.1).

For $d = 2$ there is only one surviving subset. Fourier orthogonality therefore gives the exact identity

$$\mathcal{C}_2(\delta + f) = \delta^4 + \|f\|_{U^2}^4. \quad (\text{III.17.4})$$

For larger d , the surviving terms are not arbitrary. Most four- and five-vertex subsets still contribute zero. Their complete classification is the main task of the next sections.

III.18 Integer value lattices and Fourier constraints

Source 09, delivered Section 4.

III.18.1 A general exact formula

Order a subset $S = \{v_1, \dots, v_s\} \subseteq V_d$ and form the $(d+1) \times s$ integer matrix

$$M_S = \begin{pmatrix} 1 & \cdots & 1 \\ v_1 & \cdots & v_s \end{pmatrix}. \quad (\text{III.18.1})$$

Let $\mathcal{L}_S$ be the integer lattice generated by its rows in $\mathbb{Z}^s$. Define the character constraint group

$$K_G(S) = \left\{ (\chi_j) \in \widehat{G}^s : \prod_j \chi_j = 1, \quad \prod_j \chi_j^{(v_j)_i} = 1 \ (1 \leq i \leq d) \right\}. \quad (\text{III.18.2})$$

Proposition III.18.1 (Fourier–lattice identity). *For functions $f_j : G \rightarrow \mathbb{C}$ with Fourier coefficients $a_{j,\chi}$,*

$$\mathbb{E}_{x,h} \prod_{j=1}^s f_j(L_{v_j}(x, h)) = \sum_{(\chi_j) \in K_G(S)} \prod_{j=1}^s a_{j,\chi_j}. \quad (\text{III.18.3})$$

If all f_j have mean zero, only tuples with every $\chi_j \neq 1$ can contribute.

Proof. Insert Fourier inversion for every factor. The average over x vanishes unless $\prod_j \chi_j = 1$. Independently, the average over h_i vanishes unless $\prod_j \chi_j^{(v_j)_i} = 1$. Every surviving character average is one. All sums are finite, so no interchange issue arises. $\square$

If $\mathcal{L}_S = \mathbb{Z}^s$, then the constraints force all $\chi_j = 1$. More generally, when M_S has full column rank, the quotient $\mathbb{Z}^s / \mathcal{L}_S$ is finite; its invariant factors specify the possible torsion characters. For example, an index-two quotient permits only one order-two parameter. An index-three quotient permits only one order-three parameter. The support of the corresponding relation still matters: a forced trivial character at even one vertex kills the moment.

When the rank is $s - 1$, there can instead be a free character parameter coming from a real affine relation. If the row lattice is saturated in its rational span, that relation describes the entire constraint group, without additional torsion components. These are the cases that give ordinary fourth moments and the quintic statistic below.

III.18.2 Small determinant bounds

Lemma III.18.2. *Every 2×2 binary matrix has determinant of absolute value at most one; every 3×3 binary matrix has determinant of absolute value at most two; every 4×4 binary matrix has determinant of absolute value at most three.*

Proof. The first claim follows from the determinant formula. For an $n \times n$ binary matrix B , introduce the $(n+1) \times (n+1)$ sign matrix

$$H = \begin{pmatrix} 1 & \mathbf{1}^T \\ \mathbf{1} & J - 2B \end{pmatrix}.$$

Subtracting its first row from each remaining row shows $\det H = (-2)^n \det B$. Hadamard's determinant inequality gives

$$|\det B| \leq \frac{(n+1)^{(n+1)/2}}{2^n}.$$

For $n = 3$ this is two; for $n = 4$ it is less than four, so the integral determinant is at most three in absolute value. $\square$

Any minor of M_S which includes the all-ones row can be reduced, after moving one vertex to zero by cube-coordinate flips, to a binary minor one size smaller. This permits Lemma III.18.2 to control both primitive affine relations and possible lattice indices.

Lemma III.18.3 (A plane contains at most four cube vertices). *An affine subspace of real dimension r contains at most 2^r vertices of a Boolean cube. In particular, five distinct cube vertices have augmented rank at least four.*

Proof. Choose r coordinate functionals whose restrictions are independent on the direction space. Projection onto these coordinates is injective on the affine subspace. A cube vertex projects to an element of $\{0, 1\}^r$, of which there are 2^r . $\square$

III.19 The complete four-vertex classification

Source 09, delivered Section 5.

Vectors denoted by u, v, w, z in a normal form below are binary vectors with pairwise disjoint, nonempty supports. Coordinates unused by any of them are permitted. Cube symmetries mean coordinate permutations and coordinate flips, not arbitrary affine transformations of the cube.

Theorem III.19.1 (Four selected vertices). *For real mean-zero f , a four-vertex moment can be nonzero only in the following two types, up to cube symmetries:*

Type	Normal form	Moment
Parallelogram	$\{0, u, v, u + v\}$	$\sum_{\chi} a_{\chi} ^4$
Binary torsion	$\{0, u + v, u + w, v + w\}$	$\sum_{\chi^2=1} a_{\chi} ^4$

All other four-vertex moments vanish over every finite abelian group.

Proof. Any three selected vertices have augmented rank three and a primitive minor, by Lemma III.17.1. Thus the four-vertex rank is three or four.

Suppose first that it is three. A primitive relation has no zero coefficient, since any three vertices are independent. Choose three independent rows including the all-ones row. The cofactors giving its relation have absolute value at most one: after a cube flip, they are 2×2 binary determinants. Hence the relation has four coefficients ± 1 . Their sum is zero, so two have each sign. Moving one vertex to zero reduces the relation to $u + v = w$, and binarity forces u and v to have disjoint supports. Both are nonempty. The value relation is an ordinary parallelogram relation, and the primitive three-vertex minor excludes additional torsion. Formula (III.18.3) gives $\sum_{\chi} a_{\chi}^2 a_{\chi^{-1}}^2 = \sum_{\chi} |a_{\chi}|^4$.

Suppose next that the rank is four. Some full minor including the all-ones row is nonzero, and it has absolute value at most two. Therefore the lattice index is one or two. Index one makes the moment zero. At index two the nonzero relation modulo two is unique. Its support has even size because of the all-ones row; it cannot have size two because the vertices are distinct. It therefore uses all four vertices.

Move one vertex to zero. In each coordinate, the remaining three bits have even sum. The only patterns are 000, 110, 101, 011. Full rank requires all three nonzero patterns to occur. Grouping equal patterns produces precisely $\{0, u + v, u + w, v + w\}$ with three disjoint nonempty blocks. Its quotient has order two, and its character constraints are (χ, χ, χ, χ) with $\chi^2 = 1$. Such a Fourier coefficient is real, so its fourth power is $|a_\chi|^4$. $\square$

Proposition III.19.2 (Counting the four-vertex types). *The numbers of parallelogram and binary-torsion subsets of V_d are respectively*

$$P_d = \frac{2^d}{8}(3^d - 2 \cdot 2^d + 1) = \frac{6^d - 2 \cdot 4^d + 2^d}{8}, \quad (\text{III.19.1})$$

$$T_d = \frac{2^d}{24}(4^d - 3 \cdot 3^d + 3 \cdot 2^d - 1) = \frac{8^d - 3 \cdot 6^d + 3 \cdot 4^d - 2^d}{24}. \quad (\text{III.19.2})$$

Proof. For a parallelogram, choose a base vertex in 2^d ways and assign each coordinate to the unused block, the support of u , or the support of v , requiring both active blocks to occur. Inclusion–exclusion gives $3^d - 2 \cdot 2^d + 1$ assignments. Each resulting subset is counted for four choices of base and two orders of the active blocks, so divide by eight.

For the second type, choose a base and assign coordinates to an unused block or one of three nonempty active blocks. There are $4^d - 3 \cdot 3^d + 3 \cdot 2^d - 1$ assignments. Each subset has four base choices and $3!$ orders of the blocks, so divide by twenty-four. $\square$

In particular, the fourth-order coefficient is never negative. Its arithmetic dependence is entirely through the order-two part of the character group. There are no other fourth-order corrections, even on composite groups with large exponents.

[write] **6 October 2026; sources 06–10.** Theorem III.19.1 and Proposition III.19.2 are source 03’s Lemma III.2.3 with its counts and source 08’s Lemmas III.8.1 and III.8.2: P_d is 03’s and 08’s R_d , T_d is theirs, and $P_d + T_d = A_d$ is 08’s F_d and 03’s K_d (checked for $d = 2, \dots, 7$ at the second write). Three independent proofs.

III.20 The complete five-vertex classification

Source 09, delivered Section 6.

Theorem III.20.1 (Five selected vertices). *For real mean-zero f , every five-vertex moment vanishes except possibly for the following two types, up to cube symmetries:*

$$\text{star:} \quad \{0, u, v, w, u + v + w\}, \quad (\text{III.20.1})$$

$$\text{ternary torsion:} \quad \{0, u + v + w, u + v + z, u + w + z, v + w + z\}. \quad (\text{III.20.2})$$

The star moment is

$$\sum_{\chi \in \widehat{G}} |a_\chi|^2 a_\chi^2 \overline{a_{\chi^2}}, \quad (\text{III.20.3})$$

and the ternary-torsion moment is

$$\sum_{\chi^3=1} a_\chi^4 \overline{a_\chi}. \quad (\text{III.20.4})$$

Proof. By Lemma III.18.3, the augmented rank is four or five.

Rank four, with a zero in the unique relation. The relation must involve exactly four vertices, and those four form a parallelogram. Put them in the form $0, u, v, u + v$, with u, v supported on disjoint nonempty coordinate blocks U, V . Let w be the fifth vertex. It lies outside their real affine plane. Therefore at least one of the following holds: w is nonzero outside $U \cup V$; its bits vary within U ; or its bits vary within V .

In the first case, a coordinate outside $U \cup V$, together with one coordinate in each of U, V , gives a determinant-one minor for $0, u, v, w$. In the second case, take two coordinates in U where the bits of w differ and one in V ; their determinant is ± 1 . The third case is symmetric. Thus the four values at $0, u, v, w$ are jointly uniform over every group. The fourth parallelogram value is determined by the first three, while the value at w is independent. Its mean-zero factor kills the entire moment. This argument rules out hidden torsion, rather than merely using rational independence.

Rank four, with all five relation coefficients nonzero. Choose four independent rows including the all-ones row. Every cofactor has absolute value at most two, by Lemma III.18.2. The primitive relation therefore has coefficients of absolute values one or two, with sum zero. Up to an overall sign and permutation, the only possibilities are

$$(1, 1, 1, -1, -2), \quad (2, 2, -2, -1, -1).$$

Indeed, the number of odd coefficients is even; a primitive vector cannot have all coefficients even. Enumerating one or three even coefficients gives these two possibilities.

The second is impossible for distinct cube vertices. In any coordinate, the zero-sum condition forces the two vertices with coefficient -1 to have equal bits, since all other contributions are even. Those two vertices would therefore coincide. For the first relation, move the coefficient- -2 vertex to zero. If u, v, w are the coefficient-1 vertices and a is the coefficient- -1 vertex, the relation reads $u + v + w = a$. Binariness forces the supports of u, v, w to be disjoint; distinctness makes them nonempty. This gives (III.20.1).

There is no extra torsion in this case. The cofactor vector is an integer multiple of the primitive relation. Since one coefficient has absolute value two and all cofactors have absolute value at most two, that multiple has absolute value one. Some cofactor is consequently ± 1 , so the row lattice is saturated. In the order $(0, u, v, w, u + v + w)$, a primitive relation is $(-2, 1, 1, 1, -1)$. The character tuple is therefore $(\chi^{-2}, \chi, \chi, \chi, \chi^{-1})$. Its Fourier product is $a_\chi^3 \overline{a_\chi} \overline{a_{\chi^2}}$, which is (III.20.3).

Rank five. A nonzero full minor including the all-ones row has absolute value at most three. The row-lattice index is therefore one, two, or three. Index one gives zero. At index two the unique nonzero relation modulo two has even support; distinctness excludes support two, so its support is four. The remaining vertex has a forced trivial character and the moment vanishes.

At index three, take a nonzero relation modulo three. Its coefficients are $0, 1, -1$. It cannot have support at most three, by the primitive three-vertex property. If it had support four, the all-ones row would force two plus signs and two minus signs. In each binary coordinate the corresponding integer sum lies in $[-2, 2]$; divisibility by three would force the sum to be zero as an integer. This would be a real parallelogram relation, contradicting rank five. Hence the relation has full support.

The all-ones row now forces four coefficients of one sign and one of the other. After rescaling the relation modulo three, write them as $(-1, 1, 1, 1, 1)$, and move the exceptional vertex to zero.

Each coordinate of the other four vertices has either zero or three ones. Thus its pattern is 0000 or the complement of a unit vector. Rank five requires all four nonzero pattern types. Grouping equal patterns gives (III.20.2), with four nonempty disjoint blocks. The constraint tuples are $(\chi^{-1}, \chi, \chi, \chi, \chi)$ with $\chi^3 = 1$. Their Fourier products give (III.20.4). $\square$

Proposition III.20.2 (Counting the five-vertex types). *The numbers of star and ternary-torsion subsets are respectively*

$$Q_d = \frac{2^d}{6}(4^d - 3 \cdot 3^d + 3 \cdot 2^d - 1), \quad (\text{III.20.5})$$

$$S_d = \frac{2^d}{24}(5^d - 4 \cdot 4^d + 6 \cdot 3^d - 4 \cdot 2^d + 1). \quad (\text{III.20.6})$$

Proof. For a star, the coefficient- -2 vertex is intrinsically distinguished. Choose this vertex and then choose three nonempty active coordinate blocks. Only their $3!$ orders produce multiple counting. This gives (III.20.5).

For a ternary configuration the exceptional coefficient in its unique modulo-three relation is distinguished. Choose that vertex and four nonempty active blocks, dividing by $4!$. Inclusion-exclusion gives (III.20.6). Unlike the binary-torsion case, one does not divide by the number of vertices: the exceptional vertex is unique. $\square$

The Stirling expressions (F.14.5) follow without any algebraic guessing. Assign d labeled coordinates to k nonempty active blocks and one possibly empty inactive block. Adjoin one extra labeled element to the inactive block. After forgetting the names of the active blocks, this is a partition of $d + 1$ elements into $k + 1$ nonempty blocks, with the block of the extra element distinguished. The number of assignments is therefore $k! \left\{ \begin{matrix} d+1 \\ k+1 \end{matrix} \right\}$.

[write] **6 October 2026; sources 06–10.** The star moment (III.20.3) is source 04's $B_5(f)$ ((III.3.8)) and source 08's $S_5(f)$; the ternary moment (III.20.4) is source 03's (III.2.29). This classification answers the fifth-order part of source 03's Research question on the fifth and sixth coefficients (note there).

III.21 Exact expansion and quantitative consequences

Source 09, delivered Section 7.

Define

$$E_4(f) = \sum_{\chi} |a_{\chi}|^4, \quad (\text{III.21.1})$$

$$T_2(f) = \sum_{\chi^2=1} |a_{\chi}|^4, \quad (\text{III.21.2})$$

$$M_5(f) = \sum_{\chi} |a_{\chi}|^2 a_{\chi}^2 \overline{a_{\chi^2}}, \quad (\text{III.21.3})$$

$$T_{3,5}(f) = \sum_{\chi^3=1} a_{\chi}^4 \overline{a_{\chi}}. \quad (\text{III.21.4})$$

The square in a_{χ}^2 means the square of a Fourier coefficient; the subscript in a_{χ^2} means evaluation at the squared character. These operations must not be confused. Both quintic statistics are real: conjugation permutes the summands by $\chi \mapsto \chi^{-1}$. They need not be nonnegative.

Theorem III.21.1 (Exact fourth and fifth orders). *Let G be finite abelian, $d \geq 3$, $m = 2^d$, $\delta \geq 0$, and $f : G \rightarrow \mathbb{R}$ have mean zero. With $\varepsilon = \|f\|_{U^d}$,*

$$\begin{aligned} \mathcal{C}_d(\delta + f) &= \delta^m + \delta^{m-4}(P_d \mathbf{E}_4(f) + T_d \mathbf{T}_2(f)) \\ &\quad + \delta^{m-5}(Q_d \mathbf{M}_5(f) + S_d \mathbf{T}_{3,5}(f)) + R_6, \end{aligned} \quad (\text{III.21.5})$$

where

$$R_6 = \sum_{\substack{S \subseteq V_d \\ |S| \geq 6}} \delta^{m-|S|} T_S(f), \quad |R_6| \leq B_{m,6}(\delta, \varepsilon).$$

The coefficients are given by (F.14.5) and satisfy $P_d + T_d = A_d$ and $Q_d = 4T_d$.

Proof. Start with (III.17.3). Apply Lemma III.17.1, Theorems III.19.1 and III.20.1, and the counting Propositions III.19.2 and III.20.2. The remaining subsets are exactly those defining R_6 . Apply Lemma III.16.1 to each one. The two coefficient identities follow from (III.19.1)–(III.20.6). $\square$

[write] **6 October 2026; sources 15–20.** Two further independent derivations: source 16’s Theorem III.39.1 (quintic part stated for odd order) and source 18’s Theorem III.40.1 (every finite abelian group, with a Smith-form proof that only 2 and 3 enter through order five). Neither source could see this one.

d	P_d	T_d	Q_d	S_d
2	1	0	0	0
3	12	2	8	0
4	100	40	160	16
5	720	520	2080	480
6	4816	5600	22400	8960
7	30912	54432	217728	134400

III.21.1 Useful special cases

For three-dimensional cubes,

$$\mathcal{C}_3(\delta + f) = \delta^8 + \delta^4(12\mathbf{E}_4 + 2\mathbf{T}_2) + 8\delta^3\mathbf{M}_5 + R_6, \quad (\text{III.21.6})$$

with

$$|R_6| \leq 28\delta^2\varepsilon^6 + 8\delta\varepsilon^7 + \varepsilon^8.$$

For four-dimensional cubes the fourth and fifth corrections are

$$\delta^{12}(100\mathbf{E}_4 + 40\mathbf{T}_2), \quad \delta^{11}(160\mathbf{M}_5 + 16\mathbf{T}_{3,5}).$$

If $|G|$ is odd, then $\mathbf{T}_2 = 0$. If $3 \nmid |G|$, then $\mathbf{T}_{3,5} = 0$. These vanishings include the trivial character because $a_1 = 0$. If G has exponent two, every $\chi^2 = 1$, so $\mathbf{M}_5 = 0$ and $\mathbf{T}_2 = \mathbf{E}_4$; there is also no ternary term. If G has exponent three, then $\chi^2 = \chi^{-1}$ and $\mathbf{M}_5 = \mathbf{T}_{3,5}$.

III.21.2 A purely Gowers-norm upper bound

Corollary III.21.2. *Under the hypotheses of Theorem III.21.1,*

$$\mathcal{C}_d(\delta + f) \leq \delta^m + A_d \delta^{m-4} \varepsilon^4 + (Q_d + S_d) \delta^{m-5} \varepsilon^5 + B_{m,6}(\delta, \varepsilon). \quad (\text{III.21.7})$$

If $|G|$ is coprime to six, A_d can be replaced by P_d and $Q_d + S_d$ by Q_d .

Proof. Each nonzero type is a subset moment and is bounded in absolute value by ε to the size of its support. Sum over the counted subsets. For a coprime-to-six group the torsion terms vanish. $\square$

For an indicator with $\varepsilon^m \leq \alpha$, this gives the explicit replacement for (F.14.1) obtained by multiplying

$$\delta^m + A_d \delta^{m-4} \alpha^{4/m} + (Q_d + S_d) \delta^{m-5} \alpha^{5/m} + \sum_{s=6}^m \binom{m}{s} \delta^{m-s} \alpha^{s/m}$$

by N^{d+1} . The separate exact formula (III.17.4) applies when $d = 2$.

III.21.3 Keeping Fourier information instead of discarding it

Let

$$\tau = \|f\|_{U^2}, \quad \rho = \max_{\chi} |a_{\chi}|, \quad \mathsf{T}_{3,4}(f) = \sum_{\chi^3=1} |a_{\chi}|^4.$$

Then $\rho \leq \tau \leq \varepsilon$, and directly from the definitions,

$$|\mathsf{M}_5| \leq \rho \tau^4, \quad |\mathsf{T}_{3,5}| \leq \rho \mathsf{T}_{3,4} \leq \rho \tau^4. \quad (\text{III.21.8})$$

Consequently,

$$\begin{aligned} \mathcal{C}_d(\delta + f) - \delta^m &\leq \delta^{m-4} (P_d \tau^4 + T_d \mathsf{T}_2) \\ &\quad + \delta^{m-5} \rho (Q_d \tau^4 + S_d \mathsf{T}_{3,4}) + B_{m,6}(\delta, \varepsilon). \end{aligned} \quad (\text{III.21.9})$$

This is useful when ordinary Fourier uniformity is substantially stronger than the available higher-order uniformity. The exact formula shows that all terms through degree five are ordinary Fourier statistics; one should not pay a higher-order uniformity bound for them unnecessarily.

III.21.4 Certificates of nonuniformity

For $F : G \rightarrow [0, 1]$, put $\Delta = \mathcal{C}_d(F) - \delta^m \geq 0$. Since $|f| \leq 1$, one has $\varepsilon \leq 1$. Therefore

$$\varepsilon \geq \left[\frac{\Delta}{\binom{m}{4} (1 + \delta)^{m-4}} \right]^{1/4}. \quad (\text{III.21.10})$$

This follows from Theorem III.17.2 and (III.16.5). A sharper, still explicit denominator follows from (III.21.7) by replacing every ε^s , $s \geq 4$, by ε^4 .

If the fourth and fifth Fourier corrections have been measured, define

$$D_6 = \mathcal{C}_d(F) - \delta^m - \delta^{m-4} (P_d \mathsf{E}_4 + T_d \mathsf{T}_2) - \delta^{m-5} (Q_d \mathsf{M}_5 + S_d \mathsf{T}_{3,5}).$$

Then

$$\varepsilon \geq \left[\frac{|D_6|}{\binom{m}{6}(1+\delta)^{m-6}} \right]^{1/6} \quad (d \geq 3). \quad (\text{III.21.11})$$

These are lower bounds on a uniformity norm. They do not, by themselves, produce a polynomial phase, a nilsequence, or a density increment. Calling them inverse theorems would overstate their content.

III.21.5 Local derivatives at a constant

For a fixed mean-zero direction f , the map $t \mapsto \mathcal{C}_d(\delta + tf)$ is a polynomial. Its first three derivatives at zero vanish, and

$$\begin{aligned} \left. \frac{d^4}{dt^4} \mathcal{C}_d(\delta + tf) \right|_{t=0} &= 4! \delta^{m-4} (P_d \mathbf{E}_4(f) + T_d \mathbf{T}_2(f)), \\ \left. \frac{d^5}{dt^5} \mathcal{C}_d(\delta + tf) \right|_{t=0} &= 5! \delta^{m-5} (Q_d \mathbf{M}_5(f) + S_d \mathbf{T}_{3,5}(f)). \end{aligned}$$

Thus the cube-count functional is flat through third order along the mean-zero hyperplane at a positive constant. Its first nonzero variation is quartic, and its arithmetic anisotropy is already visible there. This is a statement about a specific functional at a specific base point, not a claim of vanishing Hessians at arbitrary functions.

III.22 Sharpness, signs, and transfer to genuine sets

Source 09, delivered Section 8.

III.22.1 The fourth-order exponent and its universal coefficient

Proposition III.22.1. *For every $d \geq 2$ and $0 < \delta < 1$, no uniform replacement of the fourth-order error by $O_{d,\delta}(\varepsilon^{4+\eta})$, $\eta > 0$, is possible. This remains true when groups are restricted to have odd order. If all finite abelian groups are allowed, the coefficient A_d of $\delta^{m-4}\varepsilon^4$ in (III.21.7) is optimal as a leading small- ε coefficient.*

Proof. Fix any nonzero real mean-zero function g on a finite group and put $F_t = \delta + tg$, with $t > 0$ small enough that $0 \leq F_t \leq 1$. Its balanced norm is $t\|g\|_{U^d}$. The fourth-order coefficient in Theorem III.21.1 is positive because $P_d > 0$ and $\mathbf{E}_4(g) > 0$. For $d = 2$, use (III.17.4) instead. Thus the excess is a positive constant times $t^4 + O(t^5)$ and cannot be of order $t^{4+\eta}$. A nonzero cosine on a cyclic group of odd prime order at least seventeen gives the same conclusion among odd-order groups.

For the coefficient assertion, take a nontrivial order-two character $\chi : G \rightarrow \{\pm 1\}$ and let $g = \chi$. Then $\|g\|_{U^d} = 1$, $\mathbf{E}_4(g) = \mathbf{T}_2(g) = 1$, and the leading coefficient is exactly $P_d + T_d = A_d$. This rules out a smaller universal leading coefficient. $\square$

There is also a closed formula for the last example:

$$\mathcal{C}_d(\delta + t\chi) = 2^{-d-1}((\delta + t)^m + (\delta - t)^m) + (1 - 2^{-d})(\delta^2 - t^2)^{m/2}. \quad (\text{III.22.1})$$

To prove it, condition on $(\chi(h_1), \dots, \chi(h_d))$. With probability 2^{-d} all signs are positive and every vertex has sign $\chi(x)$, whose two values are equiprobable. Otherwise exactly half the cube vertices have each sign. In dimension three, (III.22.1) reduces to

$$\mathcal{C}_3(\delta + t\chi) = \delta^8 + 14\delta^4 t^4 + t^8.$$

This also explains why deleting the binary-torsion term would give an incorrect fourth-order coefficient.

III.22.2 A negative quintic correction

Proposition III.22.2. *The fifth-order term in Theorem III.21.1 can have either sign, even on groups of prime order greater than three. In particular, the inequality*

$$\mathcal{C}_3(\delta + f) \geq \delta^8 + 12\delta^4 \|f\|_{U^2}^4 \quad (\text{III.22.2})$$

is false in general, even for $[0, 1]$ -valued functions on such groups.

Proof. Let $q \geq 17$ be prime and, for $\sigma \in \{1, -1\}$, put

$$g_\sigma(x) = \cos(2\pi x/q) + \sigma \cos(4\pi x/q).$$

Its only nonzero Fourier coefficients are $a_{\pm 1} = 1/2$ and $a_{\pm 2} = \sigma/2$, with frequencies written additively in this calculation. Therefore

$$\mathsf{E}_4(g_\sigma) = \frac{1}{4}, \quad \mathsf{M}_5(g_\sigma) = \frac{\sigma}{16}, \quad \mathsf{T}_2(g_\sigma) = \mathsf{T}_{3,5}(g_\sigma) = 0.$$

Apply (III.21.6) to $f = tg_\sigma$. At any fixed $0 < \delta < 1$,

$$\mathcal{C}_3(\delta + tg_\sigma) = \delta^8 + 3\delta^4 t^4 + \frac{\sigma}{2} \delta^3 t^5 + O_\delta(t^6). \quad (\text{III.22.3})$$

For all sufficiently small $t > 0$, one has $0 \leq \delta + tg_\sigma \leq 1$ because $|g_\sigma| \leq 2$. Taking $\sigma = -1$ makes the difference between the left side of (III.22.2) and its proposed right side negative. The $O(t^6)$ bound is explicitly supplied by (F.14.6); no finite numerical experiment is needed for this counterexample. $\square$

The same example proves that, after the exact fourth-order correction has been removed, a fifth-order remainder cannot in general be replaced by a higher power. More strongly, for every $d \geq 3$ the star count Q_d is positive, so the same two-frequency example gives a nonzero fifth-order term in that dimension.

An exact finite calculation, reproduced in Appendix III.26, yields

$$\mathcal{C}_3(\delta + tg_\sigma) = \delta^8 + 3\delta^4 t^4 + \frac{\sigma}{2} \delta^3 t^5 + \frac{3}{2} \delta^2 t^6 + \frac{1}{4} t^8. \quad (\text{III.22.4})$$

For example, when $0 < t \leq \delta/4$, the negative fifth-order term in the $\sigma = -1$ case dominates the displayed positive sixth- and eighth-order terms. The asymptotic proof above is logically independent of this stronger computational identity.

[write] **6 October 2026; sources 06–10.** (III.22.2) is the bound refuted also by source 03 (on $\mathbb{Z}/3\mathbb{Z}$) and source 08 (on $\mathbb{Z}/11\mathbb{Z}$, Theorem III.10.1); Remark W1 keeps it on record with an explicit counterexample. The proposition’s “groups of prime order greater than three” is witnessed by the proof for primes $q \geq 17$; on $\mathbb{Z}/11\mathbb{Z}$ source 08’s example is the case $\sigma = -1$ and its polynomial is (III.22.4). On $\mathbb{Z}/5\mathbb{Z}$ the fifth-order argument does not apply to g_{-1} : there $2 \cdot 2 = -1$, the coefficients at ± 2 also contribute, and $\mathsf{M}_5(g_{-1}) = 0$ (checked at the second write).

III.22.3 The sixth-order remainder is also necessary

Proposition III.22.3. *For every $d \geq 3$ and $0 < \delta < 1$, the sixth-order remainder after the exact fourth and fifth corrections cannot be uniformly replaced by $O_{d,\delta}(\varepsilon^{6+\eta})$ for any $\eta > 0$.*

Proof. Use g_+ from Proposition III.22.2. Every Fourier coefficient is nonnegative, so every subset moment is nonnegative by Proposition III.18.1. Consider the six vertices of a three-dimensional cube obtained by deleting the adjacent pair $(0, 0, 0), (1, 0, 0)$. On the three remaining vertices in the first slice assign frequencies $(1, 1, -2)$, and on the corresponding vertices in the second slice assign $(-1, -1, 2)$. Their total frequency is zero; the sum in the first cube coordinate is zero; and the sums in each of the other two coordinates cancel between the slices. This is an admissible Fourier tuple with positive coefficient product. Thus that six-vertex moment is strictly positive.

For $d > 3$, embed this subset in a three-dimensional face and give the remaining coordinates value zero. The same tuple still satisfies all constraints. Hence the coefficient of t^6 in R_6 for $f = tg_+$ is positive, and no other sixth-order contribution can cancel it. Since $\varepsilon = t\|g_+\|_{U^d}$, the claimed stronger remainder is impossible. $\square$

III.22.4 Why weighted examples are not a loophole

The following rounding lemma transfers these phenomena to indicators. It also quantifies the size of the auxiliary group needed for the transfer.

Lemma III.22.4 (Random rounding in a Gowers norm). *Let $F : G \rightarrow [0, 1]$, let $d \geq 2$, and let $m = 2^d$. There exists $A \subseteq G$ such that*

$$\|\mathbf{1}_A - F\|_{U^d} \leq \zeta := \left(\frac{\binom{m}{2}}{|G|} \right)^{1/m}. \quad (\text{III.22.5})$$

Writing $\delta = \mathbb{E}F$ and $\delta_A = |A|/|G|$, one also has

$$|\delta_A - \delta| \leq \zeta, \quad (\text{III.22.6})$$

$$|\mathcal{C}_d(\mathbf{1}_A) - \mathcal{C}_d(F)| \leq m\zeta, \quad (\text{III.22.7})$$

$$\|(\mathbf{1}_A - \delta_A) - (F - \delta)\|_{U^d} \leq 2\zeta. \quad (\text{III.22.8})$$

Proof. Choose independent Bernoulli variables $\mathbf{1}_A(x)$ of means $F(x)$, and set $R(x) = \mathbf{1}_A(x) - F(x)$. For a fixed parameterized cube whose m evaluated vertices are distinct, independence and $\mathbb{E}_A R(x) = 0$ give $\mathbb{E}_A \prod_v R(L_v) = 0$. If vertices collide, the absolute value of the expected product is at most one.

For two distinct abstract vertices v, w , the equation $L_v = L_w$ has probability $1/|G|$: one coefficient in $\sum_i (v_i - w_i)h_i$ is 1 or -1 . The union bound gives collision probability at most $\binom{m}{2}/|G|$. Therefore

$$0 \leq \mathbb{E}_A \|R\|_{U^d}^m \leq \frac{\binom{m}{2}}{|G|}.$$

Some realization satisfies (III.22.5). Now $|\mathbb{E}R| \leq \|R\|_{U^d}$ proves (III.22.6). Telescope the two cube products in (III.22.7); each of the m terms has one factor R , and all other factors are either F or $\mathbf{1}_A$, with Gowers norm at most one. Lemma III.16.1 bounds each term by ζ . Finally, subtract the mean of R and apply the triangle inequality to prove (III.22.8). $\square$

Corollary III.22.5 (Transfer of the sharpness examples). *The fourth-order exponent obstruction, the optimal universal leading coefficient A_d , the fifth-order sign obstruction, and the necessity of a sixth-order remainder persist for sequences of actual sets in growing finite abelian groups. Their densities tend to any prescribed $\delta \in (0, 1)$. The first exponent obstruction also persists in odd-order groups.*

Proof. Lift a fixed weighted example on H to $H \times K$ using the projection to H . All cube averages and Gowers norms of the lifted function are unchanged. Let $t \rightarrow 0$ and choose $|K|$ sufficiently large that the rounding error satisfies $\zeta = o(t^6)$; larger polynomial choices of $|K|$ suffice.

The balanced norm changes by at most 2ζ , the density by at most ζ , and the full cube count by at most $m\zeta$. Each of the fourth- and fifth-order statistics is itself a fixed subset moment. Telescoping it and using Gowers–Cauchy–Schwarz shows that it changes by $O_d(\zeta)$, since the balanced functions involved are bounded by one. Thus the nonzero terms at orders four, five, and six persist. For the odd-order assertion take both H and K of odd order. $\square$

Remark III.22.6 (Exact rational densities). For a prescribed rational $\delta = a/b \in (0, 1)$, the same obstructions can be realized with density exactly δ . Choose $|H \times K|$ divisible by b . After rounding, add or delete at most $\zeta|G|$ points to obtain the required cardinality. If E is the edit set, the difference D of the two indicators is supported on E and bounded by one. Hence

$$\|D\|_{U^d}^m \leq \mathbb{E}_{x,h} \left| \prod_v D(L_v) \right| \leq \frac{|E|}{|G|} \leq \zeta.$$

The total approximation error in U^d is at most $\zeta + \zeta^{1/m}$. Choosing $\zeta = o(t^{6m})$ makes this $o(t^6)$ and preserves all the sharpness conclusions at the exact fixed density. For an odd-order construction this exact-density variant applies when b is odd; arbitrary densities can still be approached by the preceding corollary. Irrational densities, of course, cannot be the exact density of a finite set.

[write] **6 October 2026; sources 06–10.** Rounding to sets is also done by sources 03, 04 and 08 (note after source 08’s Lemma III.11.2). Lemma III.22.4 has constant $((\binom{m}{2})/|G|)^{1/m}$ by taking a realization at most the mean; source 08 takes twice the mean.

III.23 A sixth-order order-five obstruction and an all-prime family

Source 09, delivered Section 9.

The small-support expansion is especially simple on groups whose order is coprime to six. That simplification does not continue indefinitely. There is already an order-five torsion configuration on six selected vertices.

Theorem III.23.1 (First possible isolated order-five contribution). *There exists a six-vertex subset of V_5 with full augmented rank and row-lattice index five, whose mean-zero moment can be nonzero on groups with order-five characters but is zero when multiplication by five is invertible on G . No such order-five-only contribution occurs on fewer than six selected cube vertices.*

Proof. Consider the binary matrix

$$B = \begin{pmatrix} 1 & 0 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 & 0 \end{pmatrix}. \quad (\text{III.23.1})$$

Its determinant is -5 . Take S to consist of the zero vector and the five columns of B . Its augmented matrix is

$$M_S = \begin{pmatrix} 1 & \mathbf{1}^T \\ 0 & B \end{pmatrix}, \quad |\det M_S| = 5.$$

For

$$r = (2, 1, 3, 2, 1, 1)^T$$

one checks exactly that

$$M_S r = (10, 5, 5, 5, 5, 5)^T. \quad (\text{III.23.2})$$

Every coordinate of r is nonzero modulo five. Since the row quotient has order five, the full character constraint group is

$$K_G(S) = \{(\chi^{r_0}, \dots, \chi^{r_5}) : \chi^5 = 1\}.$$

Consequently,

$$T_S(f) = \sum_{\chi^5=1} \prod_{j=0}^5 a_{\chi^{r_j}}. \quad (\text{III.23.3})$$

If multiplication by five is invertible on G , the only parameter is the trivial character, and the moment is zero because $a_1 = 0$. On $G = \mathbb{Z}/5\mathbb{Z}$, take $f = 5\mathbf{1}_{\{0\}} - 1$. Its trivial Fourier coefficient is zero and its four nontrivial Fourier coefficients are one. Thus (III.23.3) is exactly four.

Finally, Lemma III.17.1 and the complete four- and five-vertex classifications show that the only isolated torsion contributions before degree six have orders two and three. In particular, none can be supported purely on order-five characters. This proves the minimal support-size assertion. $\square$

The determinant in (III.23.1) can be checked by ordinary integer elimination; the accompanying exact script additionally records the Smith invariants $1, 1, 1, 1, 1, 5$ of M_S . A direct elimination certificate is given in Appendix III.27. Rescaling the displayed f by a sufficiently small t and adding a density gives a $[0, 1]$ -valued example, so this obstruction belongs to the same perturbative counting problem as the main theorem.

[write] **6 October 2026; sources 06–10.** *Checked at the second write* with SymPy 1.14.0: $\det B = -5$, $\det M_S = -5$, $M_S r = (10, 5, 5, 5, 5, 5)$, the Smith normal form of M_S is $\text{diag}(1, 1, 1, 1, 1, 5)$, the five columns of B are distinct nonzero binary vectors, and the moment (III.23.3) equals 4 for $f = 5\mathbf{1}_{\{0\}} - 1$ on $\mathbb{Z}/5\mathbb{Z}$. At four vertices only the invariant factors one and two occur (source 03's Remark III.2.4), at five also three (Theorem III.20.1); index five first occurs here, at six vertices.

Proposition III.23.2 (An isolated torsion configuration for every prime). *For every prime ℓ , there is a subset of $V_{\ell+1}$ with $\ell + 2$ vertices, full augmented rank, and row-lattice quotient $\mathbb{Z}/\ell\mathbb{Z}$, whose constraint relation has full support modulo ℓ .*

Proof. Put $n = \ell + 1$, and take the zero vector together with the n columns of $J - I_n$. The eigenvalues of $J - I_n$ are $n - 1 = \ell$ on the all-ones direction and -1 on its complementary hyperplane. Hence its determinant is $(-1)^{n-1}\ell$. Its augmented matrix has the same determinant and therefore a quotient of order ℓ . The relation modulo ℓ is

$$(-1, 1, \dots, 1),$$

because its sum is $n - 1 = \ell$ and each coordinate row has ℓ ones. Every coefficient is nonzero. The moment is

$$\sum_{\chi^\ell=1} a_\chi^{\ell+1} \overline{a_\chi}.$$

It is nonzero for $f = \ell \mathbf{1}_{\{0\}} - 1$ on $\mathbb{Z}/\ell\mathbb{Z}$. □

For $\ell = 2, 3$ this reproduces the two small torsion normal forms. For $\ell = 5$ it uses seven vertices, whereas Theorem III.23.1 uses six. Thus the uniform construction is not generally support-minimal.

One can make the resulting extremal problem precise. Let $h(\ell)$ be the least cardinality of an affinely independent Boolean-vertex set whose integer row quotient has ℓ -torsion and whose character kernel over $\mathbb{Z}/\ell\mathbb{Z}$ has a vector nonzero in every coordinate. The results above give

$$h(2) = 4, \quad h(3) = 5, \quad h(5) = 6, \quad h(\ell) \leq \ell + 2.$$

If $s = h(\ell)$, some nonzero full minor including the all-ones row is divisible by ℓ . The sign-matrix argument in Lemma III.18.2 gives the necessary condition

$$\ell \leq \frac{s^{s/2}}{2^{s-1}}. \tag{III.23.4}$$

In particular, as ℓ grows, $h(\ell) \geq (2 - o(1)) \log \ell / \log \log \ell$. There is a wide gap between this elementary obstruction and the explicit general construction. We leave its systematic improvement as a research problem rather than pretending the small examples solve it.

III.24 Heterogeneous functions and an all-orders organizing principle

Source 09, delivered Section 10.

The method is not restricted to a single set placed at every vertex. Let $F_v = \delta_v + f_v$ be real functions indexed by V_d , with $\mathbb{E}f_v = 0$, $\delta_v \geq 0$, and $\varepsilon_v = \|f_v\|_{U^d}$.

Theorem III.24.1 (Heterogeneous expansion). *One has*

$$\begin{aligned} \mathbb{E}_{x,h} \prod_{v \in V_d} F_v(L_v) &= \prod_{v \in V_d} \delta_v \\ &+ \sum_{\substack{S \subseteq V_d \\ |S| \geq 4}} \left(\prod_{v \notin S} \delta_v \right) \mathbb{E}_{x,h} \prod_{v \in S} f_v(L_v). \end{aligned} \tag{III.24.1}$$

Every four- or five-vertex term vanishes unless its vertex subset is one of the normal forms in Theorems III.19.1 and III.20.1. For a surviving term its exact value is the mixed Fourier sum in

(III.18.3). *The remainder after size five is bounded by*

$$\sum_{\substack{S \subseteq V_d \\ |S| \geq 6}} \left(\prod_{v \notin S} \delta_v \right) \left(\prod_{v \in S} \varepsilon_v \right). \quad (\text{III.24.2})$$

Proof. Expand the product. Joint uniformity for up to three selected vertices makes those mixed moments a product of zero means. In the classification proofs, every vanishing case either has fully uniform values or forces a trivial character at one selected vertex, so the same vanishing holds for different mean-zero functions. Finally, apply Lemma III.16.1 to bound each remaining mixed term. $\square$

For example, a parallelogram with ordered relation $v_1 + v_4 = v_2 + v_3$ contributes

$$\sum_{\chi} a_{1,\chi} a_{4,\chi} a_{2,\chi^{-1}} a_{3,\chi^{-1}}.$$

A binary-torsion subset contributes $\sum_{\chi^2=1} \prod_{j=1}^4 a_{j,\chi}$. Thus the homogeneous formulas are not isolated coincidences; they are the diagonal specializations of a colored cube-count expansion.

At every order, Proposition III.18.1 gives a finite algorithm: enumerate a support S , compute its integer row lattice, identify which character constraints admit full-support tuples, and sum the corresponding mixed Fourier products. The difficult part is not the existence of an algorithm but the compression of the support types into dimension-uniform, human-readable formulas. Through degree five, the four normal forms achieve precisely that compression.

III.25 Relation to progression bounds and current conjecture status

Source 09, delivered Section 13.

The local result should be placed against the right global benchmark. Gowers' 2001 theorem is not the current quantitative endpoint. For example, Leng, Sah, and Sawhney obtain, for every fixed $k \geq 5$, an upper bound of the form

$$r_k(N) \ll N \exp(-(\log \log N)^{c_k})$$

with $c_k > 0$ [2]. The present manuscript does not compete with that bound: it sharpens one local cube-count inequality, without supplying a new inverse theorem or a new iteration.

A recent primary preprint of Milićević establishes a quasipolynomial inverse theorem for $U^k(\mathbb{F}_p^n)$ in the high characteristic regime $p \geq k$ [32]. That is another reason not to describe an elementary Fourier expansion as a breakthrough inverse theorem. Its relation to this manuscript is potentially complementary: low-order terms can be evaluated before an inverse theorem is applied to a residual, but a useful quantitative implementation would need a separate argument.

The conjectural lower bounds in Section 4 of Gowers' paper also require an up-to-date reading. Shi and Dong's 2026 preprint states a disproof of Gowers' conjectured progression lower bound for every even length at least six, and records the earlier length-four disproof [33]. Their higher-length uniformity condition is U^{k-2} uniformity, not merely ordinary Fourier uniformity. We cite this as the

stated result of that preprint, rather than treating the old conjecture as still untouched or claiming its resolution here.

The cube lower bound $\mathcal{C}_d(F) \geq \delta^m$ is different. It follows from a norm inequality and remains valid. Proposition III.22.2 does not refute that bound: it refutes the stronger attempt to add the entire positive quartic correction as a global lower bound while ignoring the signed quintic term. Arithmetic progression counts and full cube counts are different linear-configuration averages; one must not transfer extremal conclusions between them without proof.

III.26 Exact two-frequency polynomial certificate

Source 09, delivered Appendix A.

For $q \geq 17$, all character constraints for eight frequencies from $\{-2, -1, 0, 1, 2\}$ can be checked as integer equalities: the total absolute frequency sum is at most sixteen, and every coordinate sum has absolute value at most eight. Thus no nonzero multiple of q can occur.

Order the eight vertices $v \in \{0, 1\}^3$. A term in the expansion of $\mathcal{C}_3(\delta + tg_\sigma)$ is indexed by frequencies $b_v \in \{-2, -1, 0, 1, 2\}$ satisfying

$$\sum_v b_v = 0, \quad \sum_v v_i b_v = 0 \quad (i = 1, 2, 3). \quad (\text{III.26.1})$$

Let s be the number of nonzero frequencies and r the number with absolute value two. Its contribution is $\delta^{8-s} t^s 2^{-s} \sigma^r$. The exact signed counts are

s	0	1	2	3	4	5	6	7	8
$\sum 1$	1	0	0	0	48	16	96	0	64
$\sum (-1)^r$	1	0	0	0	48	-16	96	0	64

Multiplying the s th column by $2^{-s} \delta^{8-s} t^s$ proves (III.22.4). The following finite loop specifies the certificate without a floating-point operation:

```
for b in product(range(-2, 3), repeat=8):
    if sum(b) != 0:
        continue
    if any(sum(b[j] for j in coordinate_slice[i]) != 0
           for i in range(3)):
        continue
    s = sum(x != 0 for x in b)
    r = sum(abs(x) == 2 for x in b)
    positive[s] += 1
    signed[s] += (-1)**r
```

The complete executable version is included in `verify_expansion.py`, along with assertions for every table entry. This is a transparent exhaustive finite certificate; the all-dimension expansion and its sharpness proofs do not depend on trusting a numerical approximation to this table.

III.27 An integer determinant certificate for the order-five example

Source 09, delivered Appendix B.

Here is a direct check of the determinant in (III.23.1). Subtract row one from rows four and five, and expand along column one. The remaining 4×4 matrix is

$$C = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 1 \\ 1 & -1 & -1 & 0 \\ 1 & -1 & 0 & -1 \end{pmatrix}.$$

Subtract its first row from each remaining row and expand again along column one. This gives

$$D = \begin{pmatrix} -1 & 1 & 1 \\ -2 & -1 & 0 \\ -2 & 0 & -1 \end{pmatrix}, \quad \det D = -1 - 2 - 2 = -5.$$

All these row operations preserve the determinant, and both expansions use the upper-left entry with positive cofactor sign. Thus $\det B = -5$. Together with (III.23.2), this proves the index and kernel claims without reliance on the Smith-normal-form implementation.

III.28 A torsion-sensitive generalized von Neumann inequality

Source 10, delivered Section 5.

The reindexing step in the proof of Theorem 3.2 of the source paper is where the ambient modulus enters. Retaining the sizes of the relevant fibres gives an explicit estimate on every finite abelian group. Retaining the norms of the other functions at the same time gives a useful density improvement in the subsequent counting argument.

Throughout this section G is a nonempty finite abelian group, $N = |G|$, and all averages and L^p norms are normalized. For an integer c put

$$G[c] = \{x \in G : cx = 0\}, \quad \kappa_G(c) = |G[c]|.$$

Thus $\kappa_G(0) = N$, and multiplication by c is invertible exactly when $\kappa_G(c) = 1$. On a cyclic group, $\kappa_{\mathbb{Z}/N\mathbb{Z}}(c) = \gcd(N, c)$, with the usual convention $\gcd(N, 0) = N$.

For $f : G \rightarrow \mathbb{C}$ set $\Delta_h f(x) = f(x) \overline{f(x+h)}$, and write

$$\|f\|_{U^s}^{2^s} = \mathbb{E}_{x, h_1, \dots, h_s \in G} \prod_{\omega \in \{0,1\}^s} \mathcal{C}^{|\omega|} f(x + \omega \cdot h), \quad s \geq 1,$$

where $\mathcal{C}$ denotes complex conjugation. These powers are nonnegative. In particular $\|f\|_{U^1} = |\mathbb{E}f|$, which is a seminorm, and for $s \geq 2$ the recursion is

$$\|f\|_{U^s}^{2^s} = \mathbb{E}_h \|\Delta_h f\|_{U^{s-1}}^{2^{s-1}}. \quad (\text{III.28.1})$$

Lemma III.28.1 (The exact fibre identity). *For every $V : G \rightarrow [0, \infty)$ and every integer c ,*

$$\mathbb{E}_u V(cu) = \kappa_G(c) \mathbb{E}_h \mathbf{1}_{cG}(h) V(h) \leq \kappa_G(c) \mathbb{E}_h V(h).$$

Proof. Every element of the image cG has exactly $\kappa_G(c)$ preimages. Counting those preimages proves the equality, and $V \geq 0$ proves the inequality. $\square$

For a coefficient vector $\mathbf{a} = (a_1, \dots, a_k)$ define

$$\Lambda_{\mathbf{a}}(f_1, \dots, f_k) = \mathbb{E}_{x,d} \prod_{i=1}^k f_i(x + a_i d).$$

Theorem III.28.2 (General coefficients and mixed L^p control). *Let $k \geq 2$, let $a_1, \dots, a_k$ be integers, and suppose that multiplication by $a_k - a_{k-1}$ is invertible on G . Set*

$$K = \prod_{i=1}^{k-1} \kappa_G(a_k - a_i), \quad M = \left(\prod_{i=1}^{k-2} \|f_i\|_{L^{2^i}} \right) \|f_{k-1}\|_{L^{2^{k-2}}}.$$

For arbitrary functions $f_i : G \rightarrow \mathbb{C}$,

$$|\Lambda_{\mathbf{a}}(f_1, \dots, f_k)| \leq MK^{1/2^{k-1}} \|f_k\|_{U^{k-1}}. \quad (\text{III.28.2})$$

No boundedness hypothesis on the functions is needed.

Proof. For $k = 2$, the map

$$(x, d) \mapsto (x + a_1 d, x + a_2 d)$$

is a bijection of G^2 . Hence the average equals $(\mathbb{E}f_1)(\mathbb{E}f_2)$, and its absolute value is at most $\|f_1\|_1 \|f_2\|_{U^1}$, as required.

Suppose $k \geq 3$ and assume the result for $k - 1$. Put $c_i = a_i - a_1$. Translate the first variable by $a_1 d$ and apply Cauchy–Schwarz in that variable. Expanding the square and writing the second difference variable as $d + h$ gives

$$\begin{aligned} |\Lambda_{\mathbf{a}}(f_1, \dots, f_k)|^2 &\leq \|f_1\|_2^2 \mathbb{E}_x \left| \mathbb{E}_d \prod_{i=2}^k f_i(x + c_i d) \right|^2 \\ &= \|f_1\|_2^2 \mathbb{E}_h \Lambda_{(c_2, \dots, c_k)}(\Delta_{c_2 h} f_2, \dots, \Delta_{c_k h} f_k). \end{aligned} \quad (\text{III.28.3})$$

The final average is real and nonnegative because it arose by expanding an average of squares. It is therefore bounded above by the average of the absolute values of its inner multilinear forms.

The induction applies to each such form: the last coefficient difference is still $a_k - a_{k-1}$. Its kernel product is

$$K' = \prod_{i=2}^{k-1} \kappa_G(a_k - a_i).$$

For every $p \geq 1$, Hölder's inequality and translation invariance give

$$\|\Delta_h f\|_{L^p} \leq \|f\|_{L^{2p}}^2. \quad (\text{III.28.4})$$

Consequently the product of the non-target norms in the induction is at most M_{rest}^2 , where

$$M_{\text{rest}} = \left(\prod_{i=2}^{k-2} \|f_i\|_{L^{2^i}} \right) \|f_{k-1}\|_{L^{2^{k-2}}}.$$

Let $q = 2^{k-2}$. A further application of Hölder, followed by Lemma III.28.1 and (III.28.1), gives

$$\begin{aligned}\mathbb{E}_h \|\Delta_{(a_k - a_1)h} f_k\|_{U^{k-2}} &\leq \left(\mathbb{E}_h \|\Delta_{(a_k - a_1)h} f_k\|_{U^{k-2}}^q \right)^{1/q} \\ &\leq \kappa_G(a_k - a_1)^{1/q} \|f_k\|_{U^{k-1}}^2.\end{aligned}$$

Substituting these bounds into (III.28.3) and taking square roots proves (III.28.2), since $M = \|f_1\|_2 M_{\text{rest}}$ and $(K' \kappa_G(a_k - a_1))^{1/(2q)} = K^{1/2^{k-1}}$. $\square$

[write] **6 October 2026; sources 06–10.** *Text repaired.* In the delivered source the subscript M_{rest} appears three times in this proof as “M_{}”, a line break and “m rest}”: apparently the two characters `\rm` of `\rm` were read as a carriage-return escape when the source was generated, and the delivered PDF prints “ $M_{m \text{ rest}}$ ”. Restored here as M_{rest} (byte scan at intake: no other control-character damage in sources 01–10).

Credits. For k -term progressions with consecutive slopes and invertible differences this is the generalized von Neumann bound of sources 03, 04 and 06 (Lemmas III.1.1, III.4.2, Theorem III.5.1) with L^∞ norms replaced by mixed L^p norms; the kernel factor $K^{1/2^{k-1}}$, which removes the invertibility assumption on all but one difference, is only here. It advances source 06’s Question 7 for one distinguished function, with explicit kernel constants that are shown sharp only for the families of Proposition III.28.4; the two-function form remains open.

[write] **6 October 2026; sources 15–20.** Source 20’s Theorem III.44.1 gives the general directional-to-global comparison with the optimal constant for each subgroup tuple, and its Proposition III.46.1 the sharp pair correction $\sqrt{m-1}$ (item III.9).

The L^p exponents assigned to the non-target functions are 1 for $k = 2$, then $(2, 2)$, $(2, 4, 4)$, $(2, 4, 8, 8)$, and so forth. Their reciprocals sum to one. The functions and coefficients can be reordered before applying the theorem, provided a coefficient with invertible difference from the target is left immediately before it. This permits optimization of the norm product when the functions have different densities or sizes.

Corollary III.28.3 (Every target in an arithmetic progression). *Let $k \geq 2$, let $f_0, \dots, f_{k-1} : G \rightarrow \mathbb{C}$ satisfy $|f_i| \leq 1$, and let $0 \leq j \leq k-1$. Then*

$$\left| \mathbb{E}_{x,d} \prod_{i=0}^{k-1} f_i(x + id) \right| \leq \left(\prod_{i \neq j} \kappa_G(i - j) \right)^{1/2^{k-1}} \|f_j\|_{U^{k-1}}. \quad (\text{III.28.5})$$

In particular, for an endpoint target the factor is $(\prod_{r=1}^{k-1} \kappa_G(r))^{1/2^{k-1}}$. It is one whenever the exponent of G is coprime to $(k-1)!$.

Proof. Every target has a neighboring coefficient with difference 1 or -1 . Place that neighbor last among the non-target functions and apply Theorem III.28.2. Its L^p product is at most one. The endpoint formula and the coprimality assertion follow directly. $\square$

For the internal target j , the kernel product is

$$\left(\prod_{r=1}^j \kappa_G(r) \right) \left(\prod_{r=1}^{k-1-j} \kappa_G(r) \right).$$

Thus coprimality of the exponent of G with $j!(k-1-j)!$ suffices for that individual estimate. The endpoint result in particular extends the prime-modulus statement to composite cyclic groups with

no prime factor below k , and to arbitrary finite abelian groups satisfying the same restriction on their prime divisors.

The invertible-neighbor hypothesis in the general-coefficient theorem is essential to the theorem as stated. For $k = 2$, coefficients $(0, 2)$ on $G = \mathbb{Z}/2\mathbb{Z}$, and opposite nontrivial characters, the multilinear average is one whereas the target U^1 seminorm is zero.

III.28.1 Sharpness and an explicit obstruction

Proposition III.28.4 (Sharp torsion growth). *For three-term progressions on $G = (\mathbb{Z}/2\mathbb{Z})^n$, the endpoint factor $|G|^{1/4}$ in (III.28.5) is exactly sharp. More generally, for $k = p + 1$ on $G = (\mathbb{Z}/p\mathbb{Z})^n$, with p prime, the endpoint factor $|G|^{1/2^p}$ has the optimal order in $|G|$, up to constants depending only on p .*

Proof. First let $G = (\mathbb{Z}/2\mathbb{Z})^n$, $N = 2^n$, and set

$$g(x_1, \dots, x_n) = i^{x_1 + \dots + x_n},$$

using representatives $x_i \in \{0, 1\}$. Every normalized Fourier coefficient of g has absolute value $N^{-1/2}$: in each coordinate the Fourier factors are $(1 + i)/2$ and $(1 - i)/2$. Therefore

$$\|g\|_{U^2}^4 = \sum_{\chi} |\hat{g}(\chi)|^4 = N^{-1}.$$

Take the two endpoint functions to be $\bar{g}, g$, and the middle function to be one. Since $2d = 0$, the progression average equals one. The upper bound is exactly $N^{1/4}N^{-1/4} = 1$.

For the general assertion write $s = p$ and $N = p^n$. Choose independent uniform unit-circle phases $g(z)$ for the points $z \in G$. For a fixed s -dimensional cube, the expectation of its alternating product is either zero or one, according as the exponents of these independent phases fail to cancel or all cancel. If its 2^s vertices are all distinct, the expectation is zero. Each pair of distinct cube vertices coincides with probability $1/N$, because their difference contains a coefficient 1 or -1 on at least one independent uniform increment. The union bound gives

$$\mathbb{E}_g \|g\|_{U^s}^{2^s} \leq \frac{\binom{2^s}{2}}{N}.$$

There is consequently a circle-valued g with at most this Gowers power. Put $\bar{g}, g$ at the two endpoints of the $(p + 1)$ -term pattern and put one at every intermediate position. The average is again one because $pd = 0$. Hence any factor valid for all such functions is at least

$$\left(\frac{N}{\binom{2^p}{2}} \right)^{1/2^p}.$$

The kernel product in the upper bound is exactly N , since the differences $1, \dots, p - 1$ are invertible. This proves the asserted optimal order. The random estimate is useful for large N ; for small N its right-hand side may exceed the trivial upper bound one. $\square$

A small explicit example also illustrates why the modulus restriction in the source theorem matters. On $\mathbb{Z}/3\mathbb{Z}$ take $g = (1, 1, -1)$ and the four functions $(\bar{g}, 1, 1, g)$. Their four-term average is one. However,

$$\|g\|_{U^3}^8 = \frac{49}{81} < 1.$$

Indeed, the zero derivative is one, and each nonzero derivative is a translate of $(1, -1, -1)$, whose U^2 fourth power is $(1/3)^4 + 2(2/3)^4 = 11/27$. The recursion gives $(1 + 2 \cdot 11/27)/3 = 49/81$.

[write] **6 October 2026; sources 06–10.** Rechecked at the second write: $(1/3)^4 + 2(2/3)^4 = 33/81 = 11/27$ and $(1 + 22/27)/3 = 49/81$. The $\mathbb{Z}/2\mathbb{Z}$ torsion examples of sources 03 and 04 (Part III above) are of the same kind; here the factor is quantified and shown sharp on $(\mathbb{Z}/2\mathbb{Z})^n$.

III.29 Density-sensitive counting and modular progression criteria

Source 10, delivered Section 6.

For convenience write

$$\Lambda_k(F_1, \dots, F_k) = \mathbb{E}_{x,d} \prod_{i=1}^k F_i(x + (i-1)d).$$

The following replacement for the counting step keeps the densities and uses only $k-2$ error terms.

Theorem III.29.1 (A density-weighted telescoping estimate). *Let $k \geq 3$ and let $A_1, \dots, A_k \subseteq G$. Put $F_i = \mathbf{1}_{A_i}$, $\delta_i = \mathbb{E}F_i$, and $b_i = F_i - \delta_i$. For $3 \leq j \leq k$ set*

$$\tau_j(G) = \left(\prod_{r=1}^{j-1} \kappa_G(r) \right)^{1/2^{j-1}}, \quad B_j = \left(\prod_{i=1}^{j-2} \delta_i^{1/2^i} \right) \delta_{j-1}^{1/2^{j-2}}, \quad D_j = \prod_{i=j+1}^k \delta_i.$$

Then

$$\left| \Lambda_k(F_1, \dots, F_k) - \prod_{i=1}^k \delta_i \right| \leq \sum_{j=3}^k D_j B_j \tau_j(G) \|b_j\|_{U^{j-1}}. \quad (\text{III.29.1})$$

Proof. For $L_i = x + (i-1)d$ use the pointwise identity

$$\prod_{i=1}^k F_i(L_i) - \prod_{i=1}^k \delta_i = \sum_{j=1}^k \left(\prod_{i < j} F_i(L_i) \right) b_j(L_j) \left(\prod_{i > j} \delta_i \right).$$

The averaged term with $j=1$ vanishes because $\mathbb{E}b_1 = 0$. The averaged term with $j=2$ also vanishes: the two adjacent forms are jointly uniform on G^2 , so its average factors and contains $\mathbb{E}b_2 = 0$. Apply Theorem III.28.2 in natural coefficient order to every remaining j -term average. The target is b_j , its kernel factor is $\tau_j(G)$, and $\|\mathbf{1}_{A_i}\|_{L^p} = \delta_i^{1/p}$ makes its mixed norm product exactly B_j . The triangle inequality proves the claim. $\square$

For one or two forms the count equals its product of densities exactly. If the exponent of G is coprime to $(k-1)!$, all the factors $\tau_j(G)$ are one. In particular, under the uniformity assumptions of Corollary 3.3 of the source paper, one has $\|b_j\|_{U^{j-1}} \leq \alpha$, and its error term can be replaced by

$$\alpha \sum_{j=3}^k D_j B_j \leq (k-2)\alpha.$$

The displayed density-dependent sum is often appreciably smaller.

Corollary III.29.2 (One-set counting). *Let $k \geq 3$, let $A \subseteq G$ have density δ , and put*

$$\eta = \|\mathbf{1}_A - \delta\|_{U^{k-1}}, \quad T_{k,G}(\delta) = \sum_{j=3}^k \delta^{k-j} \tau_j(G).$$

Then

$$|\Lambda_k(A) - \delta^k| \leq \delta \eta T_{k,G}(\delta). \quad (\text{III.29.2})$$

In the coprime case, put

$$S_k(\delta) = \sum_{m=0}^{k-3} \delta^m.$$

Then $T_{k,G}(\delta) = S_k(\delta)$ and

$$|\Lambda_k(A) - \delta^k| \leq \delta S_k(\delta) \eta. \quad (\text{III.29.3})$$

For $0 \leq \delta < 1$, $S_k(\delta) = (1 - \delta^{k-2})/(1 - \delta)$, while $S_k(1) = k - 2$.

Proof. The reciprocals in the definition of B_j sum to one, so $B_j = \delta$ when all the sets are A . Gowers norm monotonicity gives $\|\mathbf{1}_A - \delta\|_{U^{j-1}} \leq \eta$ for $j \leq k$. Theorem III.29.1 now gives both estimates.

For completeness, monotonicity follows from two applications of Cauchy–Schwarz. Writing $g = \Delta_{h_1} \cdots \Delta_{h_{s-1}} f$, one has

$$|\mathbb{E}g|^4 = \left| \mathbb{E}_t \mathbb{E}_x g(x) \overline{g(x+t)} \right|^2 \leq \mathbb{E}_t \left| \mathbb{E}_x g(x) \overline{g(x+t)} \right|^2 = \|g\|_{U^2}^4.$$

Average this inequality over the h_i , and use $(\mathbb{E}_h |\mathbb{E}g|^2)^2 \leq \mathbb{E}_h |\mathbb{E}g|^4$. The two sides identify with the appropriate cube forms and yield $\|f\|_{U^s} \leq \|f\|_{U^{s+1}}$. $\square$

Corollary III.29.3 (An explicit modular progression criterion). *Let $k \geq 3$, suppose that the exponent of G is coprime to $(k-1)!$, and let $A \subseteq G$ have positive density δ . With η as above, the number of ordered pairs (x, d) for which all k terms are distinct and lie in A is at least*

$$\delta N^2 \left(\delta^{k-1} - S_k(\delta) \eta - \frac{1}{N} \right). \quad (\text{III.29.4})$$

In particular, A contains such a progression if

$$N(\delta^{k-1} - S_k(\delta) \eta) > 1.$$

A simpler sufficient pair of conditions is

$$\eta \leq \frac{\delta^{k-1}}{2S_k(\delta)}, \quad N > 2\delta^{1-k}. \quad (\text{III.29.5})$$

Proof. There are exactly $|A| = \delta N$ counted pairs with $d = 0$. If $d \neq 0$ and two terms coincide, then $rd = 0$ for some $1 \leq r \leq k-1$, contradicting invertibility of multiplication by r . Subtracting these exactly δN degenerate pairs from (III.29.3), after multiplying by N^2 , proves (III.29.4). Either displayed condition makes this lower bound strictly positive. $\square$

In the notation of the source paper, being α -uniform of degree $k - 2$ means $\eta^{2^{k-1}} \leq \alpha$. Thus the sufficient uniformity condition in (III.29.5) can be written

$$\alpha \leq \left(\frac{\delta^{k-1}}{2S_k(\delta)} \right)^{2^{k-1}}, \quad N > 2\delta^{1-k}.$$

These improve the local modular-counting requirements. Incorporating them into a global quantitative Szemerédi argument also requires the later inverse, density-increment, and interval-transfer steps to be recomputed with their own hypotheses.

[write] **6 October 2026; sources 06–10.** Compared with the criteria of sources 03, 04 and 06 in the note after source 04’s Corollary III.4.4: the error here is δ times theirs, and in α terms the power of δ is $(k - 1)2^{k-1}$, between source 06’s $(k - \frac{1}{2})2^{k-2}$ and source 04’s $k2^{k-1}$. Not formalized.

III.29.1 Repeated terms and the appropriate main term

The torsion-sensitive estimate also gives a distinct-point criterion without a coprimality assumption. Define

$$\mathcal{D}_k(G) = \bigcup_{r=1}^{k-1} G[r].$$

A progression repeats a point exactly when $d \in \mathcal{D}_k(G)$. For each such difference, at most δN choices of x can contribute, since the first point must belong to A . Hence a sufficient criterion for a progression with k distinct points in an arbitrary finite abelian group is

$$\delta^{k-1} - \eta T_{k,G}(\delta) > \frac{|\mathcal{D}_k(G)|}{N}. \quad (\text{III.29.6})$$

In small characteristic it is sometimes preferable to reduce the pattern before estimating it. On $(\mathbb{Z}/p\mathbb{Z})^n$, if $k > p$, the homogeneous indicator product is exactly the p -term product, since coefficients repeat modulo p and indicators are idempotent. For a Bernoulli random set with inclusion probability δ , the exact expected normalized count is then

$$\left(1 - \frac{1}{N}\right) \delta^p + \frac{\delta}{N}.$$

Its leading independent-membership term is δ^p . This coefficient collision explains why a dimension-independent error tending to zero around δ^k cannot describe that pattern.

Further questions specific to these estimates. The sharpness argument determines the correct group-size order for $k = p + 1$; exact constants for larger k and general torsion profiles remain open within this investigation. A natural next problem is to retain the restricted images cG in Lemma III.28.1, instead of replacing each by all of G , and to exploit the overlap of these images. For heterogeneous sets, the telescoping order and the assignment of the L^p exponents can be optimized jointly; when all coefficient differences are invertible, the rearrangement inequality assigns the largest reciprocal exponents to the smallest densities within a fixed prefix. The finite fibre identity, mixed-norm induction, telescoping identity, and exact degenerate-pair count are also natural separate formalization targets.

III.30 An exact dimension threshold for polynomial colorings

Source 10, delivered Section 9.

There is a useful restricted question behind the recent constructions of sets with fewer arithmetic progressions than their uniformity might suggest: how many coordinates can a polynomial coloring control while forbidding reflection symmetry along every nontrivial progression? The construction of Shi and Dong uses a sum of odd-degree field norms [33]. We give an exact answer when the number of field-valued color coordinates and their total degrees are prescribed. The obstruction is a direct Chevalley–Warning argument [39, 40]; an analogous argument involving all homogeneous degrees appears in Fühner and Taranchuk [38]. Our purpose is to state the precise degree budget, prove its optimality, and identify the limit it places on this construction method. We make no claim of first discovery of these polynomial-method consequences.

Throughout this section, let $k = 2m \geq 4$ and let $p > k$ be prime. A coloring $Q : \mathbb{F}_p^d \rightarrow \mathbb{F}_p^r$ is *polynomial with coordinate degree bounds* $D_1, \dots, D_r$ if its ℓ th coordinate is represented by a polynomial Q_ℓ of total degree at most D_ℓ . A progression $(a, a + h, \dots, a + (k - 1)h)$ is *symmetrically colored* if

$$Q(a + ih) = Q(a + (k - 1 - i)h) \quad (0 \leq i < m). \quad (\text{III.30.1})$$

It is nontrivial when $h \neq 0$. The assumption $p > k$ guarantees that all k of its points are then distinct.

III.30.1 Odd coefficients encode reflection symmetry

Fix a center $z \in \mathbb{F}_p^d$ and introduce formal variables $H = (H_1, \dots, H_d)$ and T . For a polynomial P of total degree at most D , write

$$P(z + TH) = \sum_{j=0}^D C_{j,z}(H) T^j. \quad (\text{III.30.2})$$

The polynomial $C_{j,z}$ is homogeneous of degree j , or is zero. Indeed, in the expansion of a monomial, selecting the coefficient of T^j selects exactly j factors from the coordinates of H . This coefficient definition needs no differentiation or division by factorials.

Lemma III.30.1 (Reflection and the odd coefficient equations). *Suppose $1 \leq D \leq k$ and put $s = \lceil D/2 \rceil$. For $z, h \in \mathbb{F}_p^d$, the following are equivalent:*

1. *The progression with center z and direction h is symmetrically colored by P .*
2. *$C_{1,z}(h) = C_{3,z}(h) = \dots = C_{2s-1,z}(h) = 0$.*
3. *The polynomial $P(z + Th)$ is even in T .*

Proof. Put $\alpha_i = i - \frac{1}{2} \in \mathbb{F}_p$ for $1 \leq i \leq m$. The progression with center z has points $z \pm \alpha_1 h, \dots, z \pm \alpha_m h$. Its reflection equalities are $P(z + \alpha_i h) = P(z - \alpha_i h)$.

The α_i are nonzero, and their squares are pairwise distinct: for $i \neq j$, the quantities $\alpha_i - \alpha_j = i - j$ and $\alpha_i + \alpha_j = i + j - 1$ are nonzero modulo p . In particular, $1 \leq i + j - 1 \leq k - 1 < p$.

Subtracting the two evaluations in (III.30.2) cancels all even powers, leaving

$$P(z + TH) - P(z - TH) = 2 \sum_{j=1}^s C_{2j-1,z}(H) T^{2j-1}.$$

Its degree is at most $2s - 1 \leq k - 1$, even when $D = k$. After division by $2\alpha_i$, the reflection equalities become

$$\sum_{j=1}^s C_{2j-1,z}(h)(\alpha_i^2)^{j-1} = 0 \quad (1 \leq i \leq m).$$

Since $s \leq m$, the first s equations form a square Vandermonde system with determinant

$$\prod_{1 \leq i < j \leq s} (\alpha_j^2 - \alpha_i^2) \neq 0.$$

Thus all its unknown odd coefficients vanish. Conversely, vanishing of these coefficients makes the polynomial even and implies every required reflection equality. $\square$

The important distinction is that the degree budget contains only $1, 3, \dots, 2s - 1$. An even top degree contributes no new reflection equation. This is why degree bounds $2s - 1$ and $2s$ lead to the same dimension threshold.

III.30.2 The zero-count obstruction

We recall the short finite-field proof of the form of Chevalley–Warning that we need.

Lemma III.30.2 (Chevalley–Warning in the needed form). *Let $F_1, \dots, F_t \in \mathbb{F}_p[H_1, \dots, H_d]$ vanish at the origin. Omit zero polynomials from the degree sum. If $\sum_{j=1}^t \deg F_j < d$, the number of their common zeros in $\mathbb{F}_p^d$ is divisible by p . Consequently there are at least p common zeros, including at least $p - 1$ nonzero common zeros.*

Proof. By Fermat’s theorem, the polynomial function

$$I(H) = \prod_{j=1}^t (1 - F_j(H)^{p-1})$$

equals the indicator of the common zero set. Its total degree is less than $d(p - 1)$. Every monomial of I therefore has at least one variable whose exponent e satisfies $0 \leq e < p - 1$. For that exponent,

$$\sum_{u \in \mathbb{F}_p} u^e = 0 \quad \text{in } \mathbb{F}_p.$$

For $e = 0$ this is $p = 0$; for $1 \leq e < p - 1$ it is the usual finite-field power sum. Summation of each monomial over $\mathbb{F}_p^d$ factors into the corresponding one-variable sums, and hence gives zero. It follows that $\sum_h I(h) = 0$ in $\mathbb{F}_p$, which is the required divisibility. The zero count is positive because the origin is a common zero, so it is at least p . $\square$

Theorem III.30.3 (Exact dimension threshold with heterogeneous degrees). *Let $r \geq 1$, let $1 \leq D_\ell \leq k$ for $1 \leq \ell \leq r$, and put*

$$s_\ell = \left\lceil \frac{D_\ell}{2} \right\rceil, \quad B = \sum_{\ell=1}^r s_\ell^2.$$

There exists a polynomial coloring $Q : \mathbb{F}_p^d \rightarrow \mathbb{F}_p^r$, with $\deg Q_\ell \leq D_\ell$, having no nontrivial symmetrically colored k -term arithmetic progression if and only if $d \leq B$.

If $d > B$, then for every such Q and every center z , the number of directions giving a symmetrically colored progression centered at z , including the zero direction, is divisible by p . In particular, there are at least $p - 1$ nonzero such directions at every center.

Proof. For necessity, fix z and apply Lemma III.30.1 to each color coordinate. Reflection symmetry is equivalent to the common vanishing of

$$C_{\ell,1,z}(h), C_{\ell,3,z}(h), \dots, C_{\ell,2s_\ell-1,z}(h) \quad (1 \leq \ell \leq r).$$

These homogeneous polynomials vanish at the origin and have total degree sum at most

$$\sum_{\ell=1}^r \sum_{j=1}^{s_\ell} (2j-1) = \sum_{\ell=1}^r s_\ell^2 = B.$$

If $d > B$, Lemma III.30.2 gives the asserted divisibility and nonzero directions. Thus avoidance requires $d \leq B$.

For sufficiency we use the odd-degree norm construction of Shi and Dong [33, Sections 3–4], allowing a different top degree in each coordinate. For a positive odd integer t , identify $\mathbb{F}_p^t$ linearly with $\mathbb{F}_{p^t}$ and let $N_t : \mathbb{F}_p^t \rightarrow \mathbb{F}_p$ be the field norm. In degree one, take $N_1(u) = u$. We need that N_t is homogeneous of degree t and that $N_t(u) = 0$ holds exactly when $u = 0$.

Here is a polynomial description of those properties. If $\beta_1, \dots, \beta_t$ is a basis of $\mathbb{F}_{p^t}$ over $\mathbb{F}_p$, then

$$N_t(u_1, \dots, u_t) = \prod_{a=0}^{t-1} \left(\sum_{j=1}^t u_j \beta_j^{p^a} \right).$$

This is a product of t linear forms, and Frobenius permutes its factors, so its coefficients lie in $\mathbb{F}_p$. Its value is the norm of $\sum_j u_j \beta_j$, which is nonzero precisely when that field element is nonzero. In particular, its formal total degree is t , despite the alternative large-exponent expression for a field norm.

For color coordinate ℓ , introduce disjoint variable blocks

$$u_\ell^{(1)} \in \mathbb{F}_p, \quad u_\ell^{(3)} \in \mathbb{F}_p^3, \quad \dots, \quad u_\ell^{(2s_\ell-1)} \in \mathbb{F}_p^{2s_\ell-1}.$$

There are s_ℓ^2 variables in that coordinate's collection of blocks. On their full B -dimensional product define

$$Q_\ell(u) = \sum_{j=1}^{s_\ell} N_{2j-1}(u_\ell^{(2j-1)}). \quad (\text{III.30.3})$$

Its total degree is $2s_\ell - 1 \leq D_\ell$.

Suppose a progression with center z and direction h is symmetrically colored. Lemma III.30.1 says that every $Q_\ell(z + Th)$ is even. If h has a nonzero block in coordinate ℓ , let t be the largest odd index with $h_\ell^{(t)} \neq 0$. All higher-index blocks contribute constants, because their directions vanish; all lower-index blocks have degree less than t . The coefficient of T^t in $Q_\ell(z + Th)$ is therefore exactly

$$N_t(h_\ell^{(t)}) \neq 0.$$

Since t is odd, this contradicts evenness. Thus every direction block vanishes, and $h = 0$. This proves avoidance at $d = B$.

For $d < B$, restrict the construction to any linear embedding of $\mathbb{F}_p^d$ into $\mathbb{F}_p^B$. A nonzero direction remains nonzero under the embedding, and composition with a linear map does not increase total degree, so all the required properties are preserved. $\square$

[write] **6 October 2026; sources 11–14.** Source 14 reproves this threshold and determines the exact minimum count above it, $q^d(q^{\max(d-B,0)} - 1)$ over every $\mathbb{F}_q$ with $p > k$, with subspace equality and a prime-field gap (its Theorem III.36.1); the quintic question remains open (item III.19).

Corollary III.30.4 (Equal degree bounds and optimal coordinate budget). *For $1 \leq D \leq k$, a coloring by r polynomial coordinates of total degree at most D can avoid all nontrivial symmetrically colored k -APs on $\mathbb{F}_p^d$ exactly when*

$$d \leq r \lceil D/2 \rceil^2.$$

In particular, for degree at most $k = 2m$ the exact condition is $d \leq rm^2$, and for $d \geq 1$ the least possible number of polynomial coordinates is $\lceil d/m^2 \rceil$.

At the equality dimension $d = B$, the coloring (III.30.3) is surjective onto $\mathbb{F}_p^r$. Indeed, each coordinate contains its own independent linear variable $u_\ell^{(1)}$. After choosing all other variables, the r linear variables are uniquely determined by the desired color. Thus every color class has exactly p^{B-r} points.

III.30.3 An upper bound for arbitrary degree budgets

When the degree exceeds the progression length, the reflection equations can vanish without all odd coefficients vanishing. Nevertheless, they give a useful explicit dimension bound.

Proposition III.30.5 (A dimension bound in every degree). *For a positive integer s , define*

$$B_m(s) = \begin{cases} s^2, & s \leq m, \\ m(2s - m), & s \geq m. \end{cases}$$

Let $D_1, \dots, D_r \geq 1$ be arbitrary, put $s_\ell = \lceil D_\ell/2 \rceil$, and suppose $Q : \mathbb{F}_p^d \rightarrow \mathbb{F}_p^r$ is polynomial with $\deg Q_\ell \leq D_\ell$. If

$$d > \sum_{\ell=1}^r B_m(s_\ell),$$

then at every prescribed center there are at least $p - 1$ nonzero directions producing symmetrically colored k -term progressions. Thus avoidance requires $d \leq \sum_{\ell=1}^r B_m(s_\ell)$.

Proof. Fix a center z and write the odd coefficients of one coordinate as $C_{2j+1,z}(H)$, for $0 \leq j < s$, with $s = \lceil D/2 \rceil$. Let $y_i = \alpha_i^2$ for the nonzero half-integer parameters used in Lemma III.30.1, and put $v_j = (y_i^j)_{i=1}^m \in \mathbb{F}_p^m$. After dividing each reflection equality by $2\alpha_i$, the vector of reflection equations is

$$E(H) = \sum_{j=0}^{s-1} v_j C_{2j+1,z}(H) = 0.$$

If $s \leq m$, these are equivalent to the individual odd coefficient equations, whose total degree sum is s^2 .

If $s > m$, form the square matrix

$$V = (v_{s-m}, v_{s-m+1}, \dots, v_{s-1}).$$

It is the usual Vandermonde matrix multiplied on the left by the invertible diagonal matrix with entries y_i^{s-m} , so it is invertible. The equivalent system $V^{-1}E(H) = 0$ has equations

$$F_j(H) = C_{2(s-m+j)+1,z}(H) + \sum_{q=0}^{s-m-1} b_{j,q} C_{2q+1,z}(H) = 0, \quad 0 \leq j < m,$$

for scalars $b_{j,q} \in \mathbb{F}_p$. Every coefficient in the second sum has strictly smaller degree than the displayed first coefficient. Consequently

$$\deg F_j \leq 2(s-m+j)+1, \quad \sum_{j=0}^{m-1} \deg F_j \leq m(2s-m).$$

Zero polynomials may again be omitted. Although the transformed equations need not be homogeneous, they all vanish at the origin. Applying this procedure independently to each color coordinate produces a system equivalent to reflection symmetry with total degree sum at most $\sum_{\ell} B_m(s_{\ell})$. The conclusion follows from Lemma III.30.2. $\square$

For four-term progressions and a scalar degree bound $D = 5$ or 6 , Proposition III.30.5 gives $d \leq 8$. The cubic construction already attains dimension 4, so the corresponding maximum dimension lies between 4 and 8. Determining that maximum is a concrete question beyond the exact low-degree theorem. No matching construction is asserted for the arbitrary-degree bound.

III.30.4 An explicit four-dimensional example

For $k = 4$, both scalar degree bounds $D = 3$ and $D = 4$ have exact dimension threshold 4. Over $\mathbb{F}_5$, the polynomial $T^3 + T + 1$ has no root and is therefore irreducible. If $\theta^3 + \theta + 1 = 0$, the norm of $a + b\theta + c\theta^2$ is

$$\begin{aligned} N_3(a, b, c) &= \det \begin{pmatrix} a & -c & -b \\ b & a-c & -b-c \\ c & b & a-c \end{pmatrix} \\ &= a^3 - 2a^2c + ac^2 + ab^2 + 3abc - b^3 - bc^2 + c^3 \pmod{5}. \end{aligned} \quad (\text{III.30.4})$$

The determinant is that of multiplication by $a + b\theta + c\theta^2$ in the basis $1, \theta, \theta^2$. Consequently

$$Q(x_0, x_1, x_2, x_3) = x_0 + N_3(x_1, x_2, x_3)$$

is a five-coloring of $\mathbb{F}_5^4$ with five color classes of 125 points and no nontrivial symmetrically colored 4-AP.

The accompanying exact-arithmetic verification checks the determinant formula, the absence of nonzero norm zeros, and all $625 \cdot 624 = 390,000$ ordered nontrivial progressions. It finds no symmetrically colored progression. This finite check verifies the displayed example; the theorem in arbitrary dimension and characteristic follows from the preceding proof.

III.30.5 What the threshold does and does not settle

The same result holds for any prescribed centrally symmetric pattern $\{\pm\alpha_1, \dots, \pm\alpha_m\}$ in $\mathbb{F}_p$ with $\alpha_i \neq 0$ and pairwise distinct α_i^2 . The conditions $Q(z + \alpha_i h) = Q(z - \alpha_i h)$ are again equivalent

to the same odd coefficient equations, by the same Vandermonde argument. Hence the optimal dimension depends on the degree budgets and the number of reflection pairs, rather than on equal spacing itself.

For degree at most k , the theorem shows that the formal palette $\mathbb{F}_p^r$ must satisfy $r/d \geq 4/k^2$, and the equality construction uses all p^r colors. This is a sharp statement about a prescribed number of polynomial color coordinates. It is not a lower bound on the actual image size of arbitrary maps with redundant color coordinates, nor an optimality theorem for unrestricted colorings of intervals or cyclic groups. In particular, the auxiliary digit colors in Shi and Dong's cyclic construction are outside this polynomial coordinate model. The possibility of $N^{o(1)}$ colors in the Deng–Tidor–Zhao symmetric-progression problem remains outside the conclusion [37].

The restriction $D_\ell \leq k$ also matters. With higher odd degrees, agreement at the k progression parameters need not make the entire odd polynomial vanish. Thus higher-degree constructions and nonpolynomial color data provide specific directions beyond the class solved here. Within the stated class, however, both sides of the optimization problem are complete: the odd-degree sum gives a universal obstruction, and the known norm construction attains it.

III.31 Centered cube counts and their spectral decomposition

Source 13, delivered Section 7.

Lemma 3.10 bounds the normalized number of d -dimensional cubes in a set of density δ by $(\delta + \eta)^{2^d}$, where η is the appropriate uniformity norm of its balanced function. The triangle inequality proves that bound, but it treats all terms in the binomial expansion as possible. Mean zero forces many of them to vanish exactly.

In this section let $G = \mathbb{F}_p^n$, where p is an odd prime, and let $f : G \rightarrow \mathbb{R}$ have mean zero. Initially no absolute bound on f is required. Put $V_d = \{0, 1\}^d$, $m = 2^d$, and

$$L_v(x, h) = x + v \cdot h, \quad I_S(f) = \mathbb{E}_{x, h} \prod_{v \in S} f(L_v(x, h)), \quad I_\emptyset = 1.$$

For $\delta \geq 0$, define

$$\mathcal{Q}_d(\delta + f) = \mathbb{E}_{x, h} \prod_{v \in V_d} (\delta + f(L_v(x, h))) = \|\delta + f\|_{U^d}^m.$$

The last equality uses real-valuedness. For $f = \mathbf{1}_A - \delta$, this is the normalized count of all additive cubes, including degenerate ones, exactly as in the source lemma.

III.31.1 Cancellation from an affine coloop

Associate to each vertex v the column $\tilde{v} = (1, v) \in \mathbb{F}_p^{d+1}$. A vertex $v \in S$ is a *coloop* of S if its column is not in the span of the other columns in S . Call S *coloopless* if it has no coloop, with the empty set included by convention. This is the standard vector-matroid language for the affine dependencies of the cube; that matroid is a classical object [53]. The role of the terminology here is simply to identify a factor that can be averaged independently.

Lemma III.31.1 (Coloop cancellation). *If S has a coloop, then $I_S(f) = 0$. For every $S \subset V_d$,*

$$|I_S(f)| \leq \|f\|_{U^d}^{|S|}.$$

Proof. If v is a coloop, elementary linear algebra gives $w \in \mathbb{F}_p^{d+1}$ such that $\tilde{v} \cdot w = 1$ and $\tilde{u} \cdot w = 0$ for all other $u \in S$. For each $t \in G$, translate the $(d+1)$ variables by $(w_0 t, \dots, w_d t)$. Uniform measure is invariant under this translation. It changes only the factor at v , replacing it by $f(L_v + t)$. Average in t ; its average is zero. The norm bound follows from (I.25.2), placing f at vertices in S and the constant 1 elsewhere. $\square$

Let $c_{d,p}(j)$ count the coloopless j -subsets of V_d and write $\eta = \|f\|_{U^d}$. Direct expansion gives the exact formula

$$\mathcal{Q}_d(\delta + f) = \sum_{S \text{ coloopless}} \delta^{m-|S|} I_S(f). \quad (\text{III.31.1})$$

Thus the relevant coefficient polynomial is determined by the actual coefficient matroid over $\mathbb{F}_p$. For higher dimensions, one must not silently substitute characteristic-zero ranks.

III.31.2 The quartic term in every dimension

Lemma III.31.2 (Four-vertex classification). *Every three distinct cube vertices are affinely independent. In odd characteristic, an affinely dependent four-subset is exactly an ordinary parallelogram of the binary cube. Its expectation $I_S(f)$ is ρ^4 , where $\rho = \|f\|_{U^2}$.*

Proof. Reflect coordinates to move one vertex to 0. Two distinct nonzero binary vectors cannot be proportional: at a coordinate where the first is 1, the proportionality factor must be 1, forcing equality. This proves independence of three vertices.

For four dependent vertices, reflect one to 0 and call the others u, v, w . In a nonzero relation $\lambda u + \mu v + \nu w = 0$, each of $\lambda, \mu, \nu, \lambda + \mu + \nu$ is nonzero; otherwise three vertices would be dependent. A nonzero coordinate pattern among (u_i, v_i, w_i) can therefore only be 110, 101, or 011: singleton patterns and 111 are excluded. At least two pair patterns occur, or the vectors would coincide. Relabel so that 110 and 101 occur. They force $\mu = \nu = -\lambda$. Since $2\lambda \neq 0$, pattern 011 cannot occur. Consequently $u = v + w$ with disjoint supports for v, w . The four vertices form an ordinary parallelogram.

Any three forms belonging to that parallelogram are jointly uniform on G^3 ; their coefficient matrix has rank three. Hence

$$I_S(f) = \mathbb{E}_{a,b,c} f(a)f(b)f(c)f(a+b-c) = \sum_{\chi} |\hat{f}(\chi)|^4 = \rho^4.$$

$\square$

Proposition III.31.3 (The exact quartic coefficient). *The number of four-vertex parallelograms in V_d is*

$$P_d = \frac{6^d - 2 \cdot 4^d + 2^d}{8}. \quad (\text{III.31.2})$$

For $d \geq 2$,

$$\left| \mathcal{Q}_d(\delta + f) - \delta^m - P_d \delta^{m-4} \rho^4 \right| \leq \sum_{j=5}^m c_{d,p}(j) \delta^{m-j} \eta^j. \quad (\text{III.31.3})$$

An empty sum is zero; in particular $\mathcal{Q}_2(\delta + f) = \delta^4 + \rho^4$.

Proof. Coordinatewise, there are six ordered solutions to $a+b = c+e$ in $\{0, 1\}$. Thus the binary cube has 6^d ordered solutions. The degenerate ones, with the same two vertices on both sides, number $2 \cdot 4^d - 2^d$. Every nondegenerate parallelogram has eight orderings, proving (III.31.2). The values 0, 1, 2 remain distinct in odd characteristic. Equation (III.31.3) now follows from lemmas III.31.1 and III.31.2 and (III.31.1). $\square$

In particular, the error from the random-density main term starts at fourth order, rather than at first order. The exact quartic coefficient cannot be reduced for bounded real weights: replace f by tg for any fixed nonzero mean-zero real g , fix $0 < \delta < 1$, and let $t \downarrow 0$. For small t , the function $\delta + tg$ lies in $[0, 1]$. The quartic term is $P_d \delta^{m-4} t^4 \|g\|_{U^2}^4$, and all remaining terms have order at least t^5 . This is a weighted sharpness statement; it does not by itself assert an extremal theorem restricted to indicators at a fixed finite group size.

III.31.3 All surviving subsets of the three-cube

Proposition III.31.4 (The three-dimensional coefficient table). *For every odd p , the values $c_{3,p}(j)$, $j = 0, \dots, 8$, are*

$$(1, 0, 0, 0, 12, 8, 28, 8, 1).$$

Consequently, with $\eta = \|f\|_{U^3}$,

$$\mathcal{Q}_3(\delta + f) \leq \delta^8 + 12\delta^4\eta^4 + 8\delta^3\eta^5 + 28\delta^2\eta^6 + 8\delta\eta^7 + \eta^8. \quad (\text{III.31.4})$$

The quartic term may be replaced by $12\delta^4\rho^4$.

Proof. The first four entries and the twelve four-subsets follow from lemma III.31.2 and proposition III.31.3. Every affine hyperplane in $\mathbb{F}_p^3$ contains at most four binary vertices: choose a variable with a nonzero coefficient, assign the other two bits, and solve for that variable. Therefore any five vertices have full affine rank four after homogenization.

A five-subset has a coloop exactly when it contains a parallelogram. Each parallelogram extends to four five-subsets, and no five-subset contains two parallelograms. To justify the latter statement, two four-subsets of a five-set share three vertices, while three cube vertices complete to at most one parallelogram. After reflection, the possible completions of $0, u, v$ are $u+v, u-v, v-u$; at most one can be binary, according as the supports are disjoint or one strictly contains the other. Thus $12 \cdot 4 = 48$ of the $\binom{8}{5} = 56$ five-subsets have a coloop, leaving eight.

Deleting a vertex from a subset of size at least six still leaves at least five vertices and hence full rank. Every such subset is coloopless. Their counts are 28, 8, 1. Apply (III.31.1), lemma III.31.1, and $\rho \leq \eta$. $\square$

For comparison, the source bound $(\delta + \eta)^8$ has nonzero coefficients in the first three orders. Its quartic coefficient is 70, and its fifth coefficient is 56. Centering removes the first three nonconstant orders and reduces the next two coefficients to 12 and 8. These are exact combinatorial cancellations.

[write] **6 October 2026; sources 11–14.** *Credit.* The quartic coefficient P_d is source 03's R_d (Theorem III.2.6), source 04's P_d , source 08's R_d and source 09's P_d ; on odd-order groups the three-cube table $(1, 0, 0, 0, 12, 8, 28, 8, 1)$ is source 04's support count (Lemma III.3.3), source 08's Theorem III.9.2 and source 14's Appendix A (Section III.38). Here it is stated over $\mathbb{F}_p^n$; those sources prove it on every group of odd order (source 03 on every finite abelian group, with the order-two correction).

III.31.4 A complete spectral identity

Write $a_\xi = \widehat{f}(\xi)$, so $a_{-\xi} = \overline{a_\xi}$, and put

$$\sigma^2 = \mathbb{E}f^2 = \sum_{\xi} |a_\xi|^2, \quad \rho^4 = \sum_{\xi} |a_\xi|^4, \quad \zeta = \max_{\xi} |a_\xi|, \quad \eta = \|f\|_{U^3}.$$

Define the real quantities

$$T_5 = \sum_{\xi} |a_\xi|^2 a_\xi^2 \overline{a_{2\xi}}, \quad (\text{III.31.5})$$

$$B_1 = \sum_{\xi, \nu} |a_\xi|^2 |a_\nu|^2 |a_{\xi+\nu}|^2, \quad (\text{III.31.6})$$

$$B_2 = \sum_{\xi, \nu} |a_\xi|^2 a_\nu^2 a_{\xi-\nu} \overline{a_{\xi+\nu}}, \quad (\text{III.31.7})$$

$$B_3 = \sum_{\xi, \nu} a_\xi^2 a_\nu^2 a_{-\xi-\nu}^2. \quad (\text{III.31.8})$$

Finally let T_7 be the common expectation $I_S(f)$ of a seven-subset of the cube. Cube symmetries show that it is independent of the omitted vertex.

Theorem III.31.5 (Exact centered three-cube decomposition). *For every real mean-zero f on $\mathbb{F}_p^n$, p odd,*

$$\begin{aligned} \mathcal{Q}_3(\delta + f) &= \delta^8 + 12\delta^4 \rho^4 + 8\delta^3 T_5 \\ &\quad + \delta^2(12B_1 + 12B_2 + 4B_3) + 8\delta T_7 + \eta^8. \end{aligned} \quad (\text{III.31.9})$$

Moreover,

$$|T_5| \leq \zeta \rho^4, \quad |B_2|, |B_3| \leq B_1 \leq \eta^6, \quad |T_7| \leq \eta^4 \sqrt{B_1}. \quad (\text{III.31.10})$$

Proof. The eight five-circuits are the sets consisting of a vertex, its three graph neighbors, and its antipode. They form one symmetry orbit. Their unique affine relation is the sum of the three neighbors minus twice the vertex minus the antipode. Fourier expansion therefore gives (III.31.5) for every five-circuit.

The six-subsets split into three symmetry orbits, according to whether their omitted pair has Hamming distance one, two, or three. There are 12, 12, 4 such pairs, respectively. Fourier expansion imposes one equation for each of x, h_1, h_2, h_3 . The following kernel parametrizations, in lexicographic order of the retained vertices, verify the corresponding products:

Omitted pair	Six Fourier indices	Contribution
000, 001	$(u + v, -u - v, -u, u, -v, v)$	B_1
000, 011	$(u + v, -u - v, v, -u - 2v, u, v)$	B_2
000, 111	$(v, u, -u - v, -u - v, u, v)$	B_3

For the middle row set $\xi = u + v$, $\nu = v$. Each parametrization solves the four constraints and has two free coordinates; its integer pivot minor is a unit. Thus the calculation is valid over every odd field without a hidden divisor. The seven-subsets contribute $8\delta T_7$, and the full subset contributes η^8 . This proves (III.31.9).

The first bound in (III.31.10) follows termwise from (III.31.5). The bound $|B_3| \leq B_1$ also follows by taking absolute values. For B_2 , Cauchy–Schwarz bounds its absolute value by

$$\left(\sum_{\xi, \nu} |a_\xi|^2 |a_\nu|^2 |a_{\xi-\nu}|^2 \right)^{1/2} \left(\sum_{\xi, \nu} |a_\xi|^2 |a_\nu|^2 |a_{\xi+\nu}|^2 \right)^{1/2} = B_1,$$

using $|a_{-\nu}| = |a_\nu|$. Gowers–Cauchy–Schwarz applied to the corresponding six-subset gives $B_1 \leq \eta^6$.

To bound T_7 , set

$$A(h, k) = \mathbb{E}_x f(x+h) f(x+k) f(x+h+k),$$

$$B(h, k) = \mathbb{E}_x f(x) f(x+h) f(x+k) f(x+h+k).$$

Splitting the cube into parallel faces gives $T_7 = \mathbb{E}_{h,k} A(h, k) B(h, k)$. Expanding $\mathbb{E} A^2$ gives a cube missing an adjacent pair, so $\mathbb{E} A^2 = B_1$. Expanding $\mathbb{E} B^2$ gives the full cube, so $\mathbb{E} B^2 = \eta^8$. Cauchy–Schwarz proves the final bound. $\square$

[write] **6 October 2026; sources 11–14.** *Credit.* The identity (III.31.9) is source 08’s complete odd-order three-cube expansion (Theorem III.9.2), which holds on every finite abelian group of odd order; here it is proved over $\mathbb{F}_p^n$, p odd. New in this source: the orbit moments B_1, B_2, B_3, T_7 with the bounds (III.31.10), the spectral deficit below, and the sign examples.

III.31.5 A further sharp spectral deficit

The zero Fourier coefficient is absent because $\mathbb{E} f = 0$. Keeping this absence improves the elementary estimate $B_1 \leq \sigma^2 \rho^4$.

Proposition III.31.6 (A spectral upper bound with the zero-frequency loss). *If $\sigma^2 > 0$, then*

$$B_1 \leq \sigma^2 \rho^4 - \frac{\rho^8}{\sigma^2}. \quad (\text{III.31.11})$$

Equality is attained when $|\widehat{f}(\xi)|^2$ is constant for every nonzero ξ , including for a scalar multiple of $|G| \mathbf{1}_{\{0\}} - 1$.

Proof. Put $b_\xi = |a_\xi|^2$, so $b_0 = 0$ and $b_{-\xi} = b_\xi$. Translation gives the exact identity

$$\sigma^2 \rho^4 - B_1 = \frac{1}{2} \sum_{\nu} b_{\nu} \sum_{\xi} (b_{\xi} - b_{\xi+\nu})^2.$$

For each nonzero ν , retain only the two terms $\xi = 0, -\nu$. They contribute $2b_{\nu}^2$, whence the right side is at least $\sum_{\nu} b_{\nu}^3$. Cauchy–Schwarz yields

$$(\rho^4)^2 = \left(\sum_{\nu} b_{\nu}^2 \right)^2 \leq \left(\sum_{\nu} b_{\nu} \right) \left(\sum_{\nu} b_{\nu}^3 \right) = \sigma^2 \sum_{\nu} b_{\nu}^3.$$

This proves (III.31.11). If all nonzero b_{ν} are equal, the discarded translation terms vanish and the final Cauchy–Schwarz inequality is an equality. $\square$

For a balanced indicator, $\sigma^2 = \delta(1 - \delta)$ is known exactly. The right side of (III.31.11) is nonnegative, since $\rho^4 \leq \sigma^4$. Combining the proposition with theorem III.31.5 gives, for $\sigma > 0$,

$$B_1 \leq \mathcal{B} := \min \left\{ \eta^6, \sigma^2 \rho^4 - \rho^8 / \sigma^2 \right\}.$$

The case $\sigma = 0$ means $f = 0$ and is immediate.

One convenient two-sided consequence of the exact identity is

$$\begin{aligned} & \left| \mathcal{Q}_3(\delta + f) - \delta^8 - 12\delta^4 \rho^4 - 12\delta^2 B_1 - \eta^8 \right| \\ & \leq 8\delta^3 \zeta \rho^4 + 16\delta^2 B_1 + 8\delta \eta^4 \sqrt{B_1}. \end{aligned} \quad (\text{III.31.12})$$

If only an upper bound is wanted, theorem III.31.5 instead gives

$$\mathcal{Q}_3(\delta + f) \leq \delta^8 + 12\delta^4 \rho^4 + 8\delta^3 \zeta \rho^4 + 28\delta^2 \mathcal{B} + 8\delta \eta^4 \sqrt{\mathcal{B}} + \eta^8. \quad (\text{III.31.13})$$

This retains more information than the one-parameter polynomial (III.31.4); it is useful when the ordinary Fourier norm is much smaller than the higher uniformity norm.

III.31.6 Signs, characteristic, and the scope of sharpness

Odd-order circuit terms cannot simply be discarded. On $\mathbb{Z}/p\mathbb{Z}$, $p \geq 7$, take

$$g(x) = \cos(2\pi x/p) - u \cos(4\pi x/p), \quad u > 0.$$

Its only relevant Fourier modes are $\pm 1, \pm 2$, and (III.31.5) gives $T_5(g) = -u/16$. Replacing g by $-g$ reverses that sign. Multiplying by a sufficiently small number and adding a fixed $\delta \in (0, 1)$ makes this a valid $[0, 1]$ -valued weight. Likewise, for $g(x) = \cos(2\pi x/p) + u \sin(4\pi x/p)$, one has

$$B_3 = -3u^2/32 = -B_1.$$

Thus the possible negative contribution in (III.31.12) is real, even for elementary two-frequency examples.

The coloop cancellation mechanism is valid over every finite field, but the explicit odd-characteristic table is not. In characteristic two, the three-cube table is 1, 0, 0, 0, 14, 0, 28, 8, 1. Already its quartic coefficient differs. In larger dimensions one should compute $c_{d,p}(j)$ over the actual field and then apply (III.31.1). These rank questions connect the analytic problem to classical cube matroids [53], while control of more general linear systems belongs to the wider theory of true complexity [29].

Finally, neither the surviving-subset polynomial nor its spectral upper bound is asserted to be jointly optimal at every parameter tuple. We proved exact cancellation, exact identities, an exact leading coefficient, and explicitly stated inequalities with their own equality cases. Those are stronger and more precise claims than a numerical estimate, but they do not identify all simultaneous extremizers of the U^3 norm.

III.32 Interval discrepancy with the sharp length exponent

Source 13, delivered Section 8.

The proof of Lemma 3.5 bounds an interval's Fourier coefficient by frequency decay and explicitly discards the additional bound by the interval's length [1, 67]. Retaining both estimates gives a stronger local statement and an exact dual constant.

Theorem III.32.1 (Exact and explicit interval discrepancy bounds). *Let $N \geq 2$, $I \subset \mathbb{Z}/N\mathbb{Z}$ be an interval of length M , $0 \leq M \leq N$, and let f have mean zero. Put $\rho = \|f\|_{U^2}$, $\beta = M/N$, and $b = \min(\beta, 1 - \beta)$. Then*

$$|\mathbb{E}f\mathbf{1}_I| \leq \rho D_N(M), \quad D_N(M) = \left(\sum_{r=1}^{N-1} \left| \frac{\sin(\pi Mr/N)}{N \sin(\pi r/N)} \right|^{4/3} \right)^{3/4}. \quad (\text{III.32.1})$$

This constant is optimal over mean-zero real bounded functions. If $0 < M < N$, then

$$D_N(M) \leq \left(4b^{1/3} - 3N^{-1/3} \right)^{3/4} \leq 2\sqrt{2} b^{1/4}. \quad (\text{III.32.2})$$

For $M = 0$ or $M = N$, discrepancy is zero. The exponent $1/4$ cannot be replaced by a larger one, even for balanced indicators.

Proof. The geometric-series formula gives the absolute value of the normalized interval Fourier coefficient displayed in (III.32.1). Since $\widehat{f}(0) = 0$, Parseval and Hölder yield

$$|\mathbb{E}f\mathbf{1}_I| \leq \left(\sum_{r \neq 0} |\widehat{f}(r)|^4 \right)^{1/4} \left(\sum_{r \neq 0} |\widehat{\mathbf{1}}_I(r)|^{4/3} \right)^{3/4}.$$

This proves the exact upper bound. For its optimality, prescribe the Fourier coefficients of a test function by

$$\widehat{f}(r) = \widehat{\mathbf{1}}_I(r) |\widehat{\mathbf{1}}_I(r)|^{-2/3} \quad (r \neq 0), \quad \widehat{f}(0) = 0,$$

with zero used when the interval coefficient vanishes. These coefficients are conjugate symmetric, so f is real. They attain equality in Hölder. Scale f to have absolute value at most 1; the quotient of discrepancy by ρ is unchanged.

For the explicit estimate, nonzero coefficients are unchanged in absolute value when I is replaced by its complementary interval, so

$$|\widehat{\mathbf{1}}_I(r)| \leq \min\{b, (2|r|)^{-1}\},$$

where $|r|$ is the least positive centered frequency magnitude. The first bound is the interval length; the second follows from $|\sin(\pi r/N)| \geq 2|r|/N$. Let $F(x) = \min\{b, (2x)^{-1}\}^{4/3}$. This function is decreasing. Pair opposite frequencies, possibly overcounting the frequency $N/2$, and compare each summand with the integral on its preceding unit interval:

$$\sum_{r \neq 0} |\widehat{\mathbf{1}}_I(r)|^{4/3} \leq 2 \sum_{r=1}^{\lfloor N/2 \rfloor} F(r) \leq 2 \int_0^{N/2} F(x) dx.$$

For a nontrivial interval $b \geq 1/N$, the transition point $1/(2b)$ is at most $N/2$. Evaluation gives

$$2 \left[\frac{1}{2} b^{1/3} + 2^{-4/3} \int_{1/(2b)}^{N/2} x^{-4/3} dx \right] = 4b^{1/3} - 3N^{-1/3}.$$

Taking the $3/4$ power proves (III.32.2).

To prove the exponent is best possible, take $A = I$ with $\beta \rightarrow 0$ and $f = \mathbf{1}_I - \beta$. Then $\mathbb{E}f\mathbf{1}_I = \beta(1 - \beta)$, whereas Parseval and $|\widehat{\mathbf{1}}_I(r)| \leq \beta$ give $\rho^4 \leq \beta^3(1 - \beta)$. An estimate $|\mathbb{E}f\mathbf{1}_I| \leq C\rho\beta^\gamma$ with fixed C would therefore force $\gamma \leq 1/4$ as $\beta \downarrow 0$. $\square$

For $f = \mathbf{1}_A - \delta$ and the source convention of degree-one α -uniformity, $\rho \leq \alpha^{1/4}$. Multiplying the normalized estimate by N gives

$$||A \cap I| - \delta|I|| \leq 2\sqrt{2} \alpha^{1/4} N \min \left\{ \frac{|I|}{N}, 1 - \frac{|I|}{N} \right\}^{1/4}.$$

The repository's repaired Lemma 3.5 has the length-independent constant 3; the new expression improves it for every nontrivial interval and vanishes at both endpoint lengths. The exact dual constant is available if numerical constants matter. The same assertion holds for affine images of intervals under invertible slopes, because those maps permute Fourier frequencies. [6 October 2026; sources 11–14] The repaired Lemma 3.5 is the formal `lemma_3_5` (`Sections01_03.lean`, line 299; exact companion `lemma_3_5_holds`, `Proofs03Interval.lean`, line 412, at HEAD `e1db00e99`). No other source of this report treats Lemma 3.5.

Proposition III.32.2 (The small-relative-length limit). *If $M \rightarrow \infty$ and $M/N \rightarrow 0$, then*

$$\frac{D_N(M)}{(M/N)^{1/4}} \longrightarrow \left(\int_{\mathbb{R}} \left| \frac{\sin \pi t}{\pi t} \right|^{4/3} dt \right)^{3/4}, \quad (\text{III.32.3})$$

where the integrand takes its continuous value 1 at 0.

Proof. Write $\beta = M/N$ and rescale frequencies by $t = \beta r$. For bounded t , $r/N = t/M \rightarrow 0$, so the interval coefficient divided by β tends uniformly on compact sets to $\sin(\pi t)/(\pi t)$ in absolute value. The frequency mesh is $\beta \rightarrow 0$, giving the Riemann sum on every compact interval. The bound $(2|r|)^{-1}$ gives a tail, after division by $\beta^{1/3}$, of order $A^{-1/3}$ for $|r| > A/\beta$, uniformly in M, N . Let the compact cutoff A increase after taking the limit. The omission of frequency zero costs only β in the rescaled sum and disappears. Finally take the $3/4$ power. $\square$

This is the usual scaling analysis of a Dirichlet kernel, written here to identify the limiting optimal constant. The gain in the source lemma comes from retaining a parameter it had intentionally discarded.

III.33 Progression counting by telescoping

Source 13, delivered Section 9.

The 2^k factor in Corollary 3.3 comes from expanding every indicator into its mean and balanced part. A telescoping expansion needs only $k - 2$ errors, because the first two affine forms are exactly independent. We also record the precise group hypothesis needed by the argument.

Lemma III.33.1 (Endpoint generalized von Neumann inequality). *Let $k \geq 2$, and let G be a finite abelian group on which multiplication by each integer $1, \dots, k - 1$ is an automorphism. If $|f_i| \leq 1$, then*

$$\left| \mathbb{E}_{x,r \in G} \prod_{i=1}^k f_i(x + (i-1)r) \right| \leq \|f_k\|_{U^{k-1}}. \quad (\text{III.33.1})$$

The convention at $k = 2$ is $\|f\|_{U^1} = |\mathbb{E}f|$.

Proof. For $k = 2$, the map $(x, r) \mapsto (x, x + r)$ is bijective, and the average factors. Suppose the result holds at $k - 1$. Apply Cauchy–Schwarz in x and use $|f_1| \leq 1$. Expand the remaining square, write the two step variables as r and $r + u$, and replace $x + r$ by a new basepoint. With $\Delta_h f(y) = f(y)f(y + h)$, this gives

$$|\Lambda_k(f_1, \dots, f_k)|^2 \leq \mathbb{E}_u \left| \Lambda_{k-1}(\Delta_u f_2, \Delta_{2u} f_3, \dots, \Delta_{(k-1)u} f_k) \right|.$$

The induction hypothesis bounds the right side by $\mathbb{E}_u \left\| \Delta_{(k-1)u} f_k \right\|_{U^{k-2}}$. The power-mean inequality and bijectivity of multiplication by $k - 1$ bound this by

$$\left(\mathbb{E}_h \left\| \Delta_h f_k \right\|_{U^{k-2}}^{2^{k-2}} \right)^{1/2^{k-2}} = \|f_k\|_{U^{k-1}}^2.$$

The final equality is the defining derivative identity for Gowers norms. Take square roots. This is the normalized induction underlying Gowers’ Theorem 3.2 [1]. $\square$

The hypothesis holds on $\mathbb{F}_p^n$ whenever $p \geq k$, and on $\mathbb{Z}/N\mathbb{Z}$ whenever $\gcd(N, (k - 1)!) = 1$. Thus primality is a sufficient condition, not the underlying requirement. The condition cannot simply be dropped: on $\mathbb{Z}/3\mathbb{Z}$, take $k = 4$, $f_1 = f_4 = (1, 1, -1)$, and $f_2 = f_3 = 1$. The progression average is 1, since $x + 3r = x$ and $f_1(x)f_4(x) = 1$, whereas $\|f_4\|_{U^3}^8 = 49/81 < 1$. This gives an explicit failure of (III.33.1) without coefficient invertibility.

Theorem III.33.2 (A density-weighted telescoping bound). *Under the group hypothesis of lemma III.33.1, let $g_i : G \rightarrow [0, 1]$, $\delta_i = \mathbb{E}g_i$, and $f_i = g_i - \delta_i$. For $k \geq 3$,*

$$\left| \Lambda_k(g_1, \dots, g_k) - \prod_{i=1}^k \delta_i \right| \leq \sum_{j=3}^k \|f_j\|_{U^{j-1}} \prod_{i=j+1}^k \delta_i. \quad (\text{III.33.2})$$

In particular, if all the displayed norms are at most η , the error is at most $(k - 2)\eta$.

Proof. Replace g_k by $\delta_k + f_k$, then g_{k-1} by $\delta_{k-1} + f_{k-1}$ in the term containing δ_k , and continue. This is the exact identity

$$\Lambda_k(g_1, \dots, g_k) = \left(\prod_{i=3}^k \delta_i \right) \Lambda_2(g_1, g_2) + \sum_{j=3}^k \left(\prod_{i=j+1}^k \delta_i \right) \Lambda_j(g_1, \dots, g_{j-1}, f_j).$$

The first term equals $\prod_i \delta_i$ by two-form independence. Each balanced function is bounded by 1 in absolute value, so lemma III.33.1 bounds the j th error by $\|f_j\|_{U^{j-1}}$. Since each density is at most 1, there are at most $k - 2$ such errors. $\square$

The uniformity assumptions in the repository’s Corollary 3.3 say exactly that $\|f_j\|_{U^{j-1}} \leq \alpha$ for $j \geq 3$. Therefore (III.33.2) replaces its factor 2^k by

$$\sum_{j=3}^k \prod_{i=j+1}^k \delta_i \leq k - 2.$$

For unnormalized counts, multiply by $|G|^2$. [6 October 2026; sources 11–14] *Credit:* the generalized von Neumann bound and this telescope are source 03’s Lemma III.1.1 and Theorem III.1.2 and source 04’s Lemma III.4.2 and Theorem III.4.3, and also source 06’s Theorem III.5.2 and source 10’s

Theorem III.29.1; the corollary below is source 03's criterion (Corollary III.1.3; this S_k is its S_{k-2}). Sources 06 (quadratic in the norm) and 10 (error $\delta S_k \eta$) are stronger. Reversing the order gives a second valid bound with terms $\|f_j\|_{U^{k-j}} \prod_{i < j} \delta_i$, $1 \leq j \leq k-2$, but those norms require their own hypotheses; they are not supplied automatically by the forward assumptions.

Corollary III.33.3 (An explicit modular existence criterion). *Under the group hypothesis of lemma III.33.1, let $k \geq 3$, let $A \subset G$ have density $\delta > 0$, let $\eta = \|\mathbf{1}_A - \delta\|_{U^{k-1}}$, and set*

$$S_k(\delta) = \sum_{j=0}^{k-3} \delta^j.$$

If

$$\delta^k - \eta S_k(\delta) > \frac{\delta}{|G|}, \quad (\text{III.33.3})$$

then A contains a k -term progression with nonzero difference. Under the group hypothesis, its terms are distinct. A convenient sufficient pair of conditions is

$$\eta \leq \frac{\delta^k}{2S_k(\delta)}, \quad |G| > 2\delta^{1-k}.$$

Proof. Monotonicity of Gowers norms gives $\|\mathbf{1}_A - \delta\|_{U^{j-1}} \leq \eta$ for $3 \leq j \leq k$. Apply theorem III.33.2. Exactly $|A|$ pairs (x, r) have $r = 0$ and every term in A ; their normalized contribution is $\delta/|G|$. Inequality (III.33.3) leaves a nonzero-step pair. If two of its terms coincided, multiplication by an integer from 1 to $k-1$ would kill the nonzero difference, contradicting the automorphism hypothesis. $\square$

This is explicitly a modular/group conclusion. It does not, by itself, rectify a progression into the integer interval $[N]$. The source development has separate transfer modules for that purpose, and a global integer theorem must retain those steps.

III.34 The exact secondary term in the three-cube extremal problem

Source 14, delivered Section 2.

All averages are normalized. For a finite abelian group G and a real function $W : G \rightarrow \mathbb{R}$, put

$$Q_3(W) = \mathbb{E}_{x, h_1, h_2, h_3 \in G} \prod_{v \in \{0,1\}^3} W(x + v \cdot h) = \|W\|_{U^3}^8.$$

Throughout, $|G|$ is coprime to 6. The earlier leading-term result and its two-harmonic example left a gap: after subtracting $6\sqrt{2}\delta^4 u^4$, the coefficient at $\delta^{8/3} u^{16/3}$ was bounded below by $(9/4)^{1/3}$ and above by 6. We determine it exactly.

Theorem III.34.1 (Exact secondary coefficient, uniformly in the group). *Put $C_* = (9/4)^{1/3}$. There are absolute constants $c, C > 0$ such that, whenever $\delta > 0$, $f : G \rightarrow \mathbb{R}$ has mean zero, and $u = \|f\|_{U^3} \leq c\delta$,*

$$Q_3(\delta + f) \leq \delta^8 + 6\sqrt{2}\delta^4 u^4 + C_* \delta^{8/3} u^{16/3} + C \delta^{7/3} u^{17/3}. \quad (\text{III.34.1})$$

No pointwise bound on f is needed.

For $0 < \delta < 1$, define

$$M_\delta(u) = \sup_{\substack{G \text{ finite abelian, } (|G|,6)=1 \\ W:G \rightarrow [0,1], \mathbb{E}W=\delta \\ \|W-\delta\|_{U^3} \leq u}} Q_3(W).$$

Then, as $u \downarrow 0$,

$$M_\delta(u) = \delta^8 + 6\sqrt{2}\delta^4 u^4 + C_* \delta^{8/3} u^{16/3} + O_\delta(u^{17/3}). \quad (\text{III.34.2})$$

The upper constants are independent of G , even for varying groups.

This is a theorem about the local extremal cube problem. It does not by itself improve the final quantitative bound in Szemerédi’s theorem.

[write] **6 October 2026; sources 11–14.** *Source 04’s Question 1 is settled.* See Remark W4 at the end of this section for the deduction in source 04’s normalization. The “earlier project note” with the gap $[(9/4)^{1/3}, 6]$ is source 04 (Theorem III.3.8, Proposition III.3.9); its leading term $6\sqrt{2}$ and the norm gap (III.34.8) are source 04’s Theorems III.3.6 and III.3.4, reproved below; the centered expansion (III.34.7) is in sources 03, 04, 08, 09 and 13 (Appendix A, Section III.38, is its certificate here).

III.34.1 Fourier preliminaries and the previous leading estimate

Write the dual group additively, and put

$$a_r = \widehat{f}(r) = \mathbb{E}_x f(x) \overline{r(x)}, \quad a_{-r} = \overline{a_r}, \quad a_0 = 0.$$

We use the exact identities

$$\|f\|_{U^2}^4 = \sum_r |a_r|^4 =: S, \quad (\text{III.34.3})$$

$$\|f\|_{U^3}^8 = \sum_{s,t} |T(s,t)|^2, \quad T(s,t) = \sum_r a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}, \quad (\text{III.34.4})$$

$$B_5(f) := \mathbb{E}_{x,h_1,h_2,h_3} f(x) f(x+h_1) f(x+h_2) f(x+h_3) f(x+h_1+h_2+h_3) \quad (\text{III.34.5})$$

$$= \sum_r a_{2r} a_{-r}^3 a_r. \quad (\text{III.34.6})$$

The sum in (III.34.4) is unnormalized. On inserting Fourier inversion in the cube, the four orthogonality equations say that the parity-adjusted frequency labels form an affine three-cube; grouping its two parallel faces gives the identity.

The centered expansion is

$$Q_3(\delta + f) = \delta^8 + 12\delta^4 S + 8\delta^3 B_5(f) + R_6 + R_7 + u^8, \quad |R_6| \leq 28\delta^2 u^6, \quad |R_7| \leq 8\delta u^7. \quad (\text{III.34.7})$$

Indeed, one, two, or three distinct cube forms are jointly uniform, so their centered terms vanish. The twelve four-element parallelograms contribute S each; all other four-element supports are independent. The eight surviving five-element supports are cube-symmetric copies of $\{000, 100, 010, 001, 111\}$ and give $B_5(f)$. Bound the 28 sextic and 8 septic supports by cube Cauchy–Schwarz. Odd order suffices: the nonzero minors in these support arguments are ± 1 or ± 2 .

Let $\lambda_r = |a_r|^2$ and $M = \sum_r |a_r|^8$. The coordinate axes in (III.34.4) contribute

$$2\mathcal{E}(\lambda) - S^2, \quad \mathcal{E}(\lambda) = \sum_{r+s=t+w} \lambda_r \lambda_s \lambda_t \lambda_w.$$

Retaining the union of

$$(r = t, s = w), \quad (r = w, s = t), \quad (s = -r, w = -t)$$

in this positive energy sum gives $3S^2 - 3M$. Each family weighs S^2 , each pairwise intersection weighs M , and the triple intersection has $2r = 0$ and zero weight. Consequently,

$$\|f\|_{U^3}^8 \geq 5S^2 - 6M \geq 2S^2. \quad (\text{III.34.8})$$

The final inequality uses conjugate pairing, which gives $M \leq S^2/2$. Equality for nonzero f forces exactly one conjugate pair.

Choose a largest pair $\{\xi, -\xi\}$, and write

$$\rho = |a_\xi|, \quad D = \sum_{r \notin \{\xi, -\xi\}} |a_r|^4, \quad b = |a_{2\xi}|, \quad S = 2\rho^4 + D. \quad (\text{III.34.9})$$

There is no order-three character, so the pairs $\{\pm\xi\}$ and $\{\pm 2\xi\}$ are disjoint, and $2b^4 \leq D$. The axes estimate yields

$$\text{axes contribution} \geq 8\rho^8 + 20\rho^4 D + 2D^2 = 2S^2 + 12\rho^4 D, \quad (\text{III.34.10})$$

because the tail eighth-power mass is at most $D^2/2$. Maximality of ρ also gives

$$\|f\|_{U^3}^8 \geq (2 + 3D/S)S^2, \quad (\text{III.34.11})$$

by using $M \leq \rho^4 S = (S - D)S/2$ in (III.34.8).

III.34.2 Eight additional Fourier slots

Lemma III.34.2 (The off-axis correction). *With the notation above,*

$$\|f\|_{U^3}^8 \geq 2S^2 + 12\rho^4 D + 8\rho^4 b^4 - 16\rho^3 D^{5/4} - 16\rho^2 D^{3/2}. \quad (\text{III.34.12})$$

Proof. Besides the axes, retain the eight slots

$$(s, t) \in \{(\pm\xi, \pm 3\xi), (\pm 3\xi, \pm\xi)\}.$$

They are distinct and off the axes: $3\xi \neq 0$ and $\xi \neq \pm 3\xi$. Their T -values have the same modulus, by $T(s, t) = T(t, s)$ and $T(-s, t) = \overline{T(s, t)}$.

Let $a'_r = a_r$ off $\{\xi, -\xi\}$ and $a'_r = 0$ on that pair. There is an exact decomposition

$$T(\xi, 3\xi) = \rho^2 b^2 + 2 \operatorname{Re}(a_\xi \overline{a_{2\xi}} \overline{a_{4\xi}} a_{5\xi}) + T_{a'}(\xi, 3\xi). \quad (\text{III.34.13})$$

The base $r = -2\xi$ gives labels $(-2\xi, -\xi, \xi, 2\xi)$ and contributes $\rho^2 b^2$. The only other nonzero summands involving a dominant label have bases $r = \xi$ and $r = -5\xi$; they are conjugates. The other possible bases force a zero label.

To check small torsion explicitly, the four offsets are 0, 1, 3, 4. Two dominant labels differ by $\pm 2\xi$. Offset difference 2 gives the displayed main term. The only extra coincidence in an order coprime to 6 is order 5, where offset difference 3 equals -2 ; both extra summands contain a_0 . For order 5 the middle term in (III.34.13) vanishes as well, since $5\xi = 0$. For all other allowed orders, its three other labels are in the tail.

Each tail coefficient is at most $(D/2)^{1/4}$. Hölder gives $|T_{a'}(\xi, 3\xi)| \leq D$. Thus

$$|T(\xi, 3\xi) - \rho^2 b^2| \leq 2\rho(D/2)^{3/4} + D.$$

Using $|A + E|^2 \geq A^2 - 2A|E|$ for $A \geq 0$,

$$\begin{aligned} 8|T(\xi, 3\xi)|^2 &\geq 8\rho^4 b^4 - 32\rho^3 b^2 (D/2)^{3/4} - 16\rho^2 b^2 D \\ &\geq 8\rho^4 b^4 - 16\rho^3 D^{5/4} - 16\rho^2 D^{3/2}. \end{aligned}$$

The last line uses $b^2 \leq (D/2)^{1/2}$ and rounds constants upward. Add this to (III.34.10). $\square$

If the tail consists of the doubled pair alone, $D = 2b^4$. The axes penalty above $2S^2$ is then $24\rho^4 b^4$; the eight additional terms raise it to $32\rho^4 b^4$, the exact leading penalty in the two-harmonic model.

III.34.3 Uniform localization and optimization

Proof of the upper estimate. The zero case is immediate. Scale to $g = f/u$, $\|g\|_{U^3} = 1$, and $t = u/\delta$, so that $Q_3(\delta + f) = \delta^8 Q_3(1 + tg)$. In this proof the Fourier variables refer to g . Put

$$S_0 = 1/\sqrt{2}, \quad \eta = S_0 - S \geq 0, \quad F = Q_3(1 + tg) - 1 - 6\sqrt{2}t^4.$$

For $0 < t \leq 1$, the centered expansion gives

$$F = -12\eta t^4 + 8t^5 B_5(g) + R, \quad |R| \leq 37t^6. \quad (\text{III.34.14})$$

If $F \leq 0$, the desired upper bound is immediate. Assume $F > 0$.

First $|B_5(g)| \leq \rho S < 1$. Hence $\eta = O(t)$ uniformly, and $S \geq S_0/2$ for sufficiently small absolute t . By (III.34.11),

$$3DS \leq 1 - 2S^2 = 2\eta(S_0 + S) \leq 2\sqrt{2}\eta, \quad D \leq (8/3)\eta.$$

The selected pair in B_5 contributes at most $2\rho^4(D/2)^{1/4}$, while the other terms contribute at most ρD . Since $2\rho^4 \leq S \leq S_0 < 1$, $D < 1$, and $\rho < 1$, each of these two contributions is at most $D^{1/4}$. Thus $|B_5(g)| \leq 2D^{1/4}$. Therefore

$$12\eta \leq 16tD^{1/4} + 37t^2 \leq 16(8/3)^{1/4}t\eta^{1/4} + 37t^2.$$

If $\eta \leq (37/6)t^2$ the desired stronger localization follows already. Otherwise subtract $37t^2 \leq 6\eta$ and divide by $\eta^{1/4}$. Both cases give, for example,

$$\eta \leq 7t^{4/3}, \quad D \leq 19t^{4/3}, \quad (\text{III.34.15})$$

for all sufficiently small absolute t .

Substitute $\rho^4 = (S_0 - \eta - D)/2$ into Lemma III.34.2, and use $2b^4 \leq D$:

$$\begin{aligned} 2\sqrt{2}\eta &\geq 3\sqrt{2}D + 2\sqrt{2}b^4 - (6D + 4b^4)(\eta + D) \\ &\quad - 16\rho^3 D^{5/4} - 16\rho^2 D^{3/2}. \end{aligned}$$

Here the nonnegative term $2\eta^2$ was discarded. By (III.34.15), all errors are uniformly $O(t^{5/3})$, so

$$\eta \geq \frac{3}{2}D + b^4 - O(t^{5/3}). \quad (\text{III.34.16})$$

If $a_\xi = \rho e^{i\theta}$, the selected quintic term is exactly $2\rho^4 \operatorname{Re}(a_{2\xi} e^{-2i\theta})$. Thus

$$B_5(g) \leq 2\rho^4 b + \rho D \leq S_0 b + D.$$

Consequently,

$$\begin{aligned} F &\leq -18Dt^4 - 12b^4t^4 + 4\sqrt{2}bt^5 + O(t^{17/3}) \\ &\leq -48b^4t^4 + 4\sqrt{2}bt^5 + O(t^{17/3}). \end{aligned}$$

The error scales are $t^4t^{5/3} = t^{17/3}$, $t^5D = O(t^{19/3})$, and $t^6 = O(t^{17/3})$. Finally,

$$\sup_{b \geq 0} (4\sqrt{2}tb - 48b^4) = C_* t^{4/3}, \quad b = \beta_* t^{1/3}, \quad \beta_* = \left(\frac{\sqrt{2}}{48} \right)^{1/3}.$$

Indeed $b^3 = \sqrt{2}t/48$, and $3\sqrt{2}\beta_* = (9/4)^{1/3}$. Rescaling proves (III.34.1), including uniformity in G . $\square$

III.34.4 The matching model and the supremum

On a character of order greater than 8, take $a_{\pm\xi} = \rho$, $a_{\pm 2\xi} = b$, all positive, and no others. There is no aliasing in frequency parallelograms, whose two-label sums lie in $[-4, 4]$. Here is an explicit enumeration certificate. In the Fourier cube identity, every frequency belongs to $\{-2, -1, 0, 1, 2\}$; the absence of aliasing means that all the face parallelograms close over the integers. Hence the frequency labels are integer affine cubes in this five-point interval.

Reflect each direction with negative increment. This makes all three increments nonnegative without changing the numbers of vertices of each absolute frequency. Their sum is at most 4. The possible multisets of positive increments are

$$\emptyset, (1), (2), (3), (4), (1,1), (1,2), (1,3), (2,2), (1,1,1), (1,1,2).$$

For a multiset of k positive increments with sum H and multiplicities $m_1, m_2, \dots$, choose the coordinate positions and the original signs in

$$\frac{3!}{(3-k)! \prod_j m_j!} 2^k$$

ways. The minimum vertex ranges over the integers $-2, \dots, 2-H$. This gives the following complete table, where n_j counts the vertices of absolute frequency j :

(n_0, n_1, n_2)	number of frequency cubes
(8, 0, 0)	1
(4, 4, 0)	24
(4, 0, 4)	24
(3, 4, 1)	16
(2, 4, 2)	96
(0, 8, 0)	8
(0, 4, 4)	48
(0, 0, 8)	8

Each row contributes its count times $\delta^{n_0} \rho^{n_1} b^{n_2}$. Consequently,

$$\|f\|_{U^3}^8 = 8\rho^8 + 48\rho^4 b^4 + 8b^8, \quad (\text{III.34.17})$$

$$Q_3(\delta + f) = \delta^8 + 24\delta^4(\rho^4 + b^4) + 16\delta^3\rho^4 b + 96\delta^2\rho^4 b^2 + \|f\|_{U^3}^8. \quad (\text{III.34.18})$$

These are the earlier cosine identities with amplitudes $2\rho, 2b$. Choose

$$b = \beta_* \delta^{-1/3} u^{4/3}, \quad \rho^4 = -3b^4 + \sqrt{u^8/8 + 8b^8}.$$

Then $\|f\|_{U^3} = u$ exactly and $\rho^4 = u^4/(2\sqrt{2}) - 3b^4 + O(b^8/u^4)$. Substitution gives

$$Q_3(\delta + f) = \delta^8 + 6\sqrt{2}\delta^4 u^4 + C_* \delta^{8/3} u^{16/3} + O_\delta(u^{20/3}).$$

For fixed $0 < \delta < 1$ these are $[0, 1]$ weights for small u . A fixed prime cyclic group of order 17 supplies them. This proves the matching lower bound in (III.34.2). For norms smaller than the stated budget u , apply the upper estimate at the actual norm and use monotonicity of its positive displayed powers.

III.34.5 Rigidity at the secondary scale

Theorem III.34.3 (Two-harmonic rigidity). *Fix $\delta > 0$. Let G_j have order coprime to 6 and let f_j be real and centered, with $u_j = \|f_j\|_{U^3} \downarrow 0$. Suppose*

$$Q_3(\delta + f_j) = \delta^8 + 6\sqrt{2}\delta^4 u_j^4 + C_* \delta^{8/3} u_j^{16/3} + o_\delta(u_j^{16/3}).$$

Then largest pairs $\{\pm \xi_j\}$, with $a_{j,\xi_j} = \rho_j e^{i\theta_j}$, satisfy

$$|a_{j,2\xi_j}| \sim \beta_* \delta^{-1/3} u_j^{4/3}, \quad (\text{III.34.19})$$

$$\frac{a_{j,2\xi_j}}{|a_{j,2\xi_j}|} e^{-2i\theta_j} \rightarrow 1, \quad (\text{III.34.20})$$

$$\sum_{r \notin \{\pm \xi_j, \pm 2\xi_j\}} |a_{j,r}|^4 = o_\delta(u_j^{16/3}), \quad (\text{III.34.21})$$

$$\rho_j^4 = \frac{u_j^4}{2\sqrt{2}} - 3\beta_*^4 \delta^{-4/3} u_j^{16/3} + o_\delta(u_j^{16/3}). \quad (\text{III.34.22})$$

After removing the two conjugate pairs, the remainder is $o_\delta(u_j^{4/3})$ in U^2 . No L^2 approximation is asserted.

Proof. Use the normalized variables above. Put $\beta = b/t^{1/3}$ and $e = (D - 2b^4)/t^{4/3} \geq 0$. Retaining both the phase and the unused tail in the upper proof gives

$$\frac{F}{t^{16/3}} \leq 4\sqrt{2}\beta \cos \phi - 48\beta^4 - 18e + o(1), \quad \phi = \arg a_{2\xi} - 2 \arg a_\xi.$$

Here replacing $2\rho^4 b \cos \phi$ by $S_0 b \cos \phi$ is an approximation with absolute error at most $(\eta + D)b$, because $2\rho^4 = S_0 - \eta - D$. We use this error estimate, rather than a one-sided inequality whose direction could depend on $\cos \phi$. After the t^5 factor and division by $t^{16/3}$, its contribution is $O(t^{4/3}) = o(1)$ by localization. Localization bounds β, e . The polynomial $4\sqrt{2}\beta - 48\beta^4$ has unique

maximum C_* at $\beta_* > 0$. Asymptotic equality forces $\beta \rightarrow \beta_*$, $e \rightarrow 0$, and $\cos \phi \rightarrow 1$. The exact centered expansion then gives

$$\eta/t^{4/3} \rightarrow (4\sqrt{2}\beta_* - C_*)/12 = 4\beta_*^4, \quad D/t^{4/3} \rightarrow 2\beta_*^4.$$

Use $\rho^4 = (S_0 - \eta - D)/2$ and rescale. The Fourier formula for U^2 gives the claimed remainder norm. $\square$

III.34.6 Indicator sharpness

Proposition III.34.4. *For every $0 < \delta < 1$, there are prime cyclic groups and subsets A_j with densities $\delta_j \rightarrow \delta$ and $v_j = \|1_{A_j} - \delta_j\|_{U^3} \downarrow 0$, such that*

$$\frac{Q_3(1_{A_j}) - \delta_j^8 - 6\sqrt{2}\delta_j^4 v_j^4}{\delta_j^{8/3} v_j^{16/3}} \rightarrow C_*.$$

Proof. Take the two-harmonic weights at $u_j = 2^{-j}u_0$, for a sufficiently small fixed $u_0 > 0$, on sufficiently large primes p_j . Their exact formulas do not depend on the prime once it exceeds 8. Include points independently with the prescribed weights. At most $28/p_j$ of normalized three-cubes have a repeated vertex. Elsewhere independence gives the weighted expectation exactly, for both the indicator cube polynomial and the product centered at the fixed mean δ . Expectation errors are therefore $O(1/p_j)$. Changing one inclusion decision changes either polynomial by at most $8/p_j$, so a bounded-difference variance estimate gives $O(1/p_j)$ variance. The density has variance at most $1/(4p_j)$. Therefore, for large enough p_j , some realization approximates all three statistics simultaneously to any prescribed error. Recentering at the actual density costs at most $8|\delta_j - \delta|$.

Take errors $o(u_j^{28/3})$. Then $v_j^8 = u_j^8 + o(u_j^{28/3})$, whence $v_j^4 = u_j^4 + o(u_j^{16/3})$. The model expansion transfers with its exact secondary coefficient, including the replacements of δ by δ_j . Since $v_j/u_j \rightarrow 1$ and $u_{j+1}/u_j = 1/2$, the actual norms v_j decrease strictly after discarding finitely many initial indices. $\square$

Remark III.34.5 (Why boundedness alone cannot give L^2 rigidity). The indicator examples also supply an explicit obstruction to replacing the U^2 remainder in Theorem III.34.3 by an L^2 remainder tending to zero. For those examples,

$$\|1_{A_j} - \delta_j\|_2^2 = \delta_j(1 - \delta_j) \rightarrow \delta(1 - \delta) > 0.$$

Let P_j be any Fourier projection onto at most four frequencies, including a projection onto two conjugate pairs. Each Fourier coefficient has modulus at most $v_j = \|1_{A_j} - \delta_j\|_{U^3}$, by (III.34.8). Thus Parseval gives $\|P_j\|_2^2 \leq 4v_j^2 \rightarrow 0$ and, by orthogonality,

$$\|1_{A_j} - \delta_j - P_j\|_2^2 \rightarrow \delta(1 - \delta).$$

Thus even exact asymptotic secondary extremality among bounded weights does not imply small L^2 distance from the two-harmonic projection.

Remark W4 (Source 04's Question 1; added at the third write, 6 October 2026). *Claim.* In source 04's normalization the limit in its display (Q1) exists and equals $C_* = (9/4)^{1/3}$: for $0 < \delta < 1$, with

$M_\delta^{04}(u)$ the supremum of $Q_3(W)$ over prime cyclic groups of order greater than 16 and weights $0 \leq W \leq 1$ with $\mathbb{E}W = \delta$ and $\|W - \delta\|_{U^3} = u$,

$$\lim_{u \downarrow 0} \frac{M_\delta^{04}(u) - \delta^8 - 6\sqrt{2}\delta^4 u^4}{\delta^{8/3} u^{16/3}} = (9/4)^{1/3}.$$

Proof. Every prime $p > 16$ is coprime to 6, and $\|W - \delta\|_{U^3} = u$ implies $W \leq u$, so $M_\delta^{04}(u) \leq M_\delta(u)$, the supremum of Theorem III.34.1; by (III.34.2) the limsup of the displayed quotient is at most C_* . Source 04's Proposition III.3.9 gives, on $\mathbb{Z}/p\mathbb{Z}$ with $p > 16$ and norm exactly u , the quotient $(9/4)^{1/3} + o(1)$, so the liminf is at least $(9/4)^{1/3} = C_*$. *The normalizations agree:* source 04's model $f = a \cos(2\pi x/p) + b \cos(4\pi x/p)$ has Fourier coefficients $a/2$ and $b/2$, so this source's ρ, b are source 04's $a/2, b/2$; substituting $\rho = a/2$, $b = b_{04}/2$ in (III.34.17)–(III.34.18) gives source 04's identity (III.3.24) term by term, and $\beta_* = (\sqrt{2}/48)^{1/3}$ is half of source 04's $c = (\sqrt{2}/6)^{1/3}$. (Checked at the write: the model identity against a direct cube sum on $\mathbb{Z}/17\mathbb{Z}$ at two parameter points, agreement to 10^{-15} ; the normalized quotient along the model at $\delta = 1/4$ is 1.3104628 at $u = 10^{-4}$ and 1.3103709 at $u = 10^{-6}$, against $C_* = 1.3103707$.) This is a new result of source 14, not a second route; it is unrefereed and not formalized. The constants c, C of the upper bound are not explicit (source 14's Question 3). The concentration question of source 04's Question 2 is answered in U^2 by Theorem III.34.3 and fails in L^2 by the remark above.

III.35 Order five changes the next exponent

Source 14, delivered Section 3.

Even after excluding order-three characters, short additive resonances still matter. In particular, order five produces a further distinction: on groups of exponent five, the correction of order $u^{16/3}$ vanishes, and the next exponent is 6. The optimal coefficient at u^6 is not determined here.

Lemma III.35.1 (An order-five energy penalty). *If the largest Fourier character ξ has order 5, then*

$$\|f\|_{U^3}^8 \geq 2S^2 + 16\rho^6 b^2. \quad (\text{III.35.1})$$

Proof. In addition to the three energy families retained in the norm-gap proof, retain the additive quadruple

$$(\xi, \xi, -\xi, -2\xi).$$

It is additive because $2\xi = -3\xi$. Interchanging the sides, interchanging the unequal entries on a side, and negating all entries produces eight distinct quadruples, all outside the previous three families. Each has weight $\rho^6 b^2$. Thus $\mathcal{E}(\lambda) \geq 3S^2 - 3M + 8\rho^6 b^2$. The axes bound and $M \leq S^2/2$ prove the claim. $\square$

Theorem III.35.2 (Sharp correction exponent in exponent five). *Let $\delta > 0$, and let G be a nontrivial finite abelian group of exponent 5. Uniformly over such groups and real centered functions,*

$$Q_3(\delta + f) \leq \delta^8 + 6\sqrt{2}\delta^4 u^4 + O(\delta^2 u^6) \quad (u/\delta \downarrow 0).$$

For $0 < \delta < 1$, the exponent 6 cannot be increased, even on the fixed group $\mathbb{Z}/5\mathbb{Z}$. This group has $[0, 1]$ weights of mean δ , with centered norm u , satisfying

$$Q_3(W_u) = \delta^8 + 6\sqrt{2}\delta^4 u^4 + \frac{2^{3/4}}{3} \delta^2 u^6 + O_\delta(u^8). \quad (\text{III.35.2})$$

The coefficient $2^{3/4}/3$ is a lower bound, not a claim of optimality.

Uniform upper estimate. Normalize by $g = f/u$, $t = u/\delta$, as in the preceding proof, and use F, η, D, ρ, b there. If $F \leq 0$ there is nothing to prove. Otherwise the first localization step gives $\eta = O(t)$ and $D = O(\eta)$. Thus $\rho^4 = (S_0 - \eta - D)/2$ is bounded below by a positive absolute constant. By Lemma III.35.1, $b^2 = O(\eta)$, since $1 - 2S^2 \leq 2\sqrt{2}\eta$. The quintic estimate becomes

$$|B_5(g)| \leq 2\rho^4 b + \rho D = O(\eta^{1/2} + \eta).$$

The centered cube expansion gives

$$\eta \leq C_1 t \eta^{1/2} + C_2 t \eta + C_3 t^2.$$

For small t , absorb the middle term. The resulting quadratic inequality in $\sqrt{\eta}$ gives $\eta = O(t^2)$. Consequently $B_5(g) = O(t)$, and $F = O(t^6)$ uniformly. Rescaling proves the assertion. $\square$

Exact model and positive order-six correction. On $\mathbb{Z}/5\mathbb{Z}$, choose the Fourier coefficients

$$a_1 = \rho e^{i\pi/10}, \quad a_2 = b e^{i\pi/5}, \quad a_{-1} = \overline{a_1}, \quad a_{-2} = \overline{a_2}.$$

The constant coefficient of $W = \delta + f$ is δ . Put $z = e^{i\pi/10}$, so $z^5 = i$. The six symmetry types of $T(s, t)$ are as follows; multiplicities total 25.

(s, t)	multiplicity	$T(s, t)$
$(0, 0)$	1	$\delta^4 + 2\rho^4 + 2b^4$
$(0, 1)$	4	$2\delta^2 \rho^2 + 2\rho^2 b^2 + b^4$
$(0, 2)$	4	$2\delta^2 b^2 + 2\rho^2 b^2 + \rho^4$
$(1, 1)$	4	$\delta^2 \rho^2 + 2\delta \rho^2 b$
$(2, 2)$	4	$\delta^2 b^2$
$(1, 2)$	8	$\rho^2 b^2 + 2\delta \rho^2 b$

Each entry follows by summing the five bases r in (III.34.4); terms with phase $z^5 = i$ cancel with conjugates. Squaring these entries and summing with their multiplicities proves

$$\|f\|_{U^3}^8 = 8\rho^8 + 16\rho^6 b^2 + 48\rho^4 b^4 + 16\rho^2 b^6 + 8b^8, \quad (\text{III.35.3})$$

$$\begin{aligned} Q_3(\delta + f) &= \delta^8 + 24\delta^4(\rho^4 + b^4) + 16\delta^3 \rho^4 b + 96\delta^2 \rho^4 b^2 + 48\delta^2 \rho^2 b^4 \\ &\quad + 32\delta \rho^4 b^3 + \|f\|_{U^3}^8. \end{aligned} \quad (\text{III.35.4})$$

Choose

$$b = \kappa \delta^{-1} u^2, \quad \kappa = 2^{5/4}/12,$$

and choose the unique positive ρ making (III.35.3) equal u^8 . Existence follows for small u from strict increase in ρ . The expansion is

$$\rho^4 = \frac{u^4}{2\sqrt{2}} - 2^{-3/4} u^2 b^2 + O_\delta(u^8).$$

The order-six coefficient in (III.35.4) is therefore

$$-24 \cdot 2^{-3/4} \kappa^2 + 4\sqrt{2} \kappa = \frac{2^{3/4}}{3}.$$

All other terms are $O_\delta(u^8)$. The real weights are in $[0, 1]$ for small u , since $\rho, b \rightarrow 0$. $\square$

[write] **6 October 2026; sources 21–27.** *The coefficient is now determined* by sources 21 and 23, independently: $2^{3/4}/3$ is optimal, uniformly over all nontrivial groups of exponent five, with an absolute $O(u^8)$ remainder for $u \leq c\delta$ (source 21’s Theorem F.26.1, source 23’s Theorem III.58.1; Section III.49). “The coefficient $2^{3/4}/3$ is a lower bound, not a claim of optimality” stands as this source’s statement. On $\mathbb{Z}/5\mathbb{Z}$ the next coefficient is $20/9$ (source 21’s Theorem III.55.1); the universal eighth-order coefficient is open (item III.27).

The same upper argument applies whenever a largest character has order 5, even if the ambient group, still of order coprime to 6, has characters of other orders. Hence an asymptotically optimal family for the coefficient C_* cannot eventually use an order-five largest pair: its rigidity conclusion has $b \asymp t^{1/3}$ and $\eta \asymp t^{4/3}$, while the order-five penalty would force $\eta \gg b^2 \asymp t^{2/3}$.

III.35.1 The fixed-group classification

For a fixed nontrivial G of order coprime to 6, let $M_{\delta,G}(u)$ denote the weighted supremum with that group held fixed. If the exponent of G is not 5, its dual has a character of order at least 7. For order greater than 8, the positive two-harmonic model in (III.34.17)–(III.34.18) applies without change.

Here is a complete uncentered certificate for order 7, which is the only additional small case needed. Take $a_{\pm 1} = \rho$, $a_{\pm 2} = b$, and $a_0 = \delta$ in $\mathbb{Z}/7\mathbb{Z}$. Under sign changes and interchange of s, t , the following ten types exhaust all 49 slots:

(s, t)	multiplicity	$T(s, t)$
$(0, 0)$	1	$\delta^4 + 2\rho^4 + 2b^4$
$(0, 1)$	4	$2\delta^2\rho^2 + 2\rho^2b^2$
$(0, 2)$	4	$2\delta^2b^2 + \rho^4$
$(0, 3)$	4	$b^4 + 2\rho^2b^2$
$(1, 1)$	4	$\delta^2\rho^2 + 2\delta\rho^2b$
$(1, 2)$	8	$2\delta\rho^2b$
$(1, 3)$	8	ρ^2b^2
$(2, 2)$	4	δ^2b^2
$(2, 3)$	8	0
$(3, 3)$	4	$2\rho b^3$

Squaring and summing gives

$$\begin{aligned} \|f\|_{U^3}^8 &= 8\rho^8 + 48\rho^4b^4 + 32\rho^2b^6 + 8b^8, \\ Q_3(\delta + f) &= \delta^8 + 24\delta^4(\rho^4 + b^4) + 16\delta^3\rho^4b + 96\delta^2\rho^4b^2 + \|f\|_{U^3}^8. \end{aligned}$$

Thus order seven adds only $32\rho^2b^6$ to the centered norm formula and to the final norm term of the cube count.

At $b = \beta_*\delta^{-1/3}u^{4/3}$, choose ρ so that the actual norm equals u . The extra term is $O_\delta(u^{10})$ in the eighth power and changes ρ^4 by $O_\delta(u^6)$. It therefore changes the cube count only by $O_\delta(u^6)$, which is smaller than the secondary scale $u^{16/3}$. All these models lift along a character to the original fixed group, preserving normalized averages.

Consequently, if the exponent of G is not 5,

$$M_{\delta,G}(u) = \delta^8 + 6\sqrt{2}\delta^4u^4 + C_*\delta^{8/3}u^{16/3} + O_\delta(u^{17/3}).$$

If G has exponent 5, the first correction has sharp exponent 6, and its coefficient remains to be determined. The trivial group is excluded because its only centered function is zero.

[write] **6 October 2026; sources 21–27.** The coefficient is now determined: it is $2^{3/4}/3$, uniformly (sources 21 and 23; note after Theorem III.35.2).

III.36 Exact supersaturation and rigidity for polynomial colorings

Source 14, delivered Section 6.

The dimension obstruction for low-degree polynomial colorings has a stronger counting form. Once the dimension exceeds the obstruction budget, the least possible number of symmetrically colored progressions can be determined exactly, at each prescribed center and in total. Equality also has a geometric consequence: the permitted directions at each center form a linear subspace. The classical ingredients are Warning’s second theorem and the minimum-support theorem for polynomial functions on a finite field. We prove the ingredients needed here; their application gives an exact extremal answer in the specified polynomial-coordinate model. Neither the polynomial minimum-support theorem nor the norm construction is claimed as new.

This is a related finite-field problem, rather than a direct replacement for Gowers’s Corollary 8.3. That corollary concerns monochromatic four-term progressions in colorings of an interval. A symmetrically colored four-term progression may have two different colors, in the order a, b, b, a . The repository’s `HasMonochromaticAP` and `corollary_8_3` definitions encode the former condition; the finite-field symmetry condition below needs a separate definition.

III.36.1 The extremal question and its exact answer

Let $\mathbb{F}_q$ have characteristic p , and assume

$$k = 2m \geq 4, \quad p > k, \quad r \geq 1, \quad 1 \leq D_\ell \leq k \quad (1 \leq \ell \leq r).$$

The restriction concerns the characteristic, not just the cardinality q of the field. Put

$$s_\ell = \lceil D_\ell/2 \rceil, \quad B = \sum_{\ell=1}^r s_\ell^2.$$

Consider polynomial maps $Q = (Q_1, \dots, Q_r) : \mathbb{F}_q^d \rightarrow \mathbb{F}_q^r$ with $\deg Q_\ell \leq D_\ell$. At a center z , define

$$S_z(Q) = \left\{ h \in \mathbb{F}_q^d : Q(z + (i - \tfrac{1}{2})h) = Q(z - (i - \tfrac{1}{2})h) \text{ for } 1 \leq i \leq m \right\}. \quad (\text{III.36.1})$$

The zero direction is included. For $h \neq 0$, the resulting k points are distinct because $p > k$. Let

$$A_k^{\text{sym}}(Q) = \#\{(a, h) \in \mathbb{F}_q^d \times (\mathbb{F}_q^d \setminus \{0\}) : Q(a + ih) = Q(a + (k - 1 - i)h) \ (0 \leq i < m)\}.$$

This is a count of ordered pairs (a, h) ; no quotient by changes of orientation or by different parametrizations is implicit.

Theorem III.36.1 (Exact polynomial-coloring supersaturation). *For every admissible Q and every center z ,*

$$|S_z(Q)| \geq q^{\max\{d-B, 0\}}. \quad (\text{III.36.2})$$

There is one admissible Q attaining equality simultaneously at every center. Consequently

$$\min_Q A_k^{\text{sym}}(Q) = q^d (q^{\max\{d-B, 0\}} - 1). \quad (\text{III.36.3})$$

If $d \geq B$ and equality holds in (III.36.2) at a particular z , then $S_z(Q)$ is an $\mathbb{F}_q$ -linear subspace of dimension $d - B$. Equality in (III.36.3) therefore implies this subspace conclusion at every center.

[write] **6 October 2026; sources 21–27.** Source 22 extends the pointwise statement to every equality pattern and every degree at a prescribed centre (its Theorem III.61.5 and Corollary III.62.2, which recovers the low-degree case here), and shows that the quintic and sextic pointwise budget for symmetric four-term progressions is exactly eight (Section III.62).

The previous existence threshold $d \leq B$ is recovered by asking when the right side of (III.36.3) is zero. Above the threshold, the conclusion strengthens the first Chevalley–Warning argument, which supplies only $p - 1$ nonzero directions over a prime field. In dimension $d = B + e$, the exact unavoidable number is $q^e - 1$ at every center.

[write] **6 October 2026; sources 11–14.** *Credit.* The threshold case (the minimum is 0 exactly when $d \leq B$) is source 10’s Theorem III.30.3, the “separate project report” of Section F.19; it is reproved here. New: the exact counts above the threshold over every $\mathbb{F}_q$ with $p > k$, the subspace geometry of equality, and the prime-field gap. Source 10’s quintic question ($4 \leq d \leq 8$) is not answered (item III.19).

III.36.2 A self-contained minimum-support lemma

A polynomial in n variables is called reduced if its degree in each individual variable is at most $q - 1$. Replacing X_i^q by X_i repeatedly gives the unique reduced polynomial representing a given polynomial function on $\mathbb{F}_q^n$. Reduction cannot increase total degree. Uniqueness follows by induction from the fact that a nonzero one-variable polynomial of degree less than q cannot vanish at every element of $\mathbb{F}_q$.

Lemma III.36.2 (Minimum support). *Let F be a nonzero reduced polynomial on $\mathbb{F}_q^n$ with total degree at most $R < n(q - 1)$. Write $R = a(q - 1) + b$, with $0 \leq b < q - 1$. Then*

$$\#\{x : F(x) \neq 0\} \geq (q - b)q^{n-a-1}. \quad (\text{III.36.4})$$

In particular, for $0 \leq B \leq n$, degree at most $B(q - 1)$ and nonempty support imply support size at least q^{n-B} .

Proof. Successively take the leading coefficient in the last variable. More explicitly, if $F(X', X_n) = \sum_{j=0}^t F_j(X')X_n^j$ and $F_t \neq 0$, then above every point where F_t is nonzero, at least $q - t$ values of X_n make F nonzero. Induction on the number of variables therefore produces exponents $e_1, \dots, e_n$, each between 0 and $q - 1$, such that

$$\sum_i e_i \leq R, \quad \#\text{supp } F \geq \prod_i (q - e_i).$$

These exponents form a monomial of F , obtained by the successive leading-coefficient choices.

It remains to minimize the product under the displayed constraints. We may increase some e_i until their sum is R , since this only decreases the product. If $0 < e_i \leq e_j < q - 1$, transferring one unit from e_i to e_j changes the corresponding two factors from $(q - e_i)(q - e_j)$ to $(q - e_i + 1)(q - e_j - 1)$, decreasing their product. Repeating this operation leaves at most one exponent strictly between 0 and $q - 1$. The minimum is attained by a exponents equal to $q - 1$, one equal to b , and the others equal to zero. Its value is exactly $(q - b)q^{n-a-1}$. For $B = n$, the final assertion is simply that nonempty support has at least one point. $\square$

The next equality case is the $b = 0$ part of the classical minimum-weight Reed–Muller classification; see Leducq’s account [57]. A short slicing proof is included to make the geometric conclusion of Theorem III.36.1 independent of a coding-theory black box.

Lemma III.36.3 (Rigidity of minimum support). *If a nonzero reduced polynomial of degree at most $B(q-1)$ on $\mathbb{F}_q^n$ has exactly q^{n-B} nonzero values, where $0 \leq B \leq n$, its support is an affine subspace of dimension $n-B$.*

Proof. The cases $B=0$ and $B=n$ are immediate. Set $e = n - B \geq 1$ and write $S = \text{supp } F$. An invertible affine change of variables, followed by reduction, preserves the degree bound and the support size. Fix any family of q parallel affine hyperplanes and take them to be $X_1 = c$. Let t be the number of these hyperplanes missing S .

If $1 \leq t \leq q-2$, then

$$F(X) = \prod_{c: S \cap \{X_1=c\}=\emptyset} (X_1 - c) G(X)$$

as a polynomial. To see the factorization, the restriction to a missing hyperplane is a reduced polynomial that vanishes on the entire field grid, hence is the zero polynomial; the factor theorem applies to each distinct c . We have

$$\deg G \leq B(q-1) - t = (B-1)(q-1) + (q-1-t).$$

On each of the other $q-t$ hyperplanes, G has nonempty support and its nonzero values occur exactly where F is nonzero. Applying Lemma III.36.2 in $n-1$ variables gives at least $(t+1)q^{e-1}$ points on each such hyperplane. Consequently

$$|S| \geq (q-t)(t+1)q^{e-1} > q^e,$$

because $(q-t)(t+1) - q = t(q-t-1) > 0$. This is impossible. Thus every parallel family has either no missing member or exactly $q-1$ missing members.

In a family with no missing member, applying the minimum-support bound to every restriction shows that each hyperplane contains at least q^{e-1} points of S . The total is q^e , so every member contains exactly q^{e-1} points.

Some family must have a missing member. Otherwise every affine hyperplane would contain exactly q^{e-1} points of S . Choose $x \notin S$ and count pairs (H, y) with H a hyperplane through x and $y \in H \cap S$. There are $(q^n - 1)/(q - 1)$ hyperplanes through x , whereas each $y \neq x$ lies with x in $(q^{n-1} - 1)/(q - 1)$ hyperplanes. The two counts would give

$$q^{e-1}(q^n - 1) = q^e(q^{n-1} - 1),$$

which would imply $q^{e-1} = q^e$. Hence a family has exactly one member meeting S , and S is contained in a hyperplane.

Take that hyperplane to be $X_1 = 0$. Uniqueness of reduced representatives gives

$$F(X_1, X') = (1 - X_1^{q-1})G(X'), \quad G(X') = F(0, X').$$

Because $G \neq 0$, the degree of the right side is $q-1 + \deg G$, so $\deg G \leq (B-1)(q-1)$. Its support still has size q^e . Induction with $n-1$ variables and budget $B-1$ shows that this support is an affine e -dimensional subspace of the hyperplane. $\square$

Corollary III.36.4 (Warning's second theorem, with an equality case). *Suppose polynomials $F_1, \dots, F_t$ on $\mathbb{F}_q^n$ have a nonempty common zero set Z , and their total degree sum is at most $B \leq n$. Then $|Z| \geq q^{n-B}$. If equality holds, Z is an affine subspace of dimension $n-B$.*

Proof. The polynomial function

$$I(X) = \prod_{j=1}^t (1 - F_j(X)^{q-1})$$

is the indicator of Z . Its degree is at most $B(q-1)$, and it is nonzero since Z is nonempty. Reduce I and apply the two lemmas. $\square$

The numerical inequality is precisely the classical second theorem of Warning [40]. Its equality statement here is a consequence of the classical minimum-support classification.

III.36.3 Odd Taylor coefficients and the sharp construction

For fixed z , define the coefficient polynomials by

$$Q_\ell(z + TH) = \sum_{j=0}^{D_\ell} C_{\ell,j,z}(H) T^j.$$

Each nonzero $C_{\ell,j,z}$ is homogeneous of degree j in H . This definition uses polynomial expansion and requires no division by factorials.

Lemma III.36.5 (The reflection equations). *Under the hypotheses above,*

$$S_z(Q) = \{h : C_{\ell,2j-1,z}(h) = 0 \text{ for all } 1 \leq \ell \leq r, 1 \leq j \leq s_\ell\}.$$

Proof. Put $\alpha_i = i - \frac{1}{2}$. The α_i are nonzero and their squares are pairwise distinct: for $i \neq j$ both $i - j$ and $i + j - 1$ are nonzero in characteristic $p > k$. Subtracting the evaluations at $T = \alpha_i$ and $T = -\alpha_i$, then dividing by $2\alpha_i$, gives

$$\sum_{j=1}^{s_\ell} C_{\ell,2j-1,z}(h) (\alpha_i^2)^{j-1} = 0 \quad (1 \leq i \leq m).$$

Since $s_\ell \leq m$, the first s_ℓ equations have an invertible Vandermonde matrix. They are equivalent to vanishing of all the listed coefficients. The converse follows by substitution. $\square$

Proof of Theorem III.36.1. The coefficient polynomials vanish at $h = 0$ and have total degree sum at most

$$\sum_{\ell=1}^r \sum_{j=1}^{s_\ell} (2j-1) = \sum_{\ell=1}^r s_\ell^2 = B.$$

For $d \geq B$, Corollary III.36.4 therefore gives $|S_z(Q)| \geq q^{d-B}$. For $d < B$, the zero direction alone gives the asserted bound. If $d \geq B$ and equality holds, the same corollary says that $S_z(Q)$ is an affine subspace. It contains zero, so it is a linear subspace.

For sharpness, for each positive odd t let $N_t : \mathbb{F}_q^t \rightarrow \mathbb{F}_q$ be the norm from $\mathbb{F}_{q^t}$ to $\mathbb{F}_q$ in a fixed linear coordinate basis. It is a homogeneous polynomial of degree t , and $N_t(u) = 0$ if and only if $u = 0$. These facts follow, for example, by writing

$$N_t(u_1, \dots, u_t) = \prod_{a=0}^{t-1} \left(\sum_{i=1}^t u_i \beta_i^{q^a} \right),$$

where the β_i form a field basis. Frobenius permutes the factors, so the coefficients lie in $\mathbb{F}_q$.

Use disjoint blocks $u_\ell^{(2j-1)} \in \mathbb{F}_q^{2j-1}$, altogether B coordinates, and set

$$Q_\ell(u) = \sum_{j=1}^{s_\ell} N_{2j-1}(u_\ell^{(2j-1)}). \quad (\text{III.36.5})$$

This is the odd norm-layer construction used in the recent coloring literature [33]. Its degree is at most D_ℓ . Suppose a direction has a nonzero block in coordinate ℓ , and let t be its largest nonzero block index. In $Q_\ell(z + Th)$ the coefficient of T^t is exactly $N_t(h_\ell^{(t)}) \neq 0$: larger blocks have zero direction and contribute constants, whereas smaller blocks have degree less than t . Since t is odd, the reflection-coefficient lemma rules out this direction. Thus the map on $\mathbb{F}_q^B$ has $S_z = \{0\}$ at every center.

For $d \geq B$, use this map on the first B coordinates and ignore the remaining $d - B$ coordinates. Its symmetric-direction set is exactly the kernel of that projection, with size q^{d-B} at every center. For $d < B$, restrict the map along a linear injection $\mathbb{F}_q^d \hookrightarrow \mathbb{F}_q^B$; every nonzero direction remains nonzero, so $S_z = \{0\}$.

Finally, the change of variables $z = a + (k - 1)h/2$ is a bijection between start-direction pairs and center-direction pairs. Hence

$$A_k^{\text{sym}}(Q) = \sum_{z \in \mathbb{F}_q^d} (|S_z(Q)| - 1).$$

Summing the pointwise bound and using the construction proves the exact minimum. If the sum attains its lower bound, every nonnegative pointwise excess is zero, proving the final equality assertion. $\square$

There is also an adaptive version: if at a particular center some of the odd coefficient polynomials vanish identically, their degrees should be omitted. With

$$B_z = \sum_{\ell, j: C_{\ell, 2j-1, z} \neq 0} (2j - 1),$$

the same proof gives $|S_z(Q)| \geq q^{\max\{d-B_z, 0\}}$. In particular, equality at the universal bound in a dimension $d \geq B$ forces $B_z = B$.

III.36.4 A sharp gap in the first supercritical dimension

Over a prime field, homogeneity and the elementary Chevalley–Warning divisibility give considerably more than an increment of one above the minimum when $d = B + 1$.

Proposition III.36.6 (First-supercritical gap and stability). *Work over $\mathbb{F}_p$ with $p > k$ and $d = B + 1$. At every center,*

$$|S_z(Q)| = p \quad \text{or} \quad |S_z(Q)| \geq p^2. \quad (\text{III.36.6})$$

Both values p and p^2 occur for admissible maps, simultaneously at all centers in their respective examples.

Let E be the number of centers with $|S_z(Q)| > p$. Then

$$A_k^{\text{sym}}(Q) \geq p^d(p - 1) + (p^2 - p)E. \quad (\text{III.36.7})$$

In particular, if the left side is at most $p^d(p-1) + \varepsilon p^d(p^2-p)$, at least $(1-\varepsilon)p^d$ centers have exactly one projective direction of reflection symmetry: their $S_z(Q)$ is a one-dimensional linear subspace.

Proof. The defining coefficient equations are homogeneous, so their nonzero common zeros form scalar orbits of size $p-1$. Thus $|S_z(Q)| \equiv 1 \pmod{p-1}$. The degree sum is at most $B < d$, so $p \mid |S_z(Q)|$ by Chevalley–Warning. For completeness, this divisibility follows by summing the indicator polynomial from Corollary III.36.4: its total degree is less than $d(p-1)$, and every monomial has a coordinate exponent less than $p-1$. Its sum in that coordinate is zero in $\mathbb{F}_p$, including exponent zero, where the sum is $p=0$.

Writing $|S_z(Q)| = pt$, the two congruences yield $t \equiv 1 \pmod{p-1}$. Since $t \geq 1$, either $t = 1$ or $t \geq p$. This proves (III.36.6). The norm construction controlling B coordinates leaves one free coordinate and gives p directions. Restrict that avoiding norm map to a $(B-1)$ -dimensional subspace, then ignore two coordinates in the $d = B+1$ dimensional domain; this gives exactly p^2 directions. All degrees remain within the same upper bounds. Summing the local gap gives (III.36.7); the last assertion uses the equality geometry in Theorem III.36.1. $\square$

The prime-field restriction in this proposition is deliberate. Warning’s second theorem over $\mathbb{F}_q$ gives the exact minimum q^{d-B} , but the elementary divisibility proof just used supplies divisibility by the characteristic p . It does not by itself justify replacing every occurrence of p in the gap argument by a nonprime q .

III.36.5 Examples and boundaries

For scalar degree at most three or four and $k = 4$, the budget is $B = 4$. Consequently

$$\min_Q A_4^{\text{sym}}(Q) = \begin{cases} 0, & d \leq 4, \\ q^d(q^{d-4} - 1), & d \geq 4. \end{cases}$$

At $q = 5, d = 6$, this is $5^6(5^2 - 1) = 375\,000$ ordered nontrivial progressions. The example is $Q = x_0 + N_3(x_1, x_2, x_3)$ with two additional free coordinates. Each center has exactly 25 symmetric directions, including zero. At $q = 5, d = 5$, every center has either exactly five or at least twenty-five symmetric directions.

The equality subspaces may vary with the center. For example, $Q(x, y) = x + y^2$ has degree at most two, $B = 1$, and

$$S_{(a,b)}(Q) = \{(u, v) : u + 2bv = 0\}.$$

There are q directions at every center, attaining the minimum in dimension two; the one-dimensional kernel changes with b . Consequently equality does not, in general, imply that Q factors through a single fixed linear projection of dimension B .

The higher-degree question remains distinct. For a scalar quintic and $k = 4$, write $P(z + TH) = \sum_{j=0}^5 C_{j,z}(H)T^j$. Reflection at the two parameters $1/2$ and $3/2$ is equivalent to

$$C_{1,z} = \frac{9}{16}C_{5,z}, \quad C_{3,z} = -\frac{5}{2}C_{5,z}.$$

Thus the odd coefficients need not vanish individually, and the argument giving the low-degree budget $B = 9$ cannot be used as an avoidance construction for four-term progressions. Conversely, the same equations are equivalent to

$$C_{3,z} + \frac{40}{9}C_{1,z} = 0, \quad C_{5,z} - \frac{16}{9}C_{1,z} = 0.$$

These two polynomials have degrees at most three and five, respectively. Their degree sum is therefore at most $3 + 5 = 8$, giving the necessary bound $d \leq 8$ for avoidance. The cubic construction gives $d \geq 4$. Nothing in the present supersaturation theorem determines the maximum within $4 \leq d \leq 8$.

Proposition III.36.7 (Failure of the first norm extension in characteristic five). *For every prime p , the degree- p field norm $N : \mathbb{F}_{p^p} \rightarrow \mathbb{F}_p$ is constant on a nontrivial affine $\mathbb{F}_p$ -line. In particular, at $p = 5$ a quintic norm in five variables does not avoid symmetrically colored four-term progressions. Adding independent lower-degree norm blocks does not remove this counterexample.*

Proof. Choose a root θ of $X^p - X - 1$ in an algebraic closure. Then $\theta^p = \theta + 1$, and induction gives $\theta^{p^j} = \theta + j$ for $0 \leq j \leq p$. The first p elements are distinct, and the p th iterate returns to θ . Thus $X^p - X - 1$ is irreducible over $\mathbb{F}_p$, and θ lies in $\mathbb{F}_{p^p}$. The points $\theta + a$, for $a \in \mathbb{F}_p$, are precisely its Frobenius conjugates, and

$$N(\theta + a) = \prod_{b \in \mathbb{F}_p} (\theta + a + b) = \theta^p - \theta = 1.$$

They form the required affine line. In a direct sum of norm blocks, fix every other block and vary only this line in the degree- p block; the total color remains constant. $\square$

This obstruction concerns a proposed construction, not every polynomial of degree five. It therefore does not improve the upper bound eight or disprove the possibility of a different five-dimensional coloring.

III.37 Quantitative examples and what the refinements measure

Source 14, delivered Section 7.

III.37.1 Convergence of the sharp cube model

The sharp secondary term comes from a competition between two effects. A small coefficient at twice the dominant frequency creates a positive quintic contribution, linear in the secondary amplitude. Keeping the centered U^3 norm fixed requires decreasing the dominant amplitude, producing a quartic penalty in that same secondary amplitude. In normalized variables the competition is exactly

$$4\sqrt{2}tb - 48b^4.$$

The balance $b \asymp t^{1/3}$ explains the fractional power: the outer quartic scale t^4 is multiplied by $t^{4/3}$. The coefficient is determined by the penalty as well as the positive correlation. Retaining only the coordinate axes of the Fourier identity misses the eight extra penalty terms and therefore misses the sharp coefficient.

For the positive two-harmonic model, define

$$\mathcal{R}_\delta(u) = \frac{Q_3(\delta + f_u) - \delta^8 - 6\sqrt{2}\delta^4 u^4}{\delta^{8/3} u^{16/3}}.$$

At $\delta = 1/4$, the exact polynomial formulas give the following values, rounded from 90-digit decimal arithmetic.

u	$\mathcal{R}_{1/4}(u)$	$C_* = (9/4)^{1/3}$
10^{-2}	1.3532657043	1.3103706971
10^{-3}	1.3123554554	1.3103706971
10^{-4}	1.3104628080	1.3103706971
10^{-6}	1.3103708955	1.3103706971
10^{-9}	1.3103706971	1.3103706971

Figure III.37.1: The exact two-harmonic model at density $1/4$. The left panel displays the normalized secondary coefficient; the right displays its positive excess over C_* on logarithmic axes. These are evaluations of the proved polynomial identities, not fitted evidence for the theorem. The model's error after normalization is $O_\delta(u^{4/3})$; the uniform upper theorem allows a larger remainder because it controls all functions.

On an exponent-five group, the additional penalty is quadratic in b , rather than quartic at the relevant scale. The balance there is $b \asymp t$, giving a correction t^6 . This explains why a torsion assumption is substantive even after order three has been excluded. It also distinguishes a proved exponent from an optimal coefficient: the order-six exponent is sharp, while its best coefficient remains a concrete open problem.

III.37.2 A sharp stability example and a computable moment gain

Take $A = \mathbb{F}_{101} \setminus \{0\}$. Then $m = 100$ and

$$E(A) = 990\,100 = (1 - 0.0099)m^3.$$

The nearest coset is the whole field, at distance one. Thus

$$\frac{|A \Delta \mathbb{F}_{101}|}{|A|} = 0.01 = \tau(0.0099).$$

Taking a Cartesian product with full additional coordinates preserves both normalized ratios. This gives a transparent sharpness example in every cube dimension.

The same example shows why a denominator depending only on the sizes of the cross-sections can already improve a moment bound. A section of size 100 in a prime-coordinate space cannot be a coordinate coset, since such a coset has size 101^a . The cardinality defect in Corollary II.44.3 is 0.01, yielding an energy deficit 0.0099 without inspecting individual points. If every nonempty section has this same normalized defect, the eighth-arrangement lower bound gains the factor

$$(1 - 0.0099)^{-6} > 1.06$$

over the cubic-profile denominator. The gain is local and explicit; whether it survives subsequent steps depends on the parameter regime of the full argument.

III.37.3 How fast polynomial supersaturation grows

For one cubic or quartic color coordinate and symmetric four-term progressions, $B = 4$. Over $\mathbb{F}_5$ the theorem gives the exact values below. Directions include zero in the middle column and exclude it in the final column.

Dimension d	Minimum directions at each center	Minimum ordered nontrivial four-APs
4	1	0
5	5	12 500
6	25	375 000
7	125	9 687 500

The norm construction attains every row. Adding one dimension beyond the threshold does not merely force one progression somewhere: it forces four nonzero directions at every center. In the first supercritical dimension the next possible local count is at least twenty-five including zero, so a near-minimum global count strongly limits the number of exceptional centers. The equality kernels can still vary with the center, as the quadratic example in Section III.36 demonstrates.

III.38 A finite certificate for the centered cube expansion

Source 14, delivered Appendix A.

Associate to a cube vertex $\omega \in \{0, 1\}^3$ the row $(1, \omega_1, \omega_2, \omega_3)$. A vertex in a chosen support is called a *coloop* if deleting its row lowers the rank of the rows. If a support has a coloop, its product of centered functions has zero average: one may average the corresponding linear form independently of all the others.

Here is the full support classification. Ranks are over the rationals; the relevant nonzero four-by-four minors are ± 1 and ± 2 , so the same independence argument is valid over every finite abelian group of odd order.

Size	Total	With a coloop	Remaining	Contribution
0	1	0	1	Constant term
1	8	8	0	Zero
2	28	28	0	Zero
3	56	56	0	Zero
4	70	58	12	Parallelogram moment S
5	56	48	8	Five-point moment B_5
6	28	0	28	At most u^6 each
7	8	0	8	At most u^7 each
8	1	0	1	u^8

For four vertices, the dependent supports are the six faces and six diagonal parallelograms. Every other four-vertex support has full rank. For five vertices, the complement is a three-vertex set. Up to cube symmetries, its three pairwise Hamming distances are $(1, 1, 2)$, $(1, 2, 3)$, or $(2, 2, 2)$. These types have respectively 24, 24, and 8 realizations. In the first two types the five-vertex support has a coloop; the final type is the set of three neighbors of a cube vertex. Its complement is a cube-symmetric copy of $\{000, 100, 010, 001, 111\}$.

For example, the complements of $\{000, 100, 010\}$ and $\{000, 100, 111\}$ have coloops 110 and 011, respectively. In the remaining case the five forms satisfy the unique full-support dependence

$$2L_{000} - L_{100} - L_{010} - L_{001} + L_{111} = 0, \quad L_\omega = x + \omega \cdot h.$$

Orthogonality then gives the Fourier expression for B_5 used in Equation (III.34.6). Generalized cube Cauchy–Schwarz, obtained by successive Cauchy–Schwarz in the cube directions, bounds a support of size j by $\|f\|_{U_3}^j$ after inserting constant ones at the other vertices. This proves the exact expansion and the two remainder bounds in Equation (III.34.7).

The file `verify_certificates.py` enumerates all 255 nonempty supports using exact rational row reduction, checks the coloop counts and the minor values, and verifies the five-vertex description. It also checks all 25 and 49 Fourier slots in the order-five and order-seven tables with exact integer polynomial coefficients. Thus no floating point computation is needed for these certificates.

III.39 Exact fourth- and fifth-order cube corrections in every dimension

Source 16, delivered Section 8.

Gowers’s Lemma 3.10 bounds the number of cubes by applying the triangle inequality to a constant plus a balanced function. The resulting binomial bound includes many terms which vanish identically. We determine all terms through degree five in every dimension. The answer includes a three-torsion contribution which first occurs in dimension four.

III.39.1 Notation and the expansion

Let G be a finite abelian group, with normalized averages, and let $f : G \rightarrow \mathbb{R}$ satisfy $\mathbb{E}f = 0$. Put $m = 2^d$ and define

$$\mathcal{Q}_d(g) = \mathbb{E}_{x, h_1, \dots, h_d \in G} \prod_{v \in \{0,1\}^d} g(x + v \cdot h).$$

For real g , this is $\|g\|_{U^d}^m$. Write $a_\chi = \widehat{f}(\chi)$, using the normalization $f(x) = \sum_{\chi \in \widehat{G}} a_\chi \chi(x)$ and additive notation for $\widehat{G}$. Thus $a_{-\chi} = \overline{a_\chi}$ and $a_0 = 0$. Set

$$Q(f) = \sum_{\chi \in \widehat{G}} |a_\chi|^4 = \|f\|_{U^2}^4, \quad (\text{III.39.1})$$

$$\begin{aligned} Q_2(f) &= \sum_{2\chi=0} |a_\chi|^4, \\ D(f) &= \sum_{\chi \in \widehat{G}} a_{2\chi} a_\chi a_{-\chi}^3, \\ D_3(f) &= \sum_{3\chi=0} a_\chi^4 a_{-\chi}. \end{aligned} \quad (\text{III.39.2})$$

All four quantities are real. The first two are nonnegative; the last two can have either sign. In each sum the trivial character contributes zero. Define

$$\begin{aligned} P_d &= \frac{6^d - 2 \cdot 4^d + 2^d}{8}, & T_d &= \frac{8^d - 3 \cdot 6^d + 3 \cdot 4^d - 2^d}{24}, \\ F_d &= 4T_d, & H_d &= \frac{10^d - 4 \cdot 8^d + 6 \cdot 6^d - 4 \cdot 4^d + 2^d}{24}. \end{aligned} \quad (\text{III.39.3})$$

Theorem III.39.1 (The low-order cube expansion). *Let $d \geq 2$, and let $f : G \rightarrow \mathbb{R}$ have mean zero. The coefficients of t, t^2, t^3 in $\mathcal{Q}_d(\delta + tf)$ vanish. Over every finite abelian group, the coefficient of t^4 is*

$$\delta^{m-4} (P_d Q(f) + T_d Q_2(f)). \quad (\text{III.39.4})$$

If G has odd order and $d \geq 3$, then

$$\begin{aligned} \mathcal{Q}_d(\delta + tf) &= \delta^m + P_d \delta^{m-4} Q(f) t^4 \\ &\quad + \delta^{m-5} (F_d D(f) + H_d D_3(f)) t^5 + R_d(\delta, t, f). \end{aligned} \quad (\text{III.39.5})$$

Writing $\tau = \|f\|_{U^d}$, the remainder satisfies

$$|R_d(\delta, t, f)| \leq \sum_{k=6}^m \binom{m}{k} |\delta|^{m-k} |t|^k \tau^k. \quad (\text{III.39.6})$$

For $d = 2$ the exact formula is $\mathcal{Q}_2(\delta + tf) = \delta^4 + t^4 Q(f)$.

[write] 6 October 2026; sources 15–20. *Credit.* An independent third derivation of source 09's Theorem III.21.1 (on every finite abelian group; this F_d, H_d are source 09's Q_d, S_d , this P_d is source 03's R_d), also proved by source 18 (Theorem III.40.1); the quartic part is source 03's Theorem III.2.6 and source 08's. The restriction of the quintic formula to odd order is not needed: the intake found the same formula on $\mathbb{Z}/2$, $\mathbb{Z}/4$, $\mathbb{Z}/6$, $\mathbb{Z}/8$ and $(\mathbb{Z}/2)^2$, as source 09's all-groups theorem implies. The $\mathbb{Z}/3\mathbb{Z}$ example (200 and 352) is also in source 18's Section V.77. *Notation:* D here is source 04's B_5 and source 09's $\mathbf{M}_5$; D_3 is source 09's $\mathbf{T}_{3,5}$.

d	P_d	T_d	F_d	H_d
2	1	0	0	0
3	12	2	8	0
4	100	40	160	16
5	720	520	2080	480
6	4816	5600	22400	8960

For example, in dimension four and odd order,

$$\mathcal{Q}_4(\delta + tf) = \delta^{16} + 100\delta^{12}Q(f)t^4 + \delta^{11}(160D(f) + 16D_3(f))t^5 + R_4. \quad (\text{III.39.7})$$

The term $16D_3(f)$ cannot generally be dropped: it is present on groups with three-torsion. On groups of order coprime to six, only Q and D occur through degree five.

Example III.39.2 (A nonzero three-torsion correction). On $\mathbb{Z}/3\mathbb{Z}$, let $f = (2, -1, -1)$. Its two non-trivial normalized Fourier coefficients are both one, so $Q(f) = D(f) = D_3(f) = 2$. Formula (III.39.7) begins

$$\mathcal{Q}_4(\delta + tf) = \delta^{16} + 200\delta^{12}t^4 + 352\delta^{11}t^5 + O(t^6).$$

Omitting the order-three term would instead give 320 as the quintic coefficient. This is an exact algebraic distinction, not a limiting effect.

III.39.2 Vertex systems and the quartic term

For a vertex subset $S = \{v_1, \dots, v_k\} \subseteq \{0, 1\}^d$, put

$$M_f(S) = \mathbb{E}_{x,h} \prod_{i=1}^k f(x + v_i \cdot h).$$

Fourier orthogonality gives

$$M_f(S) = \sum_{\substack{\xi_1 + \dots + \xi_k = 0 \\ \sum_i v_{i,j} \xi_i = 0 \ (1 \leq j \leq d)}} \prod_{i=1}^k a_{\xi_i}. \quad (\text{III.39.8})$$

The constraints are the kernel equations of the integer matrix with columns $(1, v_i)$. Consequently the Taylor coefficient of degree k is $\delta^{m-k} \sum_{|S|=k} M_f(S)$.

Lemma III.39.3. *Any one, two, or three distinct Boolean vertices have a maximal affine minor equal to 1 or -1 . Thus $M_f(S) = 0$ for $1 \leq |S| \leq 3$.*

Proof. Reflect coordinates to put one vertex at zero. Coordinate reflection preserves the average: reflect coordinate j by replacing x with $x + h_j$ and h_j with $-h_j$. For three vertices, the two remaining nonzero distinct binary columns have at least two distinct nonzero row patterns from 10, 01, 11. Any two such patterns have determinant ± 1 . The cases of one or two vertices are immediate. The corresponding linear evaluation map onto $G^{|S|}$ is therefore surjective, so its outputs are independent uniform variables. Their product average is $(\mathbb{E}f)^{|S|} = 0$. $\square$

Lemma III.39.4 (Four-vertex classification). *For four distinct Boolean vertices, exactly one of the following applies:*

1. *They form a real parallelogram, and $M_f(S) = Q(f)$.*
2. *Their affine matrix has full rank and an affine minor ± 1 , and $M_f(S) = 0$.*
3. *They form an affine $\mathbb{F}_2$ plane which is not a real parallelogram, and $M_f(S) = Q_2(f)$.*

The numbers of configurations in the first and third cases are P_d and T_d , respectively.

Proof. Reflect one vertex to zero, leaving three binary columns. Their rational rank is two or three. In rank two, project injectively onto two suitable coordinates. The four images are all of the two-cube; hence the original vertices form a parallelogram with primitive affine relation $(1, 1, -1, -1)$. Lemma III.39.3 supplies a unimodular subsystem, so the frequency kernel is exactly $(\chi, \chi, -\chi, -\chi)$, in a suitable ordering. Formula (III.39.8) gives $Q(f)$.

In rank three, each three-by-three binary determinant is $0, \pm 1$, or ± 2 . A minor ± 1 makes the evaluation map surjective and gives zero. The sole determinant-two binary pattern, up to row and column permutations, has rows 110, 101, 011. Adding any other nonzero binary row produces a determinant-one minor with two of these rows. Therefore, if no minor ± 1 exists, every coordinate row is 000, 110, 101, or 011, and all three nonzero types occur. The kernel equations force all four frequencies to be the same χ with $2\chi = 0$. Since a_χ is real on such characters, their contribution is $Q_2(f)$.

To count parallelograms, choose their common midpoint. If r coordinates vary between the endpoints of an opposite pair, there are 2^{d-r} choices for the fixed coordinates and 2^{r-1} distinct opposite pairs about that midpoint. Thus their number is

$$\sum_{r=2}^d \binom{d}{r} 2^{d-r} \binom{2^{r-1}}{2} = \frac{6^d - 2 \cdot 4^d + 2^d}{8} = P_d.$$

There are $2^d(2^d - 1)(2^d - 2)/24$ affine two-planes in $\mathbb{F}_2^d$. Subtracting P_d gives T_d . □

III.39.3 Five-vertex circuits and the three-torsion term

Lemma III.39.5 (Five-vertex classification in odd order). *Suppose that G has odd order. For a five-element vertex subset S , the only possibly nonzero contributions are the following:*

1. *A rational affine circuit with relation $2v_0 + v_4 = v_1 + v_2 + v_3$, contributing $D(f)$. There are F_d such subsets.*
2. *An affinely independent configuration which is a signed combinatorial embedding of $\{0000, 1110, 1101, 1011, 0111\}$, contributing $D_3(f)$. There are H_d such subsets.*

Every other five-element subset has $M_f(S) = 0$.

Proof. A rational affine r -plane contains at most 2^r Boolean vertices: projection onto r suitable coordinates is injective on that plane. Hence the affine dimension of S is three or four.

First suppose it is three, and project injectively onto three coordinates. Every five vertices of a three-cube contain a unimodular four-vertex subsystem. Indeed, their affine rank modulo two is three because an affine $\mathbb{F}_2$ plane has only four points. Some affine minor is therefore odd; all such minors have absolute value at most two, so this minor is ± 1 . The frequency kernel is the free rank-one kernel of the primitive rational relation, with no additional torsion. Extra ambient coordinate rows impose no further constraints, because the same integer relation annihilates each of them.

If four vertices form a parallelogram, the unique relation has a zero coefficient at the remaining vertex. Its frequency is consequently zero, and $a_0 = 0$ makes the contribution vanish. Otherwise the relation has full support. The three-cube has precisely eight five-point circuits, namely a vertex, its three neighbors, and its antipode. To see exhaustion, classify the omitted triple by

its Hamming distances: the only types are $(1, 1, 2)$, $(1, 2, 3)$, and $(2, 2, 2)$. For the first two types take the representatives $\{000, 100, 010\}$ and $\{000, 100, 111\}$; their complements contain the parallelograms $\{001, 011, 101, 111\}$ and $\{001, 010, 101, 110\}$, respectively. The third type leaves one of the stated circuits. Its primitive relation is $2v_0 + v_4 = v_1 + v_2 + v_3$. Thus the frequency kernel is $(2\chi, -\chi, -\chi, -\chi, \chi)$, and (III.39.8) gives $D(f)$.

For the count, v_0 is the unique vertex with coefficient two and v_4 is also determined; v_1, v_2, v_3 have $3!$ possible orderings. In any coordinate the relation allows eight binary row patterns: two constants and three complementary pairs of nonconstant patterns. All three nonconstant types must occur to give affine dimension three. By inclusion–exclusion, the number of subsets is

$$\frac{2^d}{6}(4^d - 3 \cdot 3^d + 3 \cdot 2^d - 1) = F_d.$$

Now suppose the affine dimension is four. Some five-by-five affine minor is nonzero and has absolute value at most three. In fact, replacing the four binary coordinate rows by sign rows multiplies the determinant by 2^4 , while Hadamard’s inequality bounds the resulting determinant by $5^{5/2}$; hence the original integer determinant has absolute value at most $\lfloor 5^{5/2}/16 \rfloor = 3$.

A minor of absolute value one or two gives a surjective evaluation map on an odd-order group and therefore contributes zero. Otherwise every nonzero affine minor has absolute value three. Modulo three, a row basis can be extended from the nonzero constant row; rank five would therefore give an affine minor nonzero modulo three. The augmented rank modulo three is exactly four: any four of these affinely independent vertices remain independent modulo three, since their nonzero affine minors have absolute value at most two. Its one-dimensional mod-three kernel has full support. Its five nonzero coefficients are ± 1 , and their sum is zero modulo three. Four coefficients therefore have one sign and the remaining coefficient has the other sign.

Let v_0 be the uniquely distinguished vertex. Reflect it to zero. Every coordinate row of the other four vertices has either zero or three ones. All four weight-three patterns must occur, or the rational affine rank would be smaller than four. This is precisely the configuration in the statement. Its frequency equations force $\xi_i = \chi$ for $1 \leq i \leq 4$, $\xi_0 = -\chi$, and $3\chi = 0$. Thus its contribution is $D_3(f)$. In particular, only three-torsion occurs, not characters of order nine: the equations, or the adjugate of a determinant-three subsystem, give $3\chi = 0$.

There are now ten permitted coordinate patterns: two constants and four complementary pairs of nonconstant patterns. All four nonconstant types must occur. The distinguished vertex is unique and the other four have $4!$ possible orderings. Their number is therefore

$$\frac{2^d}{24}(5^d - 4 \cdot 4^d + 6 \cdot 3^d - 4 \cdot 2^d + 1) = H_d.$$

This exhausts both possible rational affine dimensions. □

Proof of Theorem III.39.1. Expand the product defining $\mathcal{Q}_d(\delta + tf)$ by its vertex subsets. Lemmas III.39.3–III.39.5 determine every coefficient through degree five. For a subset S of cardinality k , apply Gowers–Cauchy–Schwarz with f on S and the constant function one on its complement. This gives $|M_f(S)| \leq \tau^k$. Summing the remaining terms gives (III.39.6). □

Remark III.39.6 (The embedding count). If $\{ \binom{n}{r} \}$ denotes a Stirling number of the second kind, the number of signed combinatorial r -subcubes in a d -cube is

$$E_{d,r} = 2^{d-r} \left\{ \begin{matrix} d+1 \\ r+1 \end{matrix} \right\}.$$

Partition the varying coordinates into r nonempty blocks, copy or complement one latent variable on each block, and fix the remaining coordinates. The extra element in the Stirling number marks the block of fixed coordinates. The formulas above become $P_d = E_{d,2}$, $T_d = 2E_{d,3}$, $F_d = 8E_{d,3}$, and $H_d = 16E_{d,4}$.

III.39.4 Consequences, sharp moment bounds, and limits

Corollary III.39.7 (A refined version of the cube-counting upper bound). *Let $d \geq 3$, let G have odd order, let $A \subseteq G$ have density δ , and put $f = 1_A - \delta$. If $\|f\|_{U^d}^m \leq \alpha$, then*

$$\begin{aligned} Q_d(1_A) &\leq \delta^m + P_d \delta^{m-4} Q(f) + \delta^{m-5} (F_d D(f) + H_d D_3(f)) \\ &\quad + \sum_{k=6}^m \binom{m}{k} \delta^{m-k} \alpha^{k/m}. \end{aligned}$$

If only α is available, monotonicity gives $Q(f) \leq \alpha^{4/m}$. The following estimates bound the fifth-order terms as well. In particular, at fixed d and positive δ , the leading error is of order $\alpha^{4/m}$ instead of the order $\alpha^{1/m}$ appearing in the direct Minkowski bound. The exact expression retains more useful information whenever Q , D , or D_3 can be estimated separately.

Proposition III.39.8 (Sharp bounds for the quintic moment). *For real mean-zero functions on odd-order groups,*

$$|D(f)| \leq 2^{-1/4} Q(f)^{5/4}, \quad |D_3(f)| \leq 2^{-1/4} Q(f)^{5/4}.$$

If the group has no three-torsion, then

$$|D(f)| \leq 2^{-1/2} Q(f)^{5/4}.$$

The constants are sharp in their stated classes.

Proof. Pair nonzero frequencies into $\{\chi, -\chi\}$. Put $b_i = |a_\chi|$ for one representative of each pair. Doubling permutes these pairs, say by σ , because the group has odd order. Then

$$|D(f)| \leq 2 \sum_i b_i^4 b_{\sigma(i)}, \quad Q(f) = 2 \sum_i b_i^4.$$

Bounding each $b_{\sigma(i)}$ by $(\sum_j b_j^4)^{1/4}$ proves the first inequality. The same argument restricted to three-torsion proves the bound for D_3 . Equal positive Fourier coefficients on an order-three character pair attain both constants.

If three-torsion is absent, σ has no fixed points. Normalize $\sum_i b_i^4 = 1$ and let $u = \max_i b_i$. If $u^4 \leq 1/2$, the sum is at most $u \leq 2^{-1/4}$. Otherwise put $v = (1 - u^4)^{1/4}$. The largest coordinate is sent to another coordinate, at most v , while all other coordinates are sent to values at most u . Hence

$$\sum_i b_i^4 b_{\sigma(i)} \leq u^4 v + v^4 u \leq 2^{-1/4}.$$

For the last inequality, the function $(r^4 + r)/(r^4 + 1)^{5/4}$ has its maximum $2^{-1/4}$ at $r = 1$: the sign of its derivative is the sign of

$$(1 - r)(r^6 + r^5 + r^4 + 5r^3 + r^2 + r + 1).$$

Restoring the normalization proves the second constant. Equal positive Fourier coefficients on the four nontrivial characters of an order-five quotient attain it. $\square$

[write] **6 October 2026; sources 15–20.** *Credit.* The bound with $2^{-1/4}$ is source 04’s bound on B_5 (Section III.3); the constant $2^{-1/2}$ without three-torsion, sharp, is new in this report (the intake’s adversarial search found no exceedance).

Remark III.39.9 (Higher torsion and the scope of the improvement). The low-order proof suggests organizing subsequent coefficients by the integer kernels and Smith normal forms of affine Boolean vertex matrices. A full-rank k -vertex subsystem has a nonzero affine minor of absolute value at most $\lfloor k^{k/2}/2^{k-1} \rfloor$. Primes larger than this cannot produce a new torsion kernel for that subsystem. For $k = 4, 5$ this bound gives exactly the possible primes two and three.

An explicit family in dimension $r \geq 3$ consists of the $r + 1$ vertices $0, \mathbf{1} - e_1, \dots, \mathbf{1} - e_r$. Its affine determinant is $r - 1$ and its correlation is

$$\sum_{(r-1)\chi=0} a_{-\chi} a_{\chi}^r.$$

The coordinate equations force all nonzero-vertex frequencies to equal χ and then force $(r - 1)\chi = 0$. This family need not exhaust the configurations or locate the first occurrence of a given prime.

The results above are explicit local improvements to the cube-counting step. They do not, by themselves, improve a global quantitative Szemerédi bound. Their proofs are independent of the accompanying finite calculations; the exact computations serve only as reproducible checks of classification counts, signs, and normalization.

III.39.5 Optimality of the exponent for sets

The fourth-order term also gives an obstruction for genuine subsets of cyclic groups, rather than only for weighted functions.

Proposition III.39.10 (Sharp order of the small-uniformity error). *Fix $d \geq 2$ and put $m = 2^d$. There are odd cyclic groups G_n and subsets $A_n \subseteq G_n$ of density exactly $\delta = 1/3$ such that, writing $\alpha_n = \|1_{A_n} - \delta\|_{U^d}^m$, one has*

$$\alpha_n \longrightarrow 0, \quad \frac{\mathcal{Q}_d(1_{A_n}) - \delta^m}{\alpha_n^{4/m}} \longrightarrow c_d > 0.$$

Consequently a bound with a uniform error $o(\alpha^{4/m})$ is impossible, even at this fixed density and on odd cyclic groups.

Proof. On $G_0 = \mathbb{Z}/3\mathbb{Z}$, take $f_0 = (2, -1, -1)$ and $w_t = 1/3 + tf_0$, where $0 < t < 1/3$. This is a function into $[0, 1]$ of mean $1/3$. The two nontrivial Fourier coefficients of f_0 are one, so $Q(f_0) = 2$. Let $B_d = \|f_0\|_{U^d}^m > 0$. Theorem III.39.1 gives

$$\begin{aligned} \mathcal{Q}_d(w_t) &= \delta^m + 2P_d\delta^{m-4}t^4 + O_d(t^5), \\ \mathcal{Q}_d(w_t - \delta) &= B_d t^m. \end{aligned} \tag{III.39.9}$$

For $d = 2$ the first identity is exact without the error term.

We explain carefully how to realize these two moments by sets. Let $p \neq 3$ be an odd prime and independently select each $(x, y) \in G_0 \times \mathbb{Z}/p\mathbb{Z}$ with probability $w_t(x)$. For a random cube, two distinct vertices have the same second coordinate with probability $1/p$, because their difference is a

nonzero binary linear form with a coefficient 1 or -1 . Away from these collisions, the selected-point variables at its vertices are independent. Thus, for $j = 1, 2$, the expected value of

$$T_1 = \mathcal{Q}_d(1_A), \quad T_2 = \mathcal{Q}_d(1_A - \delta)$$

differs from the corresponding weighted moment in (III.39.9) by at most $2\binom{m}{2}/p$.

Likewise, products associated with two cubes are independent unless they share a selected-point variable. A union bound over their m^2 pairs of vertices gives

$$\text{Var}(T_j) \leq \frac{2m^2}{p}.$$

The density has expectation δ and variance at most $1/(12p)$. Consequently, for any $\varepsilon > 0$ and sufficiently large p , a realization exists whose density differs from δ by at most ε and whose two moments differ from their weighted targets by at most 2ε . This follows directly from Chebyshev's inequality and a union bound.

Change at most an ε fraction of the points to make the cardinality exactly p , hence the density exactly $1/3$. A telescoping product and uniformity of each vertex marginal show that this changes each T_j by at most $m\varepsilon$. Choose $\varepsilon = t^{m+1}$ and then choose $p = p(t)$ sufficiently large. The resulting set, still denoted by A_t , satisfies

$$\begin{aligned} \mathcal{Q}_d(1_{A_t}) - \delta^m &= 2P_d\delta^{m-4}t^4 + O_d(t^5), \\ \|1_{A_t} - \delta\|_{U^d}^m &= B_d t^m + O_d(t^{m+1}). \end{aligned}$$

Taking any sequence $t \downarrow 0$ and using $G_0 \times \mathbb{Z}/p\mathbb{Z} \cong \mathbb{Z}/(3p)\mathbb{Z}$ proves the claim, with

$$c_d = 2P_d\delta^{m-4}B_d^{-4/m} > 0.$$

□

[write] **6 October 2026; sources 15–20.** *Credit.* Sharpness of the exponent $4/2^d$ for sets is source 03's Corollary III.2.11, source 04's Proposition III.3.10, source 09's Proposition III.22.1 with Corollary III.22.5, and source 18's Theorem III.40.12; new here is only the packaging for sets of exact density $1/3$ in odd cyclic groups. At $d = 2$ the ratio is identically one, so that case is trivial.

III.40 Exact fourth and fifth order cube counts

Source 18, delivered Section 3.

Gowers' Lemma 3.10 applies the triangle inequality to the cube norm. The resulting estimate is convenient, but it treats the constant and balanced parts as if the first mixed term could already be nonzero. Centering actually eliminates all terms of degrees one, two, and three. We now compute the next two degrees exactly, in every dimension and on every finite abelian group. The answer distinguishes ordinary affine circuits from the extra relations created by two- and three-torsion.

Throughout this section, G is a finite abelian group, averages are normalized, and the dual group $\hat{G}$ is written additively. Our Fourier convention is

$$\hat{f}(\gamma) = \mathbb{E}_{x \in G} f(x) \overline{\gamma(x)}, \quad \hat{G}[p] = \{\gamma \in \hat{G} : p\gamma = 0\}.$$

For a real function g , define

$$\mathcal{C}_d(g) = \mathbb{E}_{x, h_1, \dots, h_d \in G} \prod_{v \in \{0,1\}^d} g(x + v \cdot h) = \|g\|_{U^d}^{2^d}.$$

Thus $|G|^{d+1} \mathcal{C}_d(1_A)$ counts parameterized cubes in A , including cubes with repeated vertices. Real-valuedness is essential to the simple identical-function expansion used below; complex cube norms carry the usual alternating conjugations.

III.40.1 The coefficient theorem

For $d \geq 3$, put $m = 2^d$ and define

$$R_d = \frac{6^d - 2 \cdot 4^d + 2^d}{8}, \quad B_d = \frac{2^d(2^d - 1)(2^d - 2)}{24}, \quad (\text{III.40.1})$$

$$Q_d = \frac{8^d - 3 \cdot 6^d + 3 \cdot 4^d - 2^d}{6}, \quad S_d = \frac{10^d - 4 \cdot 8^d + 6 \cdot 6^d - 4 \cdot 4^d + 2^d}{24}. \quad (\text{III.40.2})$$

For a real mean-zero function $f : G \rightarrow \mathbb{R}$, set

$$V_4(f) = \sum_{\gamma \in \widehat{G}} |\widehat{f}(\gamma)|^4 = \|f\|_{U^2}^4, \quad (\text{III.40.3})$$

$$E_2(f) = \sum_{\gamma \in \widehat{G}[2]} \widehat{f}(\gamma)^4, \quad (\text{III.40.4})$$

$$T_5(f) = \sum_{\gamma \in \widehat{G}} \widehat{f}(2\gamma) \widehat{f}(\gamma) \widehat{f}(-\gamma)^3, \quad (\text{III.40.5})$$

$$E_3(f) = \sum_{\gamma \in \widehat{G}[3]} \widehat{f}(-\gamma) \widehat{f}(\gamma)^4. \quad (\text{III.40.6})$$

These quantities are real: replacing γ by $-\gamma$ conjugates each summand. Moreover, $V_4(f)$ and $E_2(f)$ are nonnegative. In the latter sum, every Fourier coefficient is real because $2\gamma = 0$. The zero character contributes zero to all four expressions.

Theorem III.40.1 (Exact expansion through degree five). *Let G be any finite abelian group, $d \geq 3$, $m = 2^d$, and let $f : G \rightarrow \mathbb{R}$ have mean zero. For all real δ, t ,*

$$\begin{aligned} \mathcal{C}_d(\delta + tf) &= \delta^m + \delta^{m-4} t^4 (R_d V_4(f) + (B_d - R_d) E_2(f)) \\ &\quad + \delta^{m-5} t^5 (Q_d T_5(f) + S_d E_3(f)) + \mathcal{R}_d(\delta, t; f), \end{aligned} \quad (\text{III.40.7})$$

where, writing $\eta = \|f\|_{U^d}$,

$$|\mathcal{R}_d(\delta, t; f)| \leq \sum_{j=6}^m \binom{m}{j} |\delta|^{m-j} |t|^j \eta^j. \quad (\text{III.40.8})$$

In particular, the coefficients of t, t^2, t^3 vanish identically.

[write] **6 October 2026; sources 15–20.** *Credit.* The coefficients are those of source 09's Theorem III.21.1 on every finite abelian group ($Q_d = 2^d S(d+1, 4)$, $S_d = 2^d S(d+1, 5)$ with Stirling numbers, as source 09 writes them), also derived independently by source 16 (Theorem III.39.1, odd order for the quintic part); the quartic part is source 03's Theorem III.2.6 and source 08's. So this is the fourth independent derivation in

the report; source 18 could see none of the other three (sources 09 and 16 were not in the repository at its pin). New in method: the Smith-form and Hadamard-minor argument showing that only the primes 2 and 3 enter through order five (Corollary III.40.4). *Notation:* R_d is source 03's R_d (source 04's, 09's and 16's P_d), $B_d - R_d$ is T_d ; this Q_d is a five-circuit count (= source 09's Q_d = source 16's F_d), not a cube count.

Remark III.40.2 (Small torsion and low dimensions). If G has no nonzero element killed by 2, then $E_2(f) = 0$. If G has no nonzero element killed by 3, then $E_3(f) = 0$. The fifth order identity therefore needs no exclusion of two-torsion. For $d = 2$ the whole expansion reduces to the familiar exact identity

$$\mathcal{C}_2(\delta + tf) = \delta^4 + t^4 \|f\|_{U^2}^4.$$

The first coefficient values are

d	R_d	B_d	Q_d	S_d
3	12	14	8	0
4	100	140	160	16
5	720	1240	2080	480

The twelve four-point circuits and eight five-point circuits in the ordinary three-dimensional cube are classical; they are listed, for example, by Beerenwinkel, Pachter, and Sturmfels [74]. Here the aim is an explicit all-dimensional cube-moment formula, including the contributions of small torsion and a norm-controlled remainder. The circuit interpretation itself is not a novelty claim.

III.40.2 Fourier constraints and integer minors

For a set $W = \{v_1, \dots, v_s\} \subseteq \{0, 1\}^d$, let

$$M_W = \begin{pmatrix} 1 & \cdots & 1 \\ v_1 & \cdots & v_s \end{pmatrix}.$$

Fourier inversion and character orthogonality give

$$\mathbb{E}_{x,h} \prod_{v \in W} f(x + v \cdot h) = \sum_{\substack{\gamma_1, \dots, \gamma_s \in \widehat{G} \\ M_W \gamma = 0}} \prod_{i=1}^s \widehat{f}(\gamma_i). \quad (\text{III.40.9})$$

The matrix acts by integer multiplication in the abelian group $\widehat{G}$. Rational rank alone does not determine this kernel: the integer invariant factors must also be controlled.

Lemma III.40.3 (Small minors of Boolean affine matrices). *For a Boolean affine matrix M_W , any $k \times k$ minor containing the row of ones has absolute value at most $1, 1, 1, 2, 3$ for $k = 1, 2, 3, 4, 5$, respectively. Every three distinct columns have a 3×3 minor equal to ± 1 . Every five distinct columns have a 4×4 minor equal to ± 1 .*

Proof. For a minor containing the row of ones, reflect each selected coordinate in which the first selected vertex equals one. At the matrix level this replaces a coordinate row by the row of ones minus that row. The first selected vertex now has all selected coordinates zero. Subtracting its column from the other columns reduces the determinant, up to sign, to that of a binary $(k-1) \times (k-1)$ matrix.

If D is a binary $r \times r$ matrix, the matrix

$$H = \begin{pmatrix} 1 & \mathbf{1}^\top \\ \mathbf{1} & J - 2D \end{pmatrix}$$

has entries in $\{-1, 1\}$ and determinant $(-2)^r \det D$. Hadamard's inequality gives

$$|\det D| \leq \frac{(r+1)^{(r+1)/2}}{2^r}.$$

For $r = 1, 2, 3, 4$, taking integer parts gives $1, 1, 2, 3$.

Three distinct points of $\mathbb{F}_2^d$ have affine rank three, because an affine line contains only two points. Extend the nonzero row of ones to a row basis over $\mathbb{F}_2$ and select three independent columns. The resulting minor is odd and has absolute value at most one, so it is ± 1 .

Similarly, five distinct points have affine rank at least four over $\mathbb{F}_2$, because an affine plane contains only four points. Extending the row of ones to four independent rows and selecting four independent columns produces an odd minor of absolute value at most two. It too must equal ± 1 . $\square$

We use the elementary Smith normal form principle that unimodular integer row and column operations induce automorphisms over every abelian group. If a full-column-rank integer matrix has invariant factors $1, \dots, 1, p$, its kernel over an abelian group H is a copy of $H[p]$. For prime p , its coordinates are the multiples of a vector spanning the one-dimensional kernel modulo p .

Corollary III.40.4 (Only two small primes can occur). *For four distinct cube vertices, the rational rank is three or four. In rank three the nonzero Smith invariants are $1, 1, 1$; in rank four they are $1, 1, 1, D$ with $D \in \{1, 2\}$.*

For five distinct cube vertices, the rational rank is four or five. In rank four the nonzero invariants are $1, 1, 1, 1$; in rank five they are $1, 1, 1, 1, D$ with $D \in \{1, 2, 3\}$.

Proof. The unit minors in Lemma III.40.3 make the third determinantal divisor equal to one for a four-point set and the fourth determinantal divisor equal to one for a five-point set. In full column rank, extend the row of ones to a rational row basis. A nonzero maximal minor containing that row has absolute value at most two or three. The final determinantal divisor divides this minor. The stated lists follow. $\square$

III.40.3 The four-point coefficient

Lemma III.40.5 (Four-point classification). *For four distinct Boolean cube vertices, exactly the following possibilities can contribute to (III.40.9):*

1. *An ordinary rectangle, with primitive relation $u + v = w + z$, contributes $V_4(f)$.*
2. *Four rationally independent vertices whose XOR is zero contribute $E_2(f)$.*

All other four-point sets have zero correlation. There are R_d sets of the first type and $B_d - R_d$ of the second.

Proof. Suppose first that the rational rank is three. Its unique affine dependence has nonzero coefficients, since three distinct vertices are independent. The positive and negative coefficients split as two and two: a cube vertex cannot be a strict convex combination of other cube vertices. Write

$$au + bv = cw + ez, \quad a + b = c + e,$$

with all coefficients positive. Reflect coordinates so that $u = 0$. In every nonconstant coordinate, $v = 1$ and a nonempty proper subset of $\{c, e\}$ sums to b . Affine dimension two requires both possible nonconstant patterns. Therefore $b = c = e$ and then $a = b$. The primitive dependence is $u + v = w + z$. The unit Smith invariants show that the Fourier kernel consists exactly of the tuples $(\gamma, \gamma, -\gamma, -\gamma)$, giving $V_4(f)$.

In rational rank four, the kernel is trivial unless the final Smith invariant is two. Modulo two, the unique dependence must involve all four columns because every three are independent. It is therefore the XOR relation. The Fourier kernel is exactly

$$\{(\gamma, \gamma, \gamma, \gamma) : 2\gamma = 0\},$$

giving $E_2(f)$. A trivial Fourier kernel gives a product containing $\hat{f}(0) = 0$.

To count rectangles, there are six binary coordinate patterns satisfying $u + v = w + z$. The two degenerate matchings each give 4^d ordered tuples, and their intersection gives 2^d . Every nondegenerate rectangle has eight labelings of this form: choose which opposite pair is on the left and order the two pairs. This gives R_d in (III.40.1).

An unordered four-set has XOR zero precisely when it is an affine plane in $\mathbb{F}_2^d$. Choose its origin, then an ordered basis, and divide by the four origins and six ordered bases of one plane. The count is

$$\frac{2^d(2^d - 1)(2^d - 2)}{4 \cdot 6} = B_d.$$

Of these, R_d are ordinary rectangles, leaving $B_d - R_d$ of the second type. □

III.40.4 The five-point coefficient

Lemma III.40.6 (Ordinary five-point circuits). *Every five-point circuit of the real affine Boolean cube has, after relabeling and common sign, the primitive relation*

$$2u + v = x + y + z. \tag{III.40.10}$$

There are exactly Q_d such circuits, and each contributes $T_5(f)$ over every finite abelian group. Every rational rank-four five-point set that is not a circuit contributes zero.

Proof. In rational rank four, Corollary III.40.4 gives a unit rank-four minor. The character kernel over any $\hat{G}$ is therefore generated by the primitive integer dependence vector, without additional torsion parameters. If this vector has a zero coefficient, its support consists of four points forming a rectangle. The remaining Fourier coordinate is zero, so the correlation vanishes.

Otherwise, all five coefficients are nonzero. Their signs split as two and three, again because every cube vertex is extreme. Write the positive dependence as

$$au + bv = cx + ey + qz, \quad a + b = c + e + q,$$

where all five coefficients are positive. Reflect coordinates so that $u = 0$. Every nonconstant coordinate has $v = 1$ and corresponds to a nonempty proper subset of $\{c, e, q\}$ whose sum is b . Affine dimension three requires at least three distinct such patterns.

For three positive numbers, three distinct proper nonempty subsets can have a common sum only if all three numbers are equal. Indeed, equal-sum subsets form an antichain. A three-element antichain of proper nonempty subsets of a three-element set is either the three singletons or the three pairs: a singleton and a pair omitting it leave no third subset incomparable with both. Equality of the three singleton sums or three pair sums forces $c = e = q$. Thus $b = c$ or $b = 2c$, and $a = 2c$ or $a = c$, respectively. Interchanging u, v if necessary proves (III.40.10).

Its Fourier kernel is

$$(\gamma_u, \gamma_v, \gamma_x, \gamma_y, \gamma_z) = (2\gamma, \gamma, -\gamma, -\gamma, -\gamma),$$

which gives (III.40.5).

For the count, the coefficient-two vertex and the same-sign coefficient-one vertex are uniquely distinguished; the other three vertices have $3!$ orderings. Each coordinate row satisfying (III.40.10) is one of eight patterns: two constants and three nonconstant types together with their complements. After reflecting to $u = 0$, the three types are

$$(0, 1, 1, 0, 0), \quad (0, 1, 0, 1, 0), \quad (0, 1, 0, 0, 1).$$

Together with the row of ones, they are independent. Rational rank four holds exactly when all three types occur. Inclusion-exclusion therefore gives

$$Q_d = \frac{8^d - 3 \cdot 6^d + 3 \cdot 4^d - 2^d}{3!}.$$

□

Lemma III.40.7 (The additional three-torsion circuits). *Among rationally independent five-point subsets, exactly S_d can give nonzero centered correlation. Each has a unique dependence modulo three with coefficient pattern $(-1, 1, 1, 1, 1)$, up to common sign and relabeling, and contributes $E_3(f)$. The subsets with a nontrivial invariant factor two contribute zero.*

Proof. Let D be the last Smith invariant in Corollary III.40.4. If $D = 1$, the Fourier kernel is trivial and the correlation is zero.

If $D = 2$, the unique dependence modulo two has even support because the first row consists of ones. Its support has size at least four and at most five, so it has size four. The Smith kernel consists of two-torsion multiples of this vector. One Fourier coordinate is consequently zero, and mean zero again kills the correlation.

Suppose $D = 3$. Any four columns are rationally independent, and a nonzero four-by-four minor containing the row of ones has absolute value one or two. They are therefore independent modulo three. The unique dependence modulo three involves all five columns, with coefficients in $\{1, -1\}$. Their sum is zero modulo three. After a common sign, exactly one is negative and the other four are positive. The Fourier kernel is parameterized by

$$(-\gamma, \gamma, \gamma, \gamma, \gamma), \quad 3\gamma = 0,$$

and its correlation is $E_3(f)$.

For counting, label the distinguished negative vertex u and the others $v_1, \dots, v_4$. Coordinatewise the relation is

$$-u + v_1 + v_2 + v_3 + v_4 = 0 \pmod{3}.$$

There are ten binary row patterns: two constants and four nonconstant types together with their complements. After reflection to $u = 0$, the nonconstant rows are $(0, \mathbf{1} - e_j)$ for $1 \leq j \leq 4$. The four vectors $\mathbf{1} - e_j$ are independent over the rationals because $\det(J - I) = -3$. Thus rational rank five holds exactly when all four nonconstant types occur. Inclusion-exclusion gives

$$10^d - 4 \cdot 8^d + 6 \cdot 6^d - 4 \cdot 4^d + 2^d$$

ordered tuples. The distinguished vertex is unique, and the other four have $4!$ orderings. Division by $4!$ proves the formula for S_d . $\square$

Proof of Theorem III.40.1. Expand the m -fold product defining $\mathcal{C}_d(\delta + tf)$. A subset of j vertices contributes $\delta^{m-j}t^j$ times its f -correlation. For $j = 1, 2, 3$, the corresponding affine matrices have unit full-column-rank minors; character orthogonality forces zero Fourier coordinates, so the correlations vanish. Lemmas III.40.5, III.40.6, and III.40.7 give the fourth and fifth coefficients.

For every subset of j vertices, Gowers–Cauchy–Schwarz, applied to f at those vertices and the constant function one at the others, bounds the absolute correlation by $\|f\|_{U^d}^j$. Summing this bound over all subsets with $j \geq 6$ gives (III.40.8). $\square$

Remark III.40.8 (Characteristic two and characteristic three). If G has exponent two, then $T_5(f) = 0$ because $\hat{f}(2\gamma) = \hat{f}(0) = 0$, and $E_3(f) = 0$ as well. Every fifth order term vanishes. If G has exponent three, then $T_5(f) = E_3(f)$, after replacing γ by $-\gamma$ in one sum. The fifth coefficient is then

$$(Q_d + S_d)E_3(f), \quad Q_d + S_d = \frac{10^d - 6 \cdot 6^d + 8 \cdot 4^d - 3 \cdot 2^d}{24}.$$

These identities explain why an odd-order hypothesis suffices for the ordinary fourth coefficient but does not remove the extra fifth order contribution.

III.40.5 A quantitative strengthening of Lemma 3.10

Corollary III.40.9 (Centered cube bound). *Let $g : G \rightarrow \mathbb{R}$ have mean $\delta \geq 0$, set $f = g - \delta$, and suppose $\|f\|_{U^d} \leq \varepsilon$, with $d \geq 3$ and $m = 2^d$. Then*

$$\begin{aligned} \mathcal{C}_d(g) &\leq \delta^m + B_d \delta^{m-4} \varepsilon^4 + (Q_d + S_d) \delta^{m-5} \varepsilon^5 \\ &\quad + \sum_{j=6}^m \binom{m}{j} \delta^{m-j} \varepsilon^j. \end{aligned} \tag{III.40.11}$$

If G has no two-torsion, B_d may be replaced by R_d . If G has no three-torsion, $Q_d + S_d$ may be replaced by Q_d . The stronger signed spectral formula (III.40.7) remains available in every case.

Proof. Use Theorem III.40.1 with $t = 1$. The fourth coefficient is a sum of B_d correlations, each of absolute value at most ε^4 . The nonzero fifth types number $Q_d + S_d$, each of absolute value at most ε^5 . These estimates follow from the same Gowers–Cauchy–Schwarz inequality as the remainder bound. The stated torsion exclusions remove the corresponding terms from the exact formula. $\square$

For a set A of density δ , the balanced function is $f = 1_A - \delta$. In Gowers' normalization, degree- $(d-1)$ α -uniformity means $\|f\|_{U_d}^m \leq \alpha$. Thus (III.40.11) improves the first possible error from the order $\alpha^{1/m}$ supplied by $(\delta + \alpha^{1/m})^m$ to order $\alpha^{4/m}$, at fixed positive density and fixed d . This is a local improvement of the cube-counting lemma. An improvement of the terminal Szemerédi bound would require propagating it through an argument that uses this estimate quantitatively.

III.40.6 Sharpness, including genuine indicator sets

The unrestricted finite-group leading constant B_d is optimal. The first step is an exact weighted example; a Bernoulli approximation then transfers its leading behavior to sets.

Proposition III.40.10 (Exact order-two character example). *Let $\chi : G \rightarrow \{-1, 1\}$ be a nontrivial character, $d \geq 2$, and $m = 2^d$. Then*

$$\mathcal{C}_d(\delta + t\chi) = \frac{(\delta + t)^m + (\delta - t)^m + (2m - 2)(\delta^2 - t^2)^{m/2}}{2m}. \quad (\text{III.40.12})$$

Moreover, $\|t\chi\|_{U^d} = |t|$. At fixed $\delta > 0$,

$$\mathcal{C}_d(\delta + t\chi) = \delta^m + B_d \delta^{m-4} t^4 + O_{d,\delta}(t^6). \quad (\text{III.40.13})$$

Proof. The values of $\chi(x), \chi(h_1), \dots, \chi(h_d)$ are independent uniform signs. Consequently the signs on the cube are the evaluations of a uniformly random affine Boolean function on $\mathbb{F}_2^d$. Of its $2^{d+1} = 2m$ possible affine functions, two are constant and the other $2m - 2$ are balanced. A constant function contributes $(\delta + t)^m$ or $(\delta - t)^m$; a balanced one contributes $(\delta + t)^{m/2}(\delta - t)^{m/2}$. This proves (III.40.12).

Every d -fold cube derivative of a character is one for $d \geq 2$, so its U^d norm is one. In the even polynomial (III.40.12), the quadratic coefficient is zero and the quartic coefficient is

$$\frac{2\binom{m}{4} + (2m - 2)\binom{m/2}{2}}{2m} = \frac{m(m-1)(m-2)}{24} = B_d.$$

This proves the expansion. □

Lemma III.40.11 (Approximation of weights by sets in cube norm). *Fix $d \geq 2$, put $m = 2^d$, and let $G = \mathbb{F}_2^n$, of order N . For every function $w : G \rightarrow [0, 1]$, there is a set $A \subseteq G$ such that*

$$\|1_A - w\|_{U^d} \leq \left(\frac{m-1}{N} \right)^{1/m}. \quad (\text{III.40.14})$$

Proof. Include each $y \in G$ in A independently with probability $w(y)$, and write $z = 1_A - w$. For a cube whose m sites are distinct, independence and centering give

$$\mathbb{E}_A \prod_{v \in \{0,1\}^d} z(x + v \cdot h) = 0.$$

Every other product has absolute value at most one. A collision occurs only if $a \cdot h = 0$ for some nonzero $a \in \mathbb{F}_2^d$. For fixed nonzero a , this has probability $1/N$. A union bound over $m-1$ choices gives

$$0 \leq \mathbb{E}_A \|z\|_{U^d}^m \leq \frac{m-1}{N}.$$

Some realization is at most this average, proving the claim. □

Theorem III.40.12 (Optimal unrestricted leading coefficient for sets). *Fix $d \geq 3$ and $\delta \in (0, 1)$. There are finite groups $G_k = \mathbb{F}_2^{n_k}$ and sets $A_k \subseteq G_k$, with densities $\delta_k \rightarrow \delta$ and balanced norms $\varepsilon_k = \|1_{A_k} - \delta_k\|_{U^d} \rightarrow 0$, such that*

$$\lim_{k \rightarrow \infty} \frac{\mathcal{C}_d(1_{A_k}) - \delta_k^m}{\delta_k^{m-4} \varepsilon_k^4} = B_d. \quad (\text{III.40.15})$$

Therefore B_d in the unrestricted finite-group leading term of (III.40.11) cannot be decreased, even when the functions being counted are indicators.

Proof. Let $t_k > 0$ tend to zero, with $t_k \leq \min(\delta, 1 - \delta)$. Choose $N_k = 2^{n_k}$ sufficiently large that

$$\left(\frac{m-1}{N_k} \right)^{1/m} \leq t_k^5.$$

On G_k , choose a nontrivial sign character χ_k and set $w_k = \delta + t_k \chi_k$. This weight lies in $[0, 1]$ and has mean δ . Lemma III.40.11 gives a set A_k with $z_k = 1_{A_k} - w_k$ satisfying $\|z_k\|_{U^d} \leq t_k^5$.

The mean is bounded by the cube norm, so

$$\delta_k = \delta + \mathbb{E}z_k = \delta + O(t_k^5).$$

The balanced function of A_k is

$$1_{A_k} - \delta_k = t_k \chi_k + z_k - \mathbb{E}z_k.$$

The triangle inequality and its reverse give $\varepsilon_k = t_k + O(t_k^5)$. Also, $\|1_{A_k}\|_{U^d}, \|w_k\|_{U^d} \leq 1$, because both functions take values in $[0, 1]$. Hence

$$|\mathcal{C}_d(1_{A_k}) - \mathcal{C}_d(w_k)| \leq m \|1_{A_k} - w_k\|_{U^d} \leq m t_k^5.$$

Proposition III.40.10 now yields

$$\mathcal{C}_d(1_{A_k}) - \delta_k^m = B_d \delta^{m-4} t_k^4 + O_{d,\delta}(t_k^5).$$

Since $\delta_k^{m-4} \varepsilon_k^4 = \delta^{m-4} t_k^4 (1 + o(1))$, division proves (III.40.15). $\square$

[write] 6 October 2026; sources 15–20. *Credit.* Sharpness of B_d for sets is source 03’s Corollary III.2.11 (with exact rational densities in its Theorem III.2.12); proved again here by rounding. The best coefficient on odd-order groups, which Section V.78 asks for (“especially in dimension four”), is settled at $d = 3$ by source 04’s Theorem III.3.4 ($c_3^{\text{odd}} = 2^{-1/2}$, note there); open for $d \geq 4$ (item III.1).

This sharpness statement uses groups with two-torsion. It leaves open the best leading coefficient when multiplication by two is invertible, especially for $d \geq 4$. The exact coefficient in that case is $R_d \|f\|_{U^2}^4$, so the remaining optimization concerns the strongest possible comparison between the centered real U^2 and U^d norms.

III.41 Source 20’s chapter: quadratic counting errors at Section 3 [write]

Added in the fourth write, 6 October 2026.

The next seven sections are source 20, a manuscript on the passage from uniformity to counting in Gowers’s Section 3 (Theorem 3.2, Corollary 3.3). It keeps two functions through the last Cauchy–Schwarz step, which gives an error quadratic in the balanced uniformity norm. *Logically the chapter stands beside source 06’s Section III.5*, which proves the quadratic error first, and source 10’s Section III.28 on torsion; source 20 could see neither (only source 04’s manuscript, whose telescope is linear). It is printed here, at the end of Part III, because no number printed earlier may move. Its introduction is Section F.25; its formalization notes, questions, conclusion and source audit are in Part V (Sections V.83–V.86). Its notation is in the table at the head of this Part.

What is proved, in one paragraph. For surjective homomorphisms of finite abelian groups, two marked functions bounded by directional seminorms and one L^2 factor (Theorem III.43.3; source 06’s Theorem III.5.1 for slope systems); the directional-to-global comparison with the optimal constant for every subgroup tuple (Theorem III.44.1) and a collapsed-pair obstruction; quadratic counting with unequal densities (Theorem III.45.2) and, for one set, $|\Lambda_k(1_A) - \delta^k| \leq B_k(\delta)u^2$ (Corollary III.45.4) with B_k strictly below source 06’s coefficient (proved at the write, note there); the sharp pair correction $\sqrt{m-1}$ (Proposition III.46.1); supersaturation (Corollary III.47.1); and sharpness of the exponent 2 for three-term counts of indicator sets of density near $1/2$ on $\mathbb{F}_{29}^{2m}$ (Theorem III.48.3; new in this report). Not claimed: sharpness for $k \geq 4$ or for prime cyclic groups, a substitute for the asymmetric Corollary 3.3, a global bound.

Relation to the formal statements (checked at HEAD 0b4890a1c). `theorem_3_2` and `corollary_3_3` (Sections01_03.lean, lines 258, 276) are exact companions for prime N and $k \leq N$. Nothing in this chapter is formalized.

III.42 Normalized cubes and subgroup directions

Source 20, delivered Section 2.

All groups in this article are finite abelian groups, written additively. Every expectation uses the uniform probability measure on its indicated finite set. We put $\Delta_h f(x) = f(x)f(x+h)$. Complex conjugation is denoted by $\mathcal{C}$, so $\mathcal{C}^0 z = z$ and $\mathcal{C}^1 z = \bar{z}$. The L^p norms also use normalized measure.

Definition III.42.1 (Directional cube seminorm). For subgroups $H_1, \dots, H_s \leq G$, $s \geq 1$, define

$$D_{H_1, \dots, H_s}(f)^{2^s} = \mathbb{E}_{x \in G} \mathbb{E}_{h_r \in H_r} \prod_{\omega \in \{0,1\}^s} \mathcal{C}^{|\omega|} f(x + \omega \cdot h). \quad (\text{III.42.1})$$

Its nonnegative 2^s -th root is intended. When every $H_r = G$, this is $\|f\|_{U^s}$. In particular $\|f\|_{U^1} = |\mathbb{E}f|$.

The direction list is symmetric: a permutation of its entries simply renames the cube coordinates. Directions may coincide or be trivial. For $s = 1$,

$$D_H(f)^2 = \mathbb{E}_{q \in G/H} |\mathbb{E}_{x \in q} f(x)|^2. \quad (\text{III.42.2})$$

Thus a trivial direction is meaningful and should not be discarded.

Lemma III.42.2 (Positivity, mixed Cauchy–Schwarz, and phase invariance). *The quantity in (III.42.1) is nonnegative. For functions $f_\omega : G \rightarrow \mathbb{C}$,*

$$\left| \mathbb{E}_{x \in G} \mathbb{E}_{h_r \in H_r} \prod_{\omega} \mathcal{C}^{|\omega|} f_\omega(x + \omega \cdot h) \right| \leq \prod_{\omega} D_{H_1, \dots, H_s}(f_\omega). \quad (\text{III.42.3})$$

The resulting D satisfies the triangle inequality. If $s \geq 2$ and χ is a character of G , then $D(f\chi) = D(f)$, and in particular $\|f\chi\|_{U^s} = \|f\|_{U^s}$.

Proof. Averaging the last derivative first gives

$$D_{H_1, \dots, H_s}(f)^{2^s} = \mathbb{E}_{h_1, \dots, h_{s-1}} \mathbb{E}_{q \in G/H_s} |\mathbb{E}_{x \in q} \Delta_{h_1} \cdots \Delta_{h_{s-1}} f(x)|^2. \quad (\text{III.42.4})$$

This proves positivity directly, including $s = 1$.

For the mixed inequality introduce independent $t_r^0, t_r^1 \in H_r$ and an independent $z \in G$. Set $h_r = t_r^1 - t_r^0$ and $x = z + \sum_r t_r^0$. The resulting (x, h) is uniformly distributed, so the mixed expression becomes

$$\mathbb{E}_z \mathbb{E}_{t_r^0, t_r^1} \prod_{\omega} \mathcal{C}^{|\omega|} f_{\omega} \left(z + \sum_r t_r^{\omega_r} \right).$$

For fixed z this is a product-space box form. The box Cauchy–Schwarz inequality follows by applying ordinary Cauchy–Schwarz successively to the s coordinates. At coordinate r one regards all other variables as parameters, squares the average over t_r , and introduces its independent copy. After all s steps, the factor belonging to each ω is its diagonal box form to the power $1/2^s$. This argument also proves positivity of each diagonal box form. Applying Hölder in z , with 2^s equal exponents, gives (III.42.3), because the average of each diagonal box form is exactly (III.42.1).

Expanding the diagonal cube for $f + g$ and applying (III.42.3) to its 2^{2^s} terms gives $D(f + g)^{2^s} \leq (D(f) + D(g))^{2^s}$. Finally, an alternating cube of a character is identically one when $s \geq 2$: both its constant exponent and each linear increment exponent cancel. This proves phase invariance. $\square$

For reference, normalized Fourier coefficients are

$$\widehat{f}(\chi) = \mathbb{E}_x f(x) \overline{\chi(x)}.$$

Orthogonality gives Parseval and the fourth-moment identity

$$\sum_{\chi} |\widehat{f}(\chi)|^2 = \|f\|_2^2, \quad \|f\|_{U^2}^4 = \sum_{\chi} |\widehat{f}(\chi)|^4. \quad (\text{III.42.5})$$

The second identity follows by expanding all four factors of the parallelogram and averaging the three independent variables. Their character constraints leave one freely chosen frequency. These normalizations are used throughout the sharpness argument.

III.43 The two-function directional estimate

Source 20, delivered Section 3.

Let Ω be a finite abelian parameter group, and let $L_1, \dots, L_k : \Omega \rightarrow G$ be surjective homomorphisms. Write

$$\Lambda_L(f_1, \dots, f_k) = \mathbb{E}_{z \in \Omega} \prod_{i=1}^k f_i(L_i z), \quad K_j = \ker L_j, \quad H_{ij} = L_i(K_j) \quad (i \neq j). \quad (\text{III.43.1})$$

For a fixed position i , set

$$D_i(f) = D_{(H_{ij})_{j \neq i}}(f). \quad (\text{III.43.2})$$

This is an order $k - 1$ directional seminorm. There is no pairwise independence assumption in this definition.

III.43.1 The last two coordinates have a common quotient

Lemma III.43.1 (Joint fibers). *For distinct i, j , there is an isomorphism*

$$\theta_{ij} : G/H_{ij} \longrightarrow G/H_{ji}$$

such that the uniform law of $(L_i z, L_j z)$ can be sampled as follows: choose $q \in G/H_{ij}$ uniformly, then choose independently a uniform $u \in q$ and a uniform $v \in \theta_{ij}(q)$. Consequently

$$\mathbb{E}_z F(L_i z) Q(L_j z) = \mathbb{E}_q (\mathbb{E}_{u \in q} F(u)) \left(\mathbb{E}_{v \in \theta_{ij}(q)} Q(v) \right). \quad (\text{III.43.3})$$

Proof. Let $J = (L_i, L_j)(\Omega) \leq G \times G$. Both projections of J are surjective. Its horizontal kernel is $H_{ij} \times \{0\}$ and its vertical kernel is $\{0\} \times H_{ji}$. If $(u, v) \in J$, the class of v modulo H_{ji} depends only on the class of u modulo H_{ij} : two choices differ by a horizontal or vertical kernel element. This constructs an isomorphism θ_{ij} ; symmetry supplies its inverse. For each q , the elements of J above q are precisely the Cartesian product $q \times \theta_{ij}(q)$. These products all have the same size. A homomorphism from Ω to J has equal-size fibers, so uniform z induces uniform measure on J . Formula (III.43.3) follows. $\square$

Lemma III.43.2 (One kernel-averaging step). *Let $L : \Omega \rightarrow G$ be surjective, $K = \ker L$, and let $a : G \rightarrow \mathbb{C}$. For any $F : \Omega \rightarrow \mathbb{C}$,*

$$|\mathbb{E}_z a(Lz) F(z)|^2 \leq \|a\|_2^2 \mathbb{E}_{z \in \Omega} \mathbb{E}_{h \in K} F(z) \overline{F(z+h)}. \quad (\text{III.43.4})$$

The expression on the right after $\|a\|_2^2$ is real and nonnegative.

Proof. Disintegrate uniform measure on Ω over the fibers of L . The left-hand average is $\mathbb{E}_{v \in G} a(v) \mathbb{E}_{z \in L^{-1}(v)} F(z)$. Cauchy–Schwarz bounds its square by $\|a\|_2^2$ times the average of the squared fiber means. Two independent points in the same fiber have the form $(z, z+h)$ with h uniform in K , proving the identity and nonnegativity. $\square$

Theorem III.43.3 (Two marked functions, with an L^2 gain). *Assume $k \geq 3$. For any three distinct positions i, j, ℓ and any functions $f_1, \dots, f_k : G \rightarrow \mathbb{C}$,*

$$|\Lambda_L(f_1, \dots, f_k)| \leq D_i(f_i) D_j(f_j) \|f_\ell\|_2 \prod_{r \notin \{i, j, \ell\}} \|f_r\|_\infty. \quad (\text{III.43.5})$$

For $k = 2$, the corresponding assertion is $|\Lambda_L(f_1, f_2)| \leq D_1(f_1) D_2(f_2)$. The numerical constant one is best possible.

Proof. If an unmarked factor is identically zero, there is nothing to prove. By homogeneity, normalize all factors outside $\{i, j, \ell\}$ to have supremum norm at most one. Eliminate the $r = k - 2$ unmarked positions in an order $a_1 = \ell, a_2, \dots, a_r$.

After t eliminations let $h_b \in K_{a_b}$, $1 \leq b \leq t$, and put

$$F_q^{(t)}(z; h) = \Delta_{L_q h_1} \cdots \Delta_{L_q h_t} f_q(L_q z), \quad A_t = \mathbb{E}_{h_1, \dots, h_t, z} \prod_{q \notin \{a_1, \dots, a_t\}} F_q^{(t)}(z; h).$$

Thus $A_0 = \Lambda_L(f)$. Lemma III.43.2, first with L_ℓ , gives $|A_0|^2 \leq \|f_\ell\|_2^2 A_1$. At a later step, the factor $F_{a_{t+1}}^{(t)}$ is invariant under $z \mapsto z + h_{t+1}$ for $h_{t+1} \in K_{a_{t+1}}$, and is one-bounded. Apply the same

averaging and Cauchy–Schwarz argument on the product probability space of z and all previous h_b . It gives $|A_t|^2 \leq A_{t+1}$. Each A_{t+1} so obtained is nonnegative. Iteration yields

$$|\Lambda_L(f)|^{2^r} \leq \|f_\ell\|_2^{2^r} A_r. \quad (\text{III.43.6})$$

Only i, j remain in A_r .

For a fixed list $h = (h_1, \dots, h_r)$ apply Lemma III.43.1 to their derivative functions. Define

$$M_i(h, q) = \mathbb{E}_{x \in q} \Delta_{L_i h_1} \cdots \Delta_{L_i h_r} f_i(x),$$

and define M_j using the corresponding coset $\theta_{ij}(q)$. Then $A_r = \mathbb{E}_{h, q} M_i(h, q) M_j(h, \theta_{ij}(q))$. Cauchy–Schwarz on this joint probability space gives

$$|A_r| \leq (\mathbb{E}_{h, q} |M_i(h, q)|^2)^{1/2} (\mathbb{E}_{h, q} |M_j(h, \theta_{ij}(q))|^2)^{1/2}.$$

The first squared moment is exactly

$$\mathbb{E}_{h_1, \dots, h_r} \mathbb{E}_{x \in G} \mathbb{E}_{t \in H_{ij}} \Delta_{L_i h_1} \cdots \Delta_{L_i h_r} f_i(x) \overline{\Delta_{L_i h_1} \cdots \Delta_{L_i h_r} f_i(x+t)} = D_i(f_i)^{2^{r+1}}.$$

Indeed $L_i h_b$ is uniform in H_{i, a_b} , and these images are independent for different b . The same computation gives $D_j(f_j)^{2^{r+1}}$ for the other moment. Combining with (III.43.6) and taking the 2^r -th root proves (III.43.5). Restoring the normalized supremum norms gives the stated homogeneous form.

For $k = 2$, apply Cauchy–Schwarz directly to (III.43.3) and use (III.42.2). Taking every function to be the constant one shows that the numerical constant cannot be decreased. $\square$

[write] **6 October 2026; sources 15–20.** *Credit.* For admissible slope systems this is source 06’s Theorem III.5.1, display (III.5.7); here for arbitrary surjective homomorphisms, with directional seminorms. The one-function form is Gowers’s Theorem 3.2 (`theorem_3_2`, `Sections01_03.lean`, line 258; exact companion `theorem_3_2_holds`, `Proofs03ProgressionAverage.lean`, line 381, at HEAD 0b4890a1c, for prime N and $k \leq N$).

Corollary III.43.4 (Pair-independent systems). *If $(L_i, L_j) : \Omega \rightarrow G^2$ is surjective for every $i \neq j$, then*

$$|\Lambda_L(f)| \leq \|f_i\|_{U^{k-1}} \|f_j\|_{U^{k-1}} \|f_\ell\|_2 \prod_{r \notin \{i, j, \ell\}} \|f_r\|_\infty. \quad (\text{III.43.7})$$

Proof. Pair surjectivity is equivalent to $H_{ij} = G$ for all distinct pairs, so all directional norms in Theorem III.43.3 are global norms. $\square$

Remark III.43.5 (Why two functions survive). The last step in a one-function proof bounds the penultimate function by one. In (III.43.6) we stop one step earlier and estimate the two remaining conditional means symmetrically. Their squares supply the last direction for both marked functions. This is why the output is a product, not merely the smaller of two one-function bounds.

For $k = 3$ and the usual progression forms, Fourier inversion gives a useful independent check:

$$\Lambda_3(f, g, h) = \sum_x \widehat{f}(\chi) \widehat{g}(\chi^{-2}) \widehat{h}(\chi).$$

When multiplication by two is invertible, Hölder with exponents 4, 4, 2, and Parseval, gives any appropriate two U^2 factors and one L^2 factor. Theorem III.43.3 extends this mechanism beyond the Fourier-linear case and records the exact subgroups when invertibility fails.

III.44 Sharp conversion from directional to global norms

Source 20, delivered Section 4.

Theorem III.44.1 (Finite-index comparison, with equality examples). *Let $s \geq 2$, let $H_1, \dots, H_s \leq G$, and put $m_r = [G : H_r]$. For every $f : G \rightarrow \mathbb{C}$,*

$$D_{H_1, \dots, H_s}(f) \leq \left(\prod_{r=1}^s m_r \right)^{1/2^s} \|f\|_{U^s}. \quad (\text{III.44.1})$$

For this fixed subgroup tuple, the displayed constant is optimal. In fact equality holds for every nonzero function supported on a single coset of $H_ := \bigcap_r H_r$.*

Proof. The annihilator $H_r^\perp$ consists of the m_r characters trivial on H_r . Orthogonality gives

$$m_r 1_{H_r}(h) = \sum_{\chi \in H_r^\perp} \chi(h).$$

Insert these identities into the normalized directional cube. Its 2^s -th power becomes a sum of $\prod_r m_r$ full-group cube forms, each twisted by $\prod_r \chi_r(h_r)$. The twist can be absorbed into characters multiplying the vertex functions, since $\chi_r(h_r) = \chi_r(x + h_r) \overline{\chi_r(x)}$. More explicitly, multiply the origin function by $\prod_r \overline{\chi_r}$ and the function at singleton vertex e_r by $\overline{\chi_r}$; conjugation at the singleton supplies the required positive character. All other vertex functions remain f . Lemma III.42.2 bounds the absolute value of each twisted form by $\|f\|_{U^s}^{2^s}$, using $s \geq 2$ for character invariance. Summing proves (III.44.1).

If $\text{supp } f \subset x_0 + H_*$, every nonzero cube integrand has its origin and each singleton vertex in that coset. Hence every increment lies in H_* , and in particular in its prescribed H_r . The unrestricted and restricted cube sums therefore have identical nonzero summands. Only their normalizations differ, by exactly $\prod_r [G : H_r]$. This proves equality of the powers and thus equality in (III.44.1). The all-zero list of the first $s - 1$ increments in (III.42.4) shows that $U^s(f) > 0$ for nonzero f when $s \geq 2$. Thus these examples prove optimality of the constant. $\square$

[write] **6 October 2026; sources 15–20.** *Relation to source 10.* Source 10's Theorem III.28.2 pays a kernel factor $K^{1/2^{k-1}}$ for non-invertible coefficient differences, sharp on $(\mathbb{Z}/2\mathbb{Z})^n$ (Proposition III.28.4); this theorem is the general directional-to-global conversion, with the optimal constant for every fixed subgroup tuple. With Proposition III.46.1 it answers source 06's Question 7 for the norm-conversion step (item III.9); the full multilinear optimum stays open (this source's Section V.84).

The restriction $s \geq 2$ is necessary: a nontrivial character trivial on a proper H has $D_H(f) = 1$ but $U^1(f) = 0$. Optimality in Theorem III.44.1 concerns norm conversion. It does not imply that multiplying two such constants gives the best possible constant in every multilinear counting inequality; the two equality conditions may be incompatible with the other functions.

Corollary III.44.2 (Global two-function estimate with explicit costs). *For the system (III.43.1) with $k \geq 3$, put*

$$\kappa_i = \left(\prod_{j \neq i} [G : H_{ij}] \right)^{1/2^{k-1}}. \quad (\text{III.44.2})$$

Then the right-hand side of (III.43.7), multiplied by $\kappa_i \kappa_j$, bounds $|\Lambda_L(f)|$.

Proof. Apply Theorem III.44.1 to each of the two directional norms in Theorem III.43.3. $\square$

III.44.1 Scalar progressions and composite moduli

For $L_i(x, y) = x + c_i y$, one has

$$H_{ij} = (c_i - c_j)G, \quad [G : H_{ij}] = |G[c_i - c_j]|, \quad (\text{III.44.3})$$

where $G[d] = \{x \in G : dx = 0\}$. The second identity is the finite kernel–image formula. In particular, on $\mathbb{Z}/N\mathbb{Z}$,

$$\kappa_i = \left(\prod_{j \neq i} \gcd(N, c_i - c_j) \right)^{1/2^{k-1}}. \quad (\text{III.44.4})$$

This formula remains meaningful with repeated slopes, with $\gcd(N, 0) = N$. For consecutive slopes labeled $0, \dots, k-1$,

$$\kappa_i \leq (i!(k-1-i)!)^{1/2^{k-1}}. \quad (\text{III.44.5})$$

Indeed each positive greatest common divisor is at most the corresponding nonzero integer difference. The central positions minimize this crude factorial envelope; this need not identify the minimizing positions for the actual gcd product for a given modulus.

As a small example, the slopes $0, 1, 2$ on $\mathbb{Z}/6\mathbb{Z}$ have $\kappa_0 = \kappa_2 = 2^{1/4}$ and $\kappa_1 = 1$. A bound using the middle position and either endpoint has conversion cost $2^{1/4}$; a bound using both endpoints has cost $\sqrt{2}$. Choosing the marked positions is therefore a genuinely quantitative decision when the available norm bounds are unequal.

III.44.2 Why a torsion-independent global bound can fail

Proposition III.44.3 (A collapsed-pair obstruction). *For fixed $s \geq 2$ there are one-bounded functions on groups $G_n = \mathbb{F}_2^n$ whose U^s norms tend to zero but for which a three-term progression average with two such marked functions is one. Thus no group-size-independent global two-function bound can ignore collapsed directions in arbitrary finite abelian groups.*

Proof. Assign independent uniform unit-circle phases $v(x)$ to points of a group G of size N . In the expected s -cube product, a nonzero contribution requires every point to occur equally often at even and odd vertices. In particular the even origin must agree with some odd vertex. For each of the 2^{s-1} odd vertices ω , $\omega \cdot h = 0$ has probability $1/N$, because at least one coefficient is one. A union bound gives

$$\mathbb{E}_v \|v\|_{U^s}^{2^s} \leq 2^{s-1}/N.$$

There is therefore a choice v_n with $U^s(v_n) \rightarrow 0$ on G_n . Take $f_0 = v_n$, $f_1 = 1$, $f_2 = \overline{v_n}$. In characteristic two, $x + 2y = x$, so their three-term average is $\mathbb{E}_{x,y} |v_n(x)|^2 = 1$. Both marked norms tend to zero. The subgroup $H_{02} = \{0\}$ is precisely the collapsed direction that the directional theorem retains. $\square$

III.45 Second-order telescoping and counting

Source 20, delivered Section 5.

Let $a_i : G \rightarrow [0, 1]$, let $\delta_i = \mathbb{E} a_i$, and put $b_i = a_i - \delta_i$ and $\sigma_i = \|b_i\|_2$. Then $\|a_i\|_2 \leq \sqrt{\delta_i}$ and $\sigma_i \leq \sqrt{\delta_i(1 - \delta_i)}$. For indicator functions the latter inequality is equality.

Lemma III.45.1 (First-two-residual identity). *For any scalars $a_i = \delta_i + b_i$, $1 \leq i \leq k$,*

$$\begin{aligned} \prod_{r=1}^k a_r &= \prod_{r=1}^k \delta_r + \sum_{i=1}^k b_i \prod_{r \neq i} \delta_r \\ &\quad + \sum_{1 \leq i < j \leq k} \left(\prod_{\substack{r < j \\ r \neq i}} \delta_r \right) b_i b_j \prod_{r > j} a_r. \end{aligned} \quad (\text{III.45.1})$$

Proof. Expand the product by the set of positions at which b is chosen. The empty set and singleton sets give the first two terms. Every other set has unique first two elements $i < j$. All preceding positions except i contribute δ , the positions i, j contribute b , and the remaining positions are unrestricted choices of δ or b , summing to $\prod_{r > j} a_r$. This partitions all terms exactly once. $\square$

Write

$$w_{ij} = \prod_{\substack{r < j \\ r \neq i}} \delta_r, \quad u_i = \|b_i\|_{U^{k-1}}. \quad (\text{III.45.2})$$

Surjectivity of L_i kills every singleton term after averaging. When the system is pair-independent, it also kills the term with only b_i, b_j and no tail.

Theorem III.45.2 (Quadratic counting, unequal densities). *For arbitrary surjective $L_1, \dots, L_k$ with $k \geq 3$,*

$$\left| \Lambda_L(a_1, \dots, a_k) - \prod_r \delta_r \right| \leq \sum_{i < j} w_{ij} \kappa_i \kappa_j u_i u_j. \quad (\text{III.45.3})$$

If the system is pair-independent, define, for $j < k$,

$$\mathcal{R}_j = \min \left\{ \min_{\ell > j} \sqrt{\delta_\ell}, \quad \sum_{\ell > j} \left(\prod_{j < r < \ell} \delta_r \right) \sigma_\ell \right\}. \quad (\text{III.45.4})$$

Then

$$\boxed{\left| \Lambda_L(a_1, \dots, a_k) - \prod_r \delta_r \right| \leq \sum_{i < j < k} w_{ij} u_i u_j \mathcal{R}_j.} \quad (\text{III.45.5})$$

Every permutation of the positions gives another valid bound.

Proof. Apply (III.45.1) to $a_r(L_r z)$ and average. Each summand after the singleton terms is

$$w_{ij} \mathbb{E}_z b_i(L_i z) b_j(L_j z) \prod_{r > j} a_r(L_r z). \quad (\text{III.45.6})$$

Insert constant-one functions at the unused positions. Corollary III.44.2 bounds its absolute value by $w_{ij} \kappa_i \kappa_j u_i u_j$, since all unmarked factors are one-bounded. Summing proves (III.45.3).

Now assume pair independence. When $j = k$, the average in (III.45.6) factors as $(\mathbb{E} b_i)(\mathbb{E} b_j) = 0$. For $j < k$, choose any $\ell > j$ as the L^2 factor in Corollary III.43.4. This gives the first bound $u_i u_j \min_{\ell > j} \sqrt{\delta_\ell}$ for the average in (III.45.6).

For the second bound use the exact first-residual identity in the tail:

$$\prod_{r>j} a_r = \prod_{r>j} \delta_r + \sum_{\ell>j} \left(\prod_{j<r<\ell} \delta_r \right) b_\ell \prod_{r>\ell} a_r.$$

The constant-tail contribution vanishes by pair independence. In each remaining contribution use b_ℓ as the L^2 factor, retaining b_i, b_j as marked functions. This gives the second expression in (III.45.4). Taking the smaller bound for each (i, j) and summing proves (III.45.5). The proof is unchanged by a permutation of the positions. $\square$

Remark III.45.3 (Order-sensitive norms). In (III.45.5), $u_i u_j$ can be replaced term by term by $\|b_i\|_{U^{k-j+1}} \|b_j\|_{U^{k-j+1}}$. Indeed the active subsystem in (III.45.6) has $k - j + 2$ positions, and the same proof applies to it. The tail expansion does not increase that number of active positions. Equivalently one may retain constant-one positions within that subsystem. The uniform highest-order version is simpler to state; the order-sensitive version can be useful in a formal or numerical optimization of the bound.

III.45.1 A single set and an explicit coefficient

Corollary III.45.4 (Symmetric quadratic counting). *Let $A \subset G$ have density $0 < \delta < 1$, and assume pair independence of the k forms. Put $u = \|1_A - \delta\|_{U^{k-1}}$. Then*

$$\left| \Lambda_L(1_A, \dots, 1_A) - \delta^k \right| \leq B_k(\delta) u^2,$$

with B_k as in (F.25.3). Equations (F.25.5) and (F.25.6) hold.

Proof. There are $j - 1$ choices of $i < j$, each with $w_{ij} = \delta^{j-2}$. The two tail bounds in (III.45.4) become $\sqrt{\delta}$ and $\sigma \sum_{r=0}^{k-j-1} \delta^r$. This proves the formula for B_k . For $k = 3$ only $j = 2$ occurs, and the smaller tail bound is σ . Using $R_m \leq \sqrt{\delta}$ and the positive series $\sum_{r \geq 0} (r+1) \delta^r = (1 - \delta)^{-2}$ proves (F.25.5).

For $0 < \delta \leq 1/2$ and $m \geq 2$,

$$\frac{\sigma(1 + \delta + \dots + \delta^{m-1})}{\sqrt{\delta}} \geq \sqrt{1 - \delta}(1 + \delta) \geq 1.$$

The last inequality follows on squaring from $\delta(1 - \delta - \delta^2) \geq 0$ in this range. Thus $R_m = \sqrt{\delta}$ for $m \geq 2$, whereas $R_1 = \sigma$. Separating the last term of the sum gives (F.25.6). $\square$

[write] **6 October 2026; sources 15–20.** *Against source 06* (proved at the write). Source 06's Corollary III.5.5 has the coefficient $\sqrt{\delta} B_k^{(06)}(\delta)$ with $B_k^{(06)}(\delta) = \sum_{t=0}^{k-3} (t+1) \delta^t$ (III.5.10). Since $R_m(\delta) \leq \sqrt{\delta}$, putting $t = j - 2$ in (F.25.3) gives $B_k(\delta) \leq \sqrt{\delta} \sum_{t=0}^{k-3} (t+1) \delta^t = \sqrt{\delta} B_k^{(06)}(\delta)$. The inequality is strict for every $k \geq 3$ and $0 < \delta < 1$: the term $j = k - 1$ carries $R_1(\delta) = \sigma < \sqrt{\delta}$ with the positive weight $(k - 2) \delta^{k-3}$. For $k = 3$ the coefficient is σ , source 06's sharp Proposition III.5.6. Ratios: 0.8536 at $k = 4$, $\delta = 1/2$; $\sqrt{0.7} = 0.8367$ at $k = 3$, $\delta = 0.3$. This advances source 06's Question 6 without settling it (item III.8).

This coefficient is the best obtained by the two explicitly specified tail estimates at each term of this fixed telescoping identity. No claim is made that it is the optimal coefficient among all counting arguments.

δ	k	$S_{k-2}(\delta)$	$B_k(\delta)$	$\sqrt{\delta^k/(2B_k(\delta))}$

0.50	5	1.750000	1.789214	0.09344992
0.50	8	1.968750	2.612818	0.02734075

Table III.45.1: Computed coefficients. The old and new error bounds are respectively $S_{k-2}u$ and $B_k u^2$, not $S_{k-2}u^2$ and $B_k u^2$. The last column is the sufficient uniformity threshold used below.

III.45.2 A torsion-inclusive symmetric statement

Without pair independence, Corollary III.44.2 and (III.45.3) give

$$\left| \Lambda_L(1_A, \dots, 1_A) - \delta^k \right| \leq C_{L,\delta} u^2, \quad C_{L,\delta} = \sum_{j=2}^k \delta^{j-2} \kappa_j \sum_{i < j} \kappa_i. \quad (\text{III.45.7})$$

In particular $C_{L,\delta} \leq \kappa_{\max}^2 / (1 - \delta)^2$. This is an explicit bound on every finite abelian group. It may be weak when a direction collapses, and Proposition III.44.3 explains why some loss is then unavoidable.

III.46 Pair correlations as an exact torsion correction

Source 20, delivered Section 6.

The directional estimate can be complemented by an exact Fourier description of the first obstruction to a product-density baseline.

Proposition III.46.1 (Pair correction and its sharp constant). *Let $f, g : G \rightarrow \mathbb{C}$ have mean zero, let d be an integer, and put $H = dG$, $m = [G : H]$. Then*

$$Q_d(f, g) := \mathbb{E}_{x,y} f(x) g(x + dy) = \sum_{\substack{\chi \in H^\perp \\ \chi \neq 1}} \hat{f}(\chi) \hat{g}(\chi^{-1}), \quad (\text{III.46.1})$$

$$|Q_d(f, g)| \leq \sqrt{m-1} \|f\|_{U^2} \|g\|_{U^2}. \quad (\text{III.46.2})$$

For $m > 1$, the constant $\sqrt{m-1}$ is optimal, also when the functions are required to be real and one-bounded.

Proof. Fourier inversion and averaging x force the two frequencies to be inverses. Averaging dy , uniform in H , forces the surviving character to lie in $H^\perp$. The zero-frequency term vanishes by centering. Hölder on the remaining $m-1$ frequencies, with exponents 4, 4, 2, and (III.42.5) prove (III.46.2). For sharpness take

$$f = g = t \sum_{\substack{\chi \in H^\perp \\ \chi \neq 1}} \chi = t(m1_H - 1), \quad 0 < t \leq 1/(m-1).$$

These are real, centered and one-bounded. Their pair correlation is $(m-1)t^2$, while each fourth power of the U^2 norm is $(m-1)t^4$. The ratio is exactly $\sqrt{m-1}$. $\square$

For $a_i = \delta_i + b_i$, the full balanced expansion separates an exact pair contribution

$$\sum_{i < j} \left(\prod_{r \notin \{i, j\}} \delta_r \right) Q_{c_j - c_i}(b_i, b_j) \quad (\text{III.46.3})$$

from terms with at least three balanced factors. Thus on a non-admissible cyclic group, keeping (III.46.3) can be preferable to regarding it as error. In the admissible case every summand is zero. The finite-index factors and this quotient-frequency correction describe the same obstruction in different languages: one is suited to Cauchy–Schwarz iteration, the other isolates the precise pair bias.

III.47 Supersaturation and the uniformity parameter

Source 20, delivered Section 7.

A *proper ordered progression* is a pair (x, y) whose k entries $x, x+y, \dots, x+(k-1)y$ are distinct and belong to A . Let $T_k^*(A)$ denote their number.

Corollary III.47.1 (Admissible supersaturation). *Suppose the consecutive progression system is admissible, $k \geq 3$, $|G| = N$, and $A \subset G$ has density $0 < \delta < 1$. With $u = \|1_A - \delta\|_{U^{k-1}}$,*

$$T_k^*(A) \geq N^2(\delta^k - B_k(\delta)u^2) - \delta N. \quad (\text{III.47.1})$$

In particular $T_k^(A) > 0$ whenever*

$$u^2 \leq \frac{\delta^k}{2B_k(\delta)}, \quad N > 2\delta^{1-k}. \quad (\text{III.47.2})$$

Proof. The normalized count includes all N^2 parameter pairs. A repeated entry implies $(r-s)y = 0$ for $0 < |r-s| < k$, hence $y = 0$ by admissibility. Exactly $|A| = \delta N$ counted pairs have zero difference. Subtract these from the lower bound supplied by Corollary III.45.4. Conditions (III.47.2) make the resulting lower bound strictly positive. $\square$

[write] **6 October 2026; sources 15–20.** *Comparison* (at the write). Source 06’s Corollary III.5.7 needs $u^2 \leq \delta^{k-1/2}/(2B_k^{(06)}(\delta)) = \delta^k/(2\sqrt{\delta}B_k^{(06)}(\delta))$; since $B_k(\delta) \leq \sqrt{\delta}B_k^{(06)}(\delta)$, the condition (III.47.2) is weaker, so this criterion is the stronger one; for the other criteria of this report see the note after Corollary III.4.4.

In Gowers’s degree- $k-2$ convention, the power parameter corresponding to the normalized cube norm is

$$\alpha = u^{2^{k-1}}. \quad (\text{III.47.3})$$

Thus the new counting error is $B_k(\delta)\alpha^{1/2^{k-2}}$, and the sufficient condition becomes

$$\alpha \leq \left(\frac{\delta^k}{2B_k(\delta)} \right)^{2^{k-2}}. \quad (\text{III.47.4})$$

For $0 < \delta \leq 1/2$, the convenient bound $B_k(\delta) \leq 4\sqrt{\delta}$ gives the simpler sufficient condition

$$\alpha \leq \left(\frac{\delta^{k-1/2}}{8} \right)^{2^{k-2}}. \quad (\text{III.47.5})$$

This improves the local symmetric threshold derived from (F.25.1), which is $\alpha \leq (\delta^k / (2S_{k-2}(\delta)))^{2^{k-1}}$. The comparison keeps the same normalized u and distinguishes a cube norm from its 2^{k-1} -th power.

III.47.1 Removing degenerate progressions with torsion

For an arbitrary finite abelian group put

$$D_k(G) = \left| \bigcup_{r=1}^{k-1} G[r] \right|.$$

The difference y gives a repeated entry precisely when its order is less than k . For each such difference at most $|A|$ starting points can contribute. Therefore (III.45.7) gives

$$T_k^*(A) \geq N^2(\delta^k - C_{L,\delta}u^2) - \delta N D_k(G). \quad (\text{III.47.6})$$

For cyclic groups this degeneracy count has the exact formula

$$D_k(\mathbb{Z}/N\mathbb{Z}) = \sum_{\substack{d|N \\ d < k}} \varphi(d), \quad (\text{III.47.7})$$

since there are $\varphi(d)$ elements of order d . This includes the zero difference through $d = 1$.

III.47.2 The no-wrap distinction

Lemma III.47.2 (A sufficient lifting condition). *Suppose $A \subset \{0, \dots, n-1\}$ is embedded in $\mathbb{Z}/N\mathbb{Z}$ and $2(n-1) < N$. Any nonconstant modular progression of length at least three contained in A is an ordinary integer progression; reversing its order if necessary gives positive difference.*

Proof. Let $a_0, \dots, a_{k-1}$ be its integer representatives. Their consecutive differences are congruent modulo N . Each lies between $-(n-1)$ and $n-1$, so the difference between any two has absolute value less than N and must be zero. They are all the same integer, which is nonzero for a nonconstant progression. $\square$

The lemma does not show that cutting an arbitrary uniform set down to a short interval preserves its balanced norm. Such a localization step can introduce unbalanced cutoff functions at precisely the positions where our quadratic argument needs small norms. This is one reason (III.47.4) is not silently promoted to a new global Szemerédi estimate. The inverse theorem, density increment, iteration losses, and localization must all be analyzed together.

III.48 A sharp quadratic obstruction for three-term counts

Source 20, delivered Section 8.

We now prove that quadratic dependence in (F.25.4) is the correct uniform exponent when $k = 3$, not just an artifact of stopping Cauchy–Schwarz early. The construction is explicit for bounded weights; a second argument transfers its scale to actual subsets.

III.48.1 An elementary even-dimensional Gauss identity

Let $p = 29$, let $G = \mathbb{F}_p^{2m}$, $N = p^{2m}$, and set $Q(x) = x_1^2 + \cdots + x_{2m}^2$. Write $e_p(t) = \exp(2\pi it/p)$.

Lemma III.48.1 (Gauss averages). *For every nonzero $t \in \mathbb{F}_p$,*

$$\mathbb{E}_{x \in G} e_p(tQ(x)) = N^{-1/2}, \quad \left| \widehat{e_p(tQ)}(\xi) \right| = N^{-1/2} \quad (\xi \in \widehat{G}). \quad (\text{III.48.1})$$

More generally, if a quadratic form in two scalar variables over $\mathbb{F}_p$ has rank r , its sum over $2m$ independent coordinate copies has normalized exponential average $N^{-r/2}$.

Proof. Let $g(t) = \sum_{z \in \mathbb{F}_p} e_p(tz^2)$. If χ is the quadratic character, counting square roots gives $g(t) = \chi(t)g(1)$ for $t \neq 0$. The change of variables $(z, w) \mapsto (z - w, z + w)$ is invertible and gives $|g(t)|^2 = \sum_{z, w} e_p(t(z^2 - w^2)) = p$. Also $\overline{g(1)} = g(-1) = \chi(-1)g(1) = g(1)$ because $p \equiv 1$ modulo four. Hence $g(t)^2 = p$, irrespective of its possible sign. The product over $2m$ coordinates is p^m , and normalization gives the first assertion of (III.48.1). Completing the square for each linear Fourier twist proves the magnitude assertion.

Every symmetric quadratic matrix over this odd-characteristic field is diagonalizable by an invertible linear change of variables. A rank- r form has r nonzero diagonal coefficients; zero directions contribute one. For each nonzero coefficient the $2m$ coordinate copies contribute $p^{-m} = N^{-1/2}$. Their product is $N^{-r/2}$. $\square$

III.48.2 Four phases and an exact rank census

Set $a = 1/16$ and

$$h(x) = a \sum_{t \in \{-2, -1, 1, 2\}} e_p(tQ(x)), \quad f(x) = h(x) - 4aN^{-1/2}, \quad w(x) = \frac{1}{2} + f(x). \quad (\text{III.48.2})$$

The conjugate pairs make h, f, w real. Their means are $\mathbb{E}h = 4aN^{-1/2}$, $\mathbb{E}f = 0$, and $\mathbb{E}w = 1/2$. Moreover $|f| \leq 4a(1 + N^{-1/2}) \leq 1/2$, so $0 \leq w \leq 1$.

Proposition III.48.2 (Exact weighted excess). *For the functions in (III.48.2),*

$$\|f\|_{U^2}^4 \leq (4a)^4/N, \quad (\text{III.48.3})$$

$$\Lambda_3(w) - \frac{1}{8} = a^3 \left(2N^{-1/2} + 62N^{-1} - 64N^{-3/2} \right). \quad (\text{III.48.4})$$

Consequently, as $m \rightarrow \infty$, $\|f\|_{U^2} \rightarrow 0$ and

$$\Lambda_3(w) - \frac{1}{8} \geq \frac{1}{128} \|f\|_{U^2}^2. \quad (\text{III.48.5})$$

Proof. Centering removes the zero Fourier coefficient. Every other coefficient of f has absolute value at most $4aN^{-1/2}$, by Lemma III.48.1. There are at most N coefficients, so (III.42.5) proves (III.48.3).

Expand $\Lambda_3(h)$ by a triple $(t_0, t_1, t_2) \in \{-2, -1, 1, 2\}^3$. At each coordinate, the quadratic form in (x, y) has symmetric matrix

$$M_t = \begin{pmatrix} t_0 + t_1 + t_2 & t_1 + 2t_2 \\ t_1 + 2t_2 & t_1 + 4t_2 \end{pmatrix}, \quad \det M_t = t_0t_1 + 4t_0t_2 + t_1t_2. \quad (\text{III.48.6})$$

Its determinant has absolute value at most 24, so vanishing modulo 29 is equivalent to integer vanishing. The only vanishing triples are $(-1, 2, -1)$ and $(1, -2, 1)$. To check this without a search oracle, solve

$$t_1(t_0 + t_2) = -4t_0t_2.$$

If $t_0 + t_2 = 0$, the right side is nonzero. For equal endpoints the solution is $t_1 = -2t_0$, which is allowed exactly for $t_0 = \pm 1$. For unequal endpoints of the same sign the required middle value has magnitude $8/3$; for unequal endpoints of opposite signs it has magnitude 8. Neither is allowed. These exhaust the possible endpoint pairs. No matrix has rank zero: subtracting its off-diagonal entry from the bottom-right entry would give $2t_2 = 0$. Thus two of the 64 matrices have rank one and 62 have rank two. Lemma III.48.1 gives

$$\Lambda_3(h) = a^3(2N^{-1/2} + 62N^{-1}).$$

Any two progression positions are independent because p is odd. Expanding the centered triple therefore gives $\Lambda_3(f) = \Lambda_3(h) - (\mathbb{E}h)^3$. The singleton and pair terms in $\Lambda_3(1/2 + f)$ vanish. This proves (III.48.4). For $N \geq 2$, its right-hand side is at least $2a^3N^{-1/2}$, whereas (III.48.3) implies $\|f\|_{U^2}^2 \leq 16a^2N^{-1/2}$. Their ratio is at least $a/8 = 1/128$. $\square$

This construction supplies small global U^2 norm through the large rank of the quadratic phase, while the two rank-one combinations in (III.48.6) preserve a larger three-term correlation. Scaling a fixed cosine alone would not establish the same exponent: it would give a cubic correlation in its small amplitude.

III.48.3 Rounding without losing the critical scale

A naive assertion that a random rounding is “close” is insufficient: the excess itself is of order $N^{-1/2}$. We need simultaneous control of a positive count excess and a fourth power of the norm of order N^{-1} . The following argument supplies that control explicitly.

Theorem III.48.3 (Quadratic sharpness for indicator sets). *There are subsets $A_m \subset \mathbb{F}_{29}^{2m}$, for all sufficiently large m , with densities $\delta_m \rightarrow 1/2$ and $u_m = \|1_{A_m} - \delta_m\|_{U^2} \rightarrow 0$, such that*

$$\Lambda_3(1_{A_m}) - \delta_m^3 \geq c_* u_m^2 \tag{III.48.7}$$

for an absolute $c_* > 0$. Consequently, for every $\eta > 0$, no constant C_η can bound all these errors by $C_\eta u_m^{2+\eta}$. The failure also holds uniformly for densities in any fixed neighborhood of $1/2$.

Proof. Include each x independently with probability $w(x)$ from (III.48.2). Let $B_x = 1_A(x)$, $\delta_A = \mathbb{E}_x B_x$, and put

$$X_A = \Lambda_3(1_A) - \delta_A^3, \quad S_A = \|1_A - \delta_A\|_{U^2}^4.$$

We first show, for all sufficiently large N , that

$$\mathbb{E}_A X_A \geq cN^{-1/2}, \quad \mathbb{E}_A S_A \leq C/N, \quad c = a^3, \quad C = 8((4a)^4 + 2) = 513/32. \tag{III.48.8}$$

All three points of a progression are distinct unless $y = 0$. Off that diagonal, independence gives the product of the three probabilities. On the diagonal, $B_x^3 = B_x$ and $w(x) \geq w(x)^3$. Therefore $\mathbb{E}_A \Lambda_3(1_A) \geq \Lambda_3(w)$. Writing $\xi_x = B_x - w(x)$ and expanding the cube of their average gives

$$\mathbb{E}_A \delta_A^3 = \delta^3 + \frac{3\delta}{N} \mathbb{E}_x w(x)(1 - w(x)) + \frac{1}{N^2} \mathbb{E}_x w(x)(1 - w(x))(1 - 2w(x)), \tag{III.48.9}$$

where $\delta = 1/2$. Since $w(1-w) \leq 1/4$, Proposition III.48.2 yields

$$\mathbb{E}_A X_A \geq 2a^3 N^{-1/2} - \frac{3}{8N} - \frac{1}{4N^2} \geq a^3 N^{-1/2}$$

for sufficiently large N .

For the second assertion, note that $1_A - \delta_A = f + (\xi - \mathbb{E}_x \xi_x)$. By (III.42.5), subtracting the mean removes a nonnegative term from the fourth power of a U^2 norm. Also

$$\mathbb{E}_A \|\xi\|_{U^2}^4 \leq 2/N. \quad (\text{III.48.10})$$

To prove (III.48.10), expand the parallelogram. Independence and $\mathbb{E}_A \xi_x = 0$ kill any term with a point appearing exactly once. In an odd-order group, a parallelogram with no singleton among its four vertices must have $h = 0$ or $k = 0$. Indeed its three possible pairings give respectively $h = 0$, $k = 0$, or $h = k$ and $2h = 0$; the last case is also zero. The union has normalized measure at most $2/N$, and the absolute value of each expected product is at most one. The triangle inequality and $(v+w)^4 \leq 8(v^4 + w^4)$ now give

$$\mathbb{E}_A S_A \leq 8 \left(\|f\|_{U^2}^4 + \mathbb{E}_A \|\xi\|_{U^2}^4 \right) \leq C/N,$$

which proves (III.48.8).

The already proved three-term counting inequality implies $|X_A| \leq \sqrt{S_A}$ for every realization (in fact the prefactor is at most $1/2$). Let $E = \{X_A \geq c/(2\sqrt{N})\}$. By Cauchy–Schwarz,

$$\frac{c}{\sqrt{N}} \leq \mathbb{E}_A X_A \leq \frac{c}{2\sqrt{N}} + \mathbb{E}_A(1_E \sqrt{S_A}) \leq \frac{c}{2\sqrt{N}} + \sqrt{C/N} \sqrt{\Pr(E)}.$$

Consequently $\Pr(E) \geq c^2/(4C)$. Set $K = 8C^2/c^2$. Markov's inequality gives $\Pr(S_A > K/N) \leq c^2/(8C)$. Finally $\text{Var}(\delta_A) \leq 1/(4N)$, so

$$\Pr(|\delta_A - 1/2| > N^{-1/4}) \leq 1/(4\sqrt{N}).$$

For all sufficiently large N , these estimates leave a positive probability of all three events

$$X_A \geq c/(2\sqrt{N}), \quad S_A \leq K/N, \quad |\delta_A - 1/2| \leq N^{-1/4}.$$

Choose one such realization for each large m . Then $u_m^2 = \sqrt{S_{A_m}} \leq \sqrt{K/N}$ and (III.48.7) holds with $c_* = c/(2\sqrt{K}) > 0$. The norm cannot be zero when $X_A > 0$. Dividing by $u_m^{2+\eta}$ now yields a lower bound $c_* u_m^{-\eta} \rightarrow \infty$, proving the claimed impossibility. $\square$

[write] **6 October 2026; sources 15–20.** New in this report: source 06's three-term coefficient is sharp only at singletons ($\delta = 1/N$); this theorem shows that the exponent 2 cannot be raised at fixed density near $1/2$, for indicator sets on $\mathbb{F}_{29}^{2m}$. Not for prime cyclic groups or $k \geq 4$ (the source's non-claims; item III.8).

The constant c_* is intentionally crude. The theorem determines an exponent, not the optimal coefficient in the indicator-set extremal problem. The finite check of the weight construction uses $m = 1$; the existence proof for the rounded sets is asymptotic and does not claim that its crude probability thresholds are useful computationally.

III.49 Source 21's chapter: the exponent-five coefficient, with source 23's second route [write]

Added in the fifth write, 6 October 2026.

The next ten sections settle the question that source 14's Theorem III.35.2 left open: on groups of exponent five, the first correction after $6\sqrt{2}\delta^4u^4$ in the centered three-cube problem has exponent six, and its coefficient is now known. Sections III.50–III.57 are source 21, the main source; Sections III.58–III.59 are source 23's Section 7 and Appendix A, an independent proof of the same theorem, written the same day from a pin three minutes later, printed here as a credited second route. Neither source cites the other; both cite source 14's manuscript. *Logically the chapter follows source 14's Section III.35*; it is printed here, at the end of Part III, because no number printed earlier may move. Source 21's introduction, with the main theorem (Theorem F.26.1), is Section F.26; its repository interface, questions and appendices are in Part V (Sections V.87–V.90). Source 23's introduction is Section F.28. Their notation is in the table at the head of this Part.

What is proved, in one paragraph. For real centered f on any nontrivial finite abelian group of exponent five and $u = \|f\|_{U^3} \leq c\delta$, $Q_3(\delta + f) \leq \delta^8 + 6\sqrt{2}\delta^4u^4 + C_5\delta^2u^6 + Cu^8$ with $C_5 = 2^{3/4}/3$ and absolute c, C , sharp on every fixed such group (source 21's Theorem F.26.1, Corollary III.55.2; source 23's Theorem III.58.1). The mechanism is the same in both: a positive cubic statistic controls the sixth- and seventh-degree terms through the Fourier tail, and the order-five resonance makes the cost of the second harmonic quadratic. Source 21 also proves the phase envelope $C_5(\cos\theta)_+^2/(1+\cos^2\phi)$ (Theorem III.53.2), rigidity of near-extremizers (Theorem III.54.1; source 23's Theorem III.58.3 is equivalent), the next coefficient 20/9 on $\mathbb{Z}/5\mathbb{Z}$ for the maximum (Theorem III.55.1; source 23's Appendix A computes 20/9 for one model, a lower bound), indicator sharpness through u^8 as lower examples (Theorem III.56.1; source 23 through u^6) and a projection consequence of cube Cauchy–Schwarz (Proposition III.57.1). The universal coefficient of u^8 is open (item III.27).

Relation to the formal statements (checked at HEAD 2dfe46f44). `lemma_3_10` (Sections01_0 3.lean, line 340) is an exact companion (`lemma_3_10_holds`, Proofs03CubeUpper.lean, line 82), as source 21 records; no characteristic-five or cube-expansion declaration exists. Nothing in this chapter is formalized.

III.50 Fourier identities and the sharp quartic deficit

Source 21, delivered Section 2.

For $f : G \rightarrow \mathbb{C}$, our Fourier convention is

$$a_r = \widehat{f}(r) = \mathbb{E}_{x \in G} f(x) \overline{r(x)}, \quad f(x) = \sum_{r \in \widehat{G}} a_r r(x).$$

Throughout the main argument f is real and centered, so $a_{-r} = \overline{a_r}$ and $a_0 = 0$. Set

$$\lambda_r = |a_r|^2, \quad S = \sum_r |a_r|^4 = \|f\|_{U^2}^4, \quad M = \sum_r |a_r|^8. \quad (\text{III.50.1})$$

All sums on the dual group are unnormalized.

Lemma III.50.1 (A sum of Fourier squares). *Define*

$$T(s, t) = \sum_r a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}. \quad (\text{III.50.2})$$

Then

$$\|f\|_{U^3}^8 = \sum_{s,t} |T(s,t)|^2. \quad (\text{III.50.3})$$

For real f , $T(s,t)$ is real, is symmetric in s,t , and is unchanged by replacing either s or t by its negative.

Proof. Insert Fourier inversion in the eight-vertex cube. Averaging over x, h_1, h_2, h_3 imposes the four equations

$$\sum_{\omega} r_{\omega} = 0, \quad \sum_{\omega} \omega_j r_{\omega} = 0 \quad (1 \leq j \leq 3).$$

Their solutions are precisely the parity-adjusted affine frequency cubes. Grouping two opposite faces gives the expansion of the right side of (III.50.3). Equivalently, one can expand the right side and use its four free frequencies as parameters for the same four equations. This parameterization uses only invertible integer changes of variables, so the identity holds on every finite abelian group.

In (III.50.2), the substitution $r \mapsto -r - s - t$ pairs each summand with its complex conjugate because $a_{-r} = \overline{a_r}$. Hence T is real. Interchanging s, t is immediate; shifting the base r after changing the sign of one increment conjugates T , and so leaves it unchanged in the real case. $\square$

Define the positive energy

$$\mathcal{E}(\lambda) = \sum_{r+s=t+w} \lambda_r \lambda_s \lambda_t \lambda_w = \sum_v (\lambda * \lambda)(v)^2,$$

where the convolution is an unnormalized sum. Since λ is even, $T(0,t) = \sum_r \lambda_r \lambda_{r+t}$, and $T(0,0) = S$. The two axes of (III.50.3) therefore contribute exactly

$$2\mathcal{E}(\lambda) - S^2. \quad (\text{III.50.4})$$

Lemma III.50.2 (Quartic comparison and concentration). *For every real centered f on an odd-order finite abelian group,*

$$u^8 \geq 5S^2 - 6M \geq 2S^2, \quad u = \|f\|_{U^3}. \quad (\text{III.50.5})$$

If $f \neq 0$, choose a largest conjugate pair $\{\xi, -\xi\}$ and put

$$\rho = |a_{\xi}|, \quad D = \sum_{r \notin \{\xi, -\xi\}} |a_r|^4, \quad S = 2\rho^4 + D. \quad (\text{III.50.6})$$

Then

$$u^8 \geq 2S^2 + 3DS. \quad (\text{III.50.7})$$

In particular, equality in $u^8 \geq 2S^2$ for nonzero f forces exactly one conjugate Fourier pair. In exponent five, every such pair gives equality.

Proof. Write the energy as a sum over $r + s + t + w = 0$. Retain the union of the three families obtained by pairing the four entries into opposite pairs. Each family has weight S^2 , every pairwise intersection has weight M , and the triple intersection has weight zero: it requires $2r = 0$, and the zero Fourier coefficient vanishes. Thus $\mathcal{E}(\lambda) \geq 3S^2 - 3M$. Combine this with (III.50.4).

The nonzero Fourier coefficients come in conjugate pairs. If their fourth-power masses are $x_j = 2|a_{r_j}|^4$, then $S = \sum_j x_j$ and $M = \frac{1}{2} \sum_j x_j^2 \leq S^2/2$. This proves the second inequality and its necessary equality case. Maximality also gives $M \leq \rho^4 S = (S - D)S/2$, yielding (III.50.7). For a pure pair of order five, directly evaluating (III.50.3) gives $u^8 = 8\rho^8 = 2S^2$. $\square$

[write] **6 October 2026; sources 21–27.** *Credit.* The inequality $u^8 \geq 2S^2$ for real centered f on odd-order groups is source 04's Theorem III.3.4; source 14 reproves it (its display (III.34.8)). The refinement (III.50.7) with the tail D is the form used below.

The last sufficiency statement was restricted deliberately. For example, short resonances at order three change the norm of a pure pair. The present report does not silently extend an exponent-five equality formula to all odd orders.

III.51 Higher centered coefficients with a retained Fourier tail

Source 21, delivered Section 3.

The following exact expansion introduces the terms whose crude treatment prevented the earlier coefficient from being identified.

Lemma III.51.1 (Centered cube expansion). *On an exponent-five group,*

$$Q_3(\delta + f) = \delta^8 + 12\delta^4 S + 8\delta^3 B_5(f) + \delta^2 C_6(f) + \delta C_7(f) + u^8, \quad (\text{III.51.1})$$

where C_j is the sum of all j -vertex centered terms and

$$B_5(f) = \sum_r a_{2r} a_{-r}^3 a_r. \quad (\text{III.51.2})$$

The number $B_5(f)$ is real.

Proof. Expand the product over subsets of the eight vertices. One, two, or three distinct cube forms are jointly uniform, so centering kills their expectations. Among the 70 four-element supports, the 12 parallelograms have a one-dimensional relation and contribute S ; the other 58 supports are independent over $\mathbb{F}_5$.

Of the 56 five-element supports, 48 have a relation with a zero coefficient, forcing a factor a_0 in their Fourier expectation. The remaining eight are cube-symmetric copies of $\{000, 100, 010, 001, 111\}$. If the frequency at 111 is r , the four orthogonality equations force frequencies $2r, -r, -r, -r, r$ on this support. This proves (III.51.2). Negating r conjugates a summand, so the sum is real.

The support counts may also be checked by row reduction of the columns $(1, \omega_1, \omega_2, \omega_3)$, as described in Appendix V.89. The nonzero determinants needed for these classifications have absolute value at most two; in characteristic five their ranks agree with the stated ranks. $\square$

Cube Cauchy–Schwarz alone gives $|C_6| \leq 28u^6$ and $|C_7| \leq 8u^7$. The first of these bounds is too large to determine the coefficient of u^6 . We instead use the positive statistic

$$H = \sum_{r+s+t=0} \lambda_r \lambda_s \lambda_t. \quad (\text{III.51.3})$$

Theorem III.51.2 (Sextic and septic profile inequalities). *For every real centered f on an exponent-five group,*

$$|C_6(f)| \leq 28H, \quad |C_7(f)| \leq 8u^4 \sqrt{H}. \quad (\text{III.51.4})$$

For a largest pair and tail D as in (III.50.6),

$$H \leq 3\sqrt{D\mathcal{E}(\lambda)} \leq \frac{3\sqrt{3}}{2} u^4 \sqrt{D}. \quad (\text{III.51.5})$$

Consequently,

$$\begin{aligned} |C_6(f)| &\leq 42\sqrt{3}u^4D^{1/2}, \\ |C_7(f)| &\leq 8\sqrt{3\sqrt{3}/2}u^6D^{1/4}. \end{aligned} \tag{III.51.6}$$

No bound on $\|f\|_\infty$ is assumed.

Proof. Classify a six-vertex support by the two omitted vertices. Their Hamming distance is one, two, or three. The respective numbers of unordered pairs are 12, 12, 4. Fourier orthogonality gives the following representatives, with all frequency sums over $\hat{G}$:

Omitted vertices	Multiplicity	Six-vertex expectation
000, 001	12	H
000, 011	12	$J = \sum_{r,s} \lambda_r a_s^2 a_{r-s} \overline{a_{r+s}}$
000, 111	4	$K = \sum_{r+s+t=0} a_r^2 a_s^2 a_t^2$

Each formula follows by solving the same four equations used in Lemma III.50.1, now with the omitted frequencies set to zero. Clearly $|K| \leq H$. For J , Cauchy–Schwarz gives

$$\begin{aligned} |J| &\leq \sum_{r,s} \lambda_r \lambda_s \sqrt{\lambda_{r-s} \lambda_{r+s}} \\ &\leq \left(\sum_{r,s} \lambda_r \lambda_s \lambda_{r-s} \right)^{1/2} \left(\sum_{r,s} \lambda_r \lambda_s \lambda_{r+s} \right)^{1/2} = H, \end{aligned}$$

using evenness of λ . This proves the sextic bound.

For the septic bound, replace the zero Fourier coefficient in T by a real variable δ and differentiate at $\delta = 0$. The derivative is

$$L(s, t) = 2 \operatorname{Re}(a_s a_t \overline{a_{s+t}}) + 2 \operatorname{Re}(a_s \overline{a_t} \overline{a_{s-t}}). \tag{III.51.7}$$

This is the sum of the four terms obtained by choosing which of the four factors contains the differentiated zero coefficient. If indices coincide, the extra zero coefficients make the corresponding terms vanish, so the formula still applies. Each of these four cubic terms has squared ℓ^2 norm H . Thus $\|L\|_2 \leq 4\sqrt{H}$. Differentiating the sum of squares gives

$$C_7(f) = 2 \operatorname{Re}\langle T, L \rangle, \quad |C_7(f)| \leq 2\|T\|_2 \|L\|_2 \leq 8u^4\sqrt{H}.$$

Finally, no triple drawn from $\{\xi, -\xi\}$ sums to zero because ξ has order five. Every nonzero summand in H contains at least one tail index. Therefore

$$H \leq 3 \sum_{r \notin \{\xi, -\xi\}} \lambda_r (\lambda * \lambda)(-r) \leq 3\sqrt{D\mathcal{E}(\lambda)}.$$

The axes in (III.50.3) give $\mathcal{E}(\lambda) \leq (u^8 + S^2)/2$. Lemma III.50.2 gives $S^2 \leq u^8/2$, proving (III.51.5) and (III.51.6). $\square$

Remark III.51.3 (Why the two improvements must be used together). The new bounds express the higher coefficients in terms of the same tail D that lowers the quartic contribution. A merely qualitative statement that C_6 tends to zero near a pure pair would give a sharp coefficient with an unspecified little-oh error. The powers $D^{1/2}$ and $D^{1/4}$ allow the explicit $O(u^8)$ remainder.

III.52 The characteristic-five resonance and a finite bound

Source 21, delivered Section 4.

For a largest pair, set $b = |a_{2\xi}|$. The pair $\{2\xi, -2\xi\}$ is distinct from $\{\xi, -\xi\}$, so $2b^4 \leq D$. When $b > 0$, write

$$a_\xi = \rho e^{i\alpha}, \quad a_{2\xi} = be^{i\beta}, \quad \theta = 2\alpha - \beta, \quad \phi = 3\alpha + \beta. \quad (\text{III.52.1})$$

These phases are understood modulo 2π . Notice the useful identity $\theta + \phi = 5\alpha$.

Theorem III.52.1 (A joint norm penalty). *With the preceding notation,*

$$u^8 \geq 2S^2 + 12\rho^4 D + 16\rho^6 b^2. \quad (\text{III.52.2})$$

Let $D_{\text{out}} = \sum_{r \notin \langle \xi \rangle} |a_r|^4$. If $b > 0$, the stronger finite inequality is

$$u^8 \geq 2S^2 + 12\rho^4 D + 16\rho^6 b^2 + 4 \left(2\rho^3 b |\cos \phi| - D_{\text{out}} \right)_+^2. \quad (\text{III.52.3})$$

Proof. In the four-frequency zero-sum representation of $\mathcal{E}(\lambda)$, retain, in addition to the three opposite-pair families, all permutations of $(\xi, \xi, \xi, 2\xi)$ and of its negative. There are eight such ordered tuples, each with weight $\rho^6 b^2$. They sum to zero because $5\xi = 0$, and none belongs to a retained opposite-pair family. Thus

$$u^8 \geq 5S^2 - 6M + 16\rho^6 b^2.$$

Conjugate pairing in the tail gives $M \leq 2\rho^8 + D^2/2$. Expanding $S = 2\rho^4 + D$ now yields

$$5S^2 - 6M \geq 8\rho^8 + 20\rho^4 D + 2D^2 = 2S^2 + 12\rho^4 D.$$

For the stronger statement retain the four off-axis slots $(s, t) = (\pm 2\xi, \pm 2\xi)$ in (III.50.3). They are distinct, and all have the same T value. The contribution from bases in $\langle \xi \rangle$ is

$$T(2\xi, 2\xi) = a_\xi^3 a_{2\xi} + \overline{a_\xi^3 a_{2\xi}} + E = 2\rho^3 b \cos \phi + E.$$

For a base outside $\langle \xi \rangle$, all four shifted indices remain outside it. Hölder's inequality therefore gives $|E| \leq D_{\text{out}}$. The four retained squares contribute at least the final term in (III.52.3). $\square$

The extra term $16\rho^6 b^2$ is the decisive order-five resonance. Without such a quadratic cost in the second harmonic, balancing a quartic tail cost against the quintic gain can produce fractional powers, as in the earlier $u^{16/3}$ result. Here the balance is quadratic and forces the smaller second harmonic $b \asymp u^2/\delta$.

Proposition III.52.2 (Explicit finite Fourier-profile bound). *For every $\delta \geq 0$ and every nonzero real centered f on an exponent-five group,*

$$\begin{aligned} Q_3(\delta + f) &\leq \delta^8 + 12\delta^4 S + 16\delta^3 \rho^4 b \cos \theta + 8\delta^3 \rho D \\ &\quad + 42\sqrt{3} \delta^2 u^4 D^{1/2} + 8\sqrt{3\sqrt{3}/2} \delta u^6 D^{1/4} + u^8. \end{aligned} \quad (\text{III.52.4})$$

If $b = 0$, its cosine term is interpreted as zero. This bound and the constraints (III.52.2)–(III.52.3) are finite inequalities, with no asymptotic qualification.

Proof. The two selected summands $r = \pm \xi$ in (III.51.2) give $2\rho^4 b \cos \theta$ exactly. Every other summand has absolute value at most $\rho |a_r|^4$, because ρ is the largest Fourier amplitude. Hence

$$B_5(f) = 2\rho^4 b \cos \theta + E_5, \quad |E_5| \leq \rho D. \quad (\text{III.52.5})$$

Use this identity and Theorem III.51.2 in (III.51.1). $\square$

III.53 Sharp uniform optimization and the phase envelope

Source 21, delivered Section 5.

We now prove Theorem F.26.1. The proof first locates the Fourier mass and then absorbs the remaining higher-degree terms. This order is necessary: dropping the negative tail term too early would lose the eighth-order remainder.

Lemma III.53.1 (Uniform localization). *Let $\|g\|_{U^3} = 1$, let $t > 0$, and put*

$$S_0 = 2^{-1/2}, \quad \eta = S_0 - S, \quad F = Q_3(1 + tg) - 1 - 6\sqrt{2}t^4,$$

where the Fourier statistics refer to g . If $F > 0$ and t is sufficiently small, then, with absolute implied constants,

$$\eta = O(t^2), \quad D = O(t^2), \quad b = O(t). \quad (\text{III.53.1})$$

Proof. First $S \leq S_0$ by Lemma III.50.2. Cube Cauchy–Schwarz and (III.51.1) give

$$F = -12\eta t^4 + 8B_5(g)t^5 + R, \quad |R| \leq 28t^6 + 8t^7 + t^8 \leq 37t^6 \quad (t \leq 1).$$

Also $|B_5(g)| \leq \rho S \leq 1$. Thus $F > 0$ implies $\eta = O(t)$, and S is bounded below by a positive constant for small t . Equation (III.50.7) yields

$$3DS \leq 1 - 2S^2 = 2\eta(S_0 + S),$$

so $D = O(\eta)$. It follows that $\rho^4 = (S_0 - \eta - D)/2$ is bounded below. The resonance penalty in (III.52.2) now gives $b^2 = O(\eta)$.

Equation (III.52.5) gives $|B_5(g)| = O(\sqrt{\eta} + \eta)$. Substituting in the preceding expression for F gives

$$\eta \leq At\sqrt{\eta} + Bt\eta + Ct^2$$

with absolute constants. For small t , absorb $Bt\eta$. The resulting quadratic inequality in $\sqrt{\eta}$ implies $\sqrt{\eta} = O(t)$, proving all three claims. $\square$

Proof of Theorem F.26.1, upper bound. If $u = 0$, the norm property gives $f = 0$. Otherwise set $g = f/u$ and $t = u/\delta$. Then $Q_3(\delta + f) = \delta^8 Q_3(1 + tg)$. If $F \leq 0$, the asserted upper bound is immediate, so assume $F > 0$. All the following Fourier variables refer to g .

By localization,

$$\rho^4 = 2^{-3/2} + O(t^2), \quad \rho^6 = 2^{-9/4} + O(t^2).$$

Expand (III.52.2), using $1 - 2S^2 = 2\sqrt{2}\eta - 2\eta^2$, to obtain

$$\eta \geq \frac{3}{2}D + 2^{1/4}b^2 - O(t^4). \quad (\text{III.53.2})$$

The constants are absolute. Use $B_5(g) \leq S_0 b + D$ and (III.51.6) to get

$$\begin{aligned} F \leq & -18Dt^4 - 12 \cdot 2^{1/4}b^2t^4 + 4\sqrt{2}bt^5 + 8Dt^5 \\ & + K_6t^6D^{1/2} + K_7t^7D^{1/4} + O(t^8), \end{aligned} \quad (\text{III.53.3})$$

where $K_6 = 42\sqrt{3}$ and $K_7 = 8\sqrt{3\sqrt{3}/2}$.

For sufficiently small t , $-18D + 8Dt \leq -17D$. Set $D = t^4y$. All the terms involving D in (III.53.3) are then bounded above by

$$t^8(-17y + K_6\sqrt{y} + K_7y^{1/4}) = O(t^8),$$

because the continuous expression in parentheses tends to $-\infty$ as $y \rightarrow \infty$. Finally,

$$\sup_{b \geq 0} \{-12 \cdot 2^{1/4} b^2 t^4 + 4\sqrt{2} b t^5\} = C_5 t^6, \quad b = \beta_5 t. \quad (\text{III.53.4})$$

Rescaling by δ^8 proves (F.26.2). The error is $O(\delta^8 t^8) = O(u^8)$ with an absolute constant, not merely an unspecified density-dependent error. $\square$

Theorem III.53.2 (Sharp phase-dependent coefficient). *Under the hypotheses of Theorem F.26.1, choose a largest conjugate pair. If $b > 0$ and the phases are as in (III.52.1), then, with absolute $c, C > 0$,*

$$Q_3(\delta + f) \leq \delta^8 + 6\sqrt{2} \delta^4 u^4 + C_5 \frac{(\cos \theta)_+^2}{1 + \cos^2 \phi} \delta^2 u^6 + C u^8 \quad (u \leq c\delta). \quad (\text{III.53.5})$$

For $b = 0$, the same assertion holds with the u^6 coefficient zero. For each prescribed pair of phases, the coefficient in (III.53.5) is attained asymptotically by weights on $\mathbb{Z}/5\mathbb{Z}$.

Proof. As before, the case $F \leq 0$ is immediate. In the case $F > 0$, localization applies. The elementary inequality $(x - y)_+^2 \geq x^2 - 2xy$ for $x, y \geq 0$ turns (III.52.3) into

$$\eta \geq \frac{3}{2} D + 2^{1/4} (1 + \cos^2 \phi) b^2 - O(t^4 + bD).$$

The selected quintic term is $2\rho^4 b \cos \theta$. Replacing $2\rho^4$ by S_0 here introduces an absolute error $O((\eta + D)b) = O(t^3)$, regardless of the sign of the cosine; after multiplication by t^5 this is $O(t^8)$. The extra $O(bD)t^4$ is absorbed against the negative tail term because $b = O(t)$. The other tail terms are treated exactly as in (III.53.3).

The remaining one-variable optimization is

$$\sup_{b \geq 0} \{-12 \cdot 2^{1/4} (1 + \cos^2 \phi) b^2 t^4 + 4\sqrt{2} b \cos \theta t^5\} = C_5 \frac{(\cos \theta)_+^2}{1 + \cos^2 \phi} t^6.$$

The maximizing scale is

$$b = \beta_5 t \frac{(\cos \theta)_+}{1 + \cos^2 \phi}. \quad (\text{III.53.6})$$

For fixed phases with $\cos \theta > 0$, the exact five-point formulas in Section III.55, with unnormalized second amplitude $\beta_5 \delta^{-1} u^2 (\cos \theta)_+ / (1 + \cos^2 \phi)$, give a matching coefficient and an $O_\delta(u^8)$ error. The first amplitude is chosen to make the centered norm exactly u . If $\cos \theta \leq 0$, take a positive second amplitude $o(\delta^{-1} u^2)$ with the specified phase. The coefficient is then zero; for example $b = \delta^{-3} u^4$ gives an $O_\delta(u^8)$ error. The case $b = 0$ follows directly from the same absorption argument with no selected quintic term. $\square$

Remark III.53.3 (Real Fourier coefficients lose a factor of two). For a positive real dominant coefficient and a positive real second coefficient, $\theta = \phi = 0$. The phase factor in (III.53.5) is $1/2$. The full coefficient requires $\theta = 0$ and $\cos \phi = 0$, which can be achieved by $a_\xi = \rho e^{i\pi/10}$ and $a_{2\xi} = b e^{i\pi/5}$. The extremizing physical-space function is still real: the negative Fourier coefficients are the complex conjugates of the positive ones.

Figure III.53.1: The exact phase factor in Theorem III.53.2. The marked point $\theta = 0, \phi = \pi/2$ gives the full sharp coefficient; positive real coefficients give the value $1/2$ at $\theta = \phi = 0$. The factor vanishes when $\cos \theta \leq 0$.

III.54 Near equality and the scale of rigidity

Source 21, delivered Section 6.

Theorem III.54.1 (Second-term rigidity). *Fix $\delta > 0$. Suppose G_j are nontrivial exponent-five groups, f_j are real and centered, $0 < u_j = \|f_j\|_{U^3} \rightarrow 0$, and*

$$Q_3(\delta + f_j) = \delta^8 + 6\sqrt{2}\delta^4 u_j^4 + C_5 \delta^2 u_j^6 + o_\delta(u_j^6). \quad (\text{III.54.1})$$

For any choice of a largest conjugate pair $\{\pm \xi_j\}$, write $\hat{f}_j(\xi_j) = \rho_j e^{i\alpha_j}$ and $\hat{f}_j(2\xi_j) = b_j e^{i\beta_j}$. Then

$$\begin{aligned} b_j &\sim \beta_5 \delta^{-1} u_j^2, & e^{i(2\alpha_j - \beta_j)} &\longrightarrow 1, \\ e^{10i\alpha_j} &\longrightarrow -1, & \sum_{r \notin \{\pm \xi_j\}} |\hat{f}_j(r)|^4 &= o_\delta(u_j^6), \\ \rho_j^4 &= \frac{u_j^4}{2\sqrt{2}} - \frac{C_5}{24} \delta^{-2} u_j^6 + o_\delta(u_j^6). \end{aligned} \quad (\text{III.54.2})$$

Consequently the remainder after removing the dominant pair is $o_\delta(u_j^{3/2})$ in U^2 . This conclusion does not assert an $o(u_j^2)$ remainder or an L^2 approximation.

Proof. Normalize $g_j = f_j/u_j$, $t_j = u_j/\delta$. All variables in this paragraph refer to g_j . The localization lemma gives $D = O(t^2)$ and $b = O(t)$. Dividing the upper argument by t^6 , and retaining the phase and tail losses, gives

$$\frac{F}{t^6} \leq -18 \frac{D}{t^2} - 12 \cdot 2^{1/4} \left(\frac{b}{t}\right)^2 + 4\sqrt{2} \frac{b}{t} \cos \theta + o(1).$$

Here the sextic and septic errors are respectively $O(t)$ and $O(t^{3/2})$ after division, so both tend to zero. The quadratic has unique maximum C_5 at $b/t = \beta_5$, $\cos \theta = 1$. Thus $D/t^2 \rightarrow 0$, $b/t \rightarrow \beta_5$, and $e^{i\theta} \rightarrow 1$.

The phase envelope then forces $\cos \phi \rightarrow 0$, since its factor must tend to one. As $\theta + \phi = 5\alpha$, it follows that $e^{10i\alpha} \rightarrow -1$.

The exact expansion gives

$$C_5 = -12 \lim \frac{\eta}{t^2} + 4\sqrt{2}\beta_5.$$

Since $4\sqrt{2}\beta_5 = 2C_5$, this yields $\eta/t^2 \rightarrow C_5/12$. Finally, $\rho^4 = (S_0 - \eta - D)/2$ gives the last line of (III.54.2). Restore the powers of u_j and δ . The Fourier identity for U^2 identifies the fourth power of the remainder norm with the displayed tail mass. $\square$

[write] **6 October 2026; sources 21–27.** *The same conclusions in source 23* (checked at the write). Source 23's Theorem III.58.3 writes $a_\xi = \rho e^{i\theta}$, $a_{2\xi} = b e^{i\psi}$ (its θ, ψ are this theorem's α, β) and $\kappa = 2^{1/4}/6 = \beta_5$. Its $e^{i(\psi-2\theta)} \rightarrow 1$ is the second limit here; its $\cos(5\theta) \rightarrow 0$ is equivalent to $e^{10i\alpha} \rightarrow -1$; and its last line $\rho^4 = 2^{-3/2}u^4 - 2^{-3/4}\kappa^2\delta^{-2}u^6 + o(u^6)$ is the last line here, since $2^{-3/4}\kappa^2 = 2^{-1/4}/36 = C_5/24$.

III.54.1 Why the remainder scale cannot be silently strengthened

The forced second harmonic has amplitude of order u^2 , while the tail conclusion in Theorem III.54.1 is only $o(u^{3/2})$ in U^2 . These statements are consistent. A further independent harmonic of amplitude u^a , with $3/2 < a < 2$, can have fourth-power mass $o(u^6)$ while being larger than u^2 . Such a harmonic is invisible to extremality through order u^6 . To obtain sharper Fourier approximation one must control the objective at the next order as well.

The indicator examples in Section III.56 give a stronger obstruction to L^2 rigidity. For them the centered L^2 norm tends to $\sqrt{\delta(1-\delta)}$, even though every fixed finite collection of Fourier coefficients tends to zero. Thus the appropriate topology for the stated rigidity conclusion is essential.

III.55 The exact next coefficient on the five-point group

Source 21, delivered Section 7.

Let $G = \mathbb{Z}/5\mathbb{Z}$, and use normalized averages. For real mean-zero $f : G \rightarrow \mathbb{R}$, put $u = \|f\|_{U^3}$ and

$$Q_3(W) = \mathbb{E}_{x, h_1, h_2, h_3} \prod_{\omega \in \{0,1\}^3} W(x + \omega \cdot h).$$

For fixed $0 < \delta < 1$, let $M_{\delta,5}(u)$ be the maximum of $Q_3(W)$ over $W : G \rightarrow [0,1]$ with mean δ and $\|W - \delta\|_{U^3} = u$. The same conclusions hold with the boundedness restriction omitted and with any fixed $\delta > 0$.

Theorem III.55.1 (Third extremal term on $\mathbb{Z}/5\mathbb{Z}$). *As $u \downarrow 0$,*

$$M_{\delta,5}(u) = \delta^8 + 6\sqrt{2}\delta^4u^4 + \frac{2^{3/4}}{3}\delta^2u^6 + \frac{20}{9}u^8 + O_\delta(u^{10}).$$

The assertion concerns this fixed five-point group. It does not identify the coefficient of u^8 when the dimension of an exponent-five group is allowed to vary.

[write] **6 October 2026; sources 21–27.** *Credit and scope.* Source 23's Appendix A (Section III.59) computes the coefficient 20/9 for one five-point family, which bounds the coefficient of the maximum from below; the theorem here proves that 20/9 is the coefficient of the maximum on $\mathbb{Z}/5\mathbb{Z}$. The intake's independent

maximization on $\mathbb{Z}/5\mathbb{Z}$ (50-digit arithmetic) gave normalized eighth-order residuals 2.32462, 2.24655, 2.22823, 2.22372 at $t = 0.2, 0.1, 0.05, 0.025$, converging to $20/9 = 2.2222\dots$ with an $O(t^2)$ gap; that is evidence only. The universal coefficient, over groups of growing dimension, is open (item III.27).

III.55.1 An exact Fourier certificate with arbitrary phases

Write

$$\widehat{f}(1) = \rho e^{i\alpha}, \quad \widehat{f}(2) = b e^{i\beta}, \quad \widehat{f}(-r) = \overline{\widehat{f}(r)},$$

where $\rho, b \geq 0$, and set

$$\theta = 2\alpha - \beta, \quad \phi = 3\alpha + \beta, \quad \psi = \phi - \theta.$$

Interchanging the two conjugate frequency pairs, if necessary, makes $\rho \geq b$. For $a_r = \widehat{W}(r)$ define

$$T(s, t) = \sum_{r \in G} a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}.$$

Fourier expansion and orthogonality give $Q_3(W) = \sum_{s,t \in G} |T(s, t)|^2$. Because W is real, substitution $r \mapsto -r - s - t$ shows that $T(s, t)$ is real; shifts of r and interchange of s, t show that its value is unchanged under independent sign changes of s, t and their interchange. The following six representatives therefore exhaust all 25 slots:

(s, t)	multiplicity	$T(s, t)$
$(0, 0)$	1	$\delta^4 + 2\rho^4 + 2b^4$
$(0, 1)$	4	$2\delta^2\rho^2 + 2\rho^2b^2 + b^4$
$(0, 2)$	4	$2\delta^2b^2 + 2\rho^2b^2 + \rho^4$
$(1, 1)$	4	$\delta^2\rho^2 + 2\delta\rho^2b \cos \theta + 2\rho b^3 \cos(2\theta - \phi)$
$(2, 2)$	4	$\delta^2b^2 + 2\delta\rho b^2 \cos \psi + 2\rho^3b \cos \phi$
$(1, 2)$	8	$\rho^2b^2 + 2\delta\rho^2b \cos \theta + 2\delta\rho b^2 \cos \psi.$

Each row is obtained by substituting the five possible values of r . In particular, the exact centered norm is

$$\begin{aligned} N(\rho, b, \theta, \phi) := u^8 = & 8\rho^8 + 16(1 + \cos^2 \phi)\rho^6b^2 + 48\rho^4b^4 \\ & + 16(1 + \cos^2(2\theta - \phi))\rho^2b^6 + 8b^8. \end{aligned} \quad (\text{III.55.1})$$

Squaring the rows of the table gives the following complete formula:

$$\begin{aligned} Q_3(\delta + f) = & \delta^8 + 24\delta^4(\rho^4 + b^4) \\ & + 16\delta^3(\rho^4b \cos \theta + \rho b^4 \cos \psi) \\ & + 24\delta^2\left((3 + \cos 2\theta)\rho^4b^2 + (3 + \cos 2\psi)\rho^2b^4\right. \\ & \quad \left.+ 2\rho^3b^3(\cos \phi + \cos(2\theta - \phi))\right) \\ & + 16\delta\left(\rho^4b^3(3 \cos \theta + \cos(2\phi - \theta))\right. \\ & \quad \left.+ \rho^3b^4(3 \cos \psi + \cos(3\theta - \phi))\right) + N(\rho, b, \theta, \phi). \end{aligned} \quad (\text{III.55.2})$$

Thus the amplitude penalty $16\rho^6b^2$ cannot be decreased by a different phase choice. It is minimized by $\cos \phi = 0$, which is compatible with maximizing the leading quintic contribution through $\cos \theta = 1$.

III.55.2 Localization of every maximizer

We first optimize without the interval restriction. By homogeneity it suffices to take $\delta = 1$ and write $t = u/\delta$. For a five-point function the norm sphere is compact, so a maximum exists. More explicitly, the nonnegative coefficients in (III.55.1) and $\rho \geq b$ give

$$8\rho^8 \leq t^8 \leq 128\rho^8.$$

Consequently $\rho \asymp t$, uniformly in the phases, and $\|f\|_\infty \leq 2(\rho + b) = O(t)$. After rescaling back to fixed $0 < \delta < 1$, the interval restriction $0 \leq \delta + f \leq 1$ is therefore inactive for all sufficiently small u .

Put $S = 2(\rho^4 + b^4)$. The exact norm gives

$$t^8 - 2S^2 \geq 16\rho^6 b^2,$$

and hence

$$6\sqrt{2}t^4 - 24(\rho^4 + b^4) = \frac{6(t^8 - 2S^2)}{t^4/\sqrt{2} + S} \geq ct^2b^2$$

for an absolute $c > 0$. Since $b \leq \rho = O(t)$, all the quintic, sextic, and septic terms in (III.55.2) are bounded in absolute value, respectively, by Ct^4b , Ct^4b^2 , and Ct^4b^3 . In particular, for small t ,

$$Q_3(1+f) - 1 - 6\sqrt{2}t^4 \leq -c't^2b^2 + Ct^4b + t^8.$$

The pure-pair example $b = 0$ gives the value $1 + 6\sqrt{2}t^4 + t^8$. A maximizing function must therefore have $b \leq C't^2$. This is the needed compactness statement at the secondary scale: write $b = kt^2$, with k bounded independently of t .

III.55.3 The leading phase optimization

Set $q = 2^{-3/4}$ and $\rho^2 = t^2 R$. After dividing the exact norm by t^8 , its defining equation is

$$\begin{aligned} 1 &= 8R^4 + 16(1 + \cos^2 \phi)R^3 k^2 t^2 + 48R^2 k^4 t^4 \\ &\quad + 16(1 + \cos^2(2\theta - \phi))Rk^6 t^6 + 8k^8 t^8. \end{aligned}$$

At $t = 0$, its positive solution is $R = q$. The derivative with respect to R is $32q^3 > 0$, so the implicit function theorem gives a real analytic solution $R(t, k, \theta, \phi)$, uniformly on each bounded set of k . In fact it is analytic in t^2 .

Subtract the constant and quartic terms from the objective and divide by t^6 . The apparent singularity at $t = 0$ is removable. The resulting real analytic function H has the uniform expansion

$$H(t, k, \theta, \phi) = H_0(k, \theta, \phi) + t^2 H_2(k, \theta, \phi) + t^3 H_3(k, \theta, \phi) + O(t^4),$$

where

$$H_0 = -24q(1 + \cos^2 \phi)k^2 + 16q^2 k \cos \theta.$$

For $k \geq 0$, the maximum is

$$\max H_0 = \frac{8q^3}{3} = \frac{2^{3/4}}{3},$$

and equality holds precisely at

$$k_0 = q/3, \quad \theta = 0 \pmod{2\pi}, \quad \phi = \pi/2 \pmod{\pi}.$$

Indeed, $H_0 \leq -24qk^2 + 16q^2k$, with equality forcing those phases when $k > 0$, and the remaining quadratic has its unique maximum at k_0 . Compactness and uniform convergence imply that every maximizer for sufficiently small t lies near one of these two phase classes. At either class the Hessian, in coordinates (k, θ, ϕ) , is

$$\text{diag} \left(-48q, -\frac{16q^3}{3}, -\frac{16q^3}{3} \right).$$

It is negative definite. Applying the implicit function theorem to $\nabla H = 0$ produces one analytic local maximum near each class; these exhaust the global maxima. Complex conjugation interchanges the two classes and preserves the objective, so their values agree. The map $(\alpha, \beta) \mapsto (\theta, \phi)$ has determinant 5; its finite collection of lifts merely produces the translates of these same functions on the five-point group.

III.55.4 Calculation of the coefficient 20/9

At $\theta = 0$, $\phi = \pi/2$, equation (III.55.1) becomes

$$t^8 = 8\rho^8 + 16\rho^6b^2 + 48\rho^4b^4 + 16\rho^2b^6 + 8b^8.$$

Let $x = t^2$, $b = kx$, and write $\rho^2 = qxX(z)$, where $z = k^2x/q$. Then

$$X^4 + 2zX^3 + 6z^2X^2 + 2z^3X + z^4 = 1, \quad X(0) = 1.$$

Successive coefficient comparison gives

$$X(z) = 1 - \frac{1}{2}z - \frac{9}{8}z^2 + \frac{3}{4}z^3 + O(z^4),$$

and therefore

$$\rho^4 = q^2t^4 - qk^2t^6 - 2k^4t^8 + O(t^{10}).$$

The exact objective at these phases simplifies to

$$Q_3(1 + f) = 1 + 24(\rho^4 + b^4) + 16\rho^4b + 96\rho^4b^2 + 48\rho^2b^4 + 32\rho^4b^3 + t^8.$$

It follows that

$$\begin{aligned} H_0(k, 0, \pi/2) &= -24qk^2 + 16q^2k, \\ H_2(k, 0, \pi/2) &= 1 - 24k^4 - 16qk^3 + 96q^2k^2. \end{aligned}$$

At $k_0 = q/3$, using $q^4 = 1/8$, we obtain

$$H_2(k_0, 0, \pi/2) = 1 - \frac{1}{27} - \frac{2}{27} + \frac{4}{3} = \frac{20}{9}.$$

It remains to justify the claimed $O(t^{10})$ remainder, rather than merely $o(t^8)$. The analytic maximizing coordinates differ from their $t = 0$ limits by $O(t^2)$ because H has no term of order t and the Hessian of H_0 is invertible. Substitution changes H_0 by $O(t^4)$ and changes t^2H_2 by $O(t^4)$. The only possible contribution of order t^3 in H is

$$H_3(k, \theta, \phi) = 16\sqrt{q}k^4 \cos(\phi - \theta) + 48q^{3/2}k^3(\cos(2\theta - \phi) + \cos \phi).$$

It vanishes at both limiting phase classes. Thus its contribution at the moving maximizers is $O(t^5)$, and in particular $O(t^4)$. Consequently

$$\max H = \frac{2^{3/4}}{3} + \frac{20}{9}t^2 + O(t^4).$$

Multiplying by t^6 , restoring the constant and quartic terms, and rescaling by δ^8 proves Theorem III.55.1.

What the optimizing phases do. The limiting phase choice is sufficient to calculate the terms through u^8 , but it need not remain exactly optimal for positive u . The t^3H_3 perturbation can move the phases. The theorem therefore uses the analytic optimizing branch, and does not assume exact phase stationarity of the displayed elementary model away from $t = 0$.

Reproducible certificate. The accompanying Python program `verify_order5.py` independently enumerates the 5^4 solutions of the Fourier cube constraints, records their monomials, and checks the six-slot formula against direct averages over 5^4 physical cubes. It also checks the rational series coefficients and the evaluation $20/9$. These finite computations verify identities; the maximization and the asymptotic remainder follow from the argument above.

III.55.5 Sharpness on every exponent-five group

Corollary III.55.2 (Pullback of the extremizing model). *Let G be any fixed nontrivial finite abelian group of exponent five and $0 < \delta < 1$. There are $[0, 1]$ weights W_u on G , with mean δ and centered norm exactly u , for all sufficiently small $u > 0$, such that*

$$Q_3(W_u) = \delta^8 + 6\sqrt{2}\delta^4u^4 + C_5\delta^2u^6 + \frac{20}{9}u^8 + O_\delta(u^{10}). \quad (\text{III.55.3})$$

Consequently the uniform coefficient in Theorem F.26.1 is optimal on each such fixed group.

Proof. Choose a nonzero linear functional $\pi : G \rightarrow \mathbb{F}_5$. It is surjective, and the image of a uniform element of G is uniform on $\mathbb{F}_5$. For any weight V on $\mathbb{F}_5$, the pullback $V \circ \pi$ has the same mean, centered U^3 norm, and normalized cube count as V , since the four cube parameters push forward independently and uniformly. Pull back the five-point maximizers from Theorem III.55.1. $\square$

[write] 6 October 2026; sources 34–39. *Dimension-uniform* (source 38). On every group of exponent five the maximum reduces exactly to $\mathbb{Z}/5\mathbb{Z}$ for $u \leq 10^{-5}\delta$, so $20/9$ is the universal coefficient of u^8 (source 38's Theorem III.84.1); source 38 also gives the u^{10} and u^{12} coefficients (Theorem III.85.1).

For the coefficients through u^8 , an elementary explicit model already suffices. Set

$$b = \beta_5\delta^{-1}u^2, \quad a_1 = \rho e^{i\pi/10}, \quad a_2 = be^{i\pi/5}, \quad (\text{III.55.4})$$

with conjugate coefficients at $-1, -2$, and choose the unique positive ρ satisfying

$$8\rho^8 + 16\rho^6b^2 + 48\rho^4b^4 + 16\rho^2b^6 + 8b^8 = u^8. \quad (\text{III.55.5})$$

Existence and uniqueness for small u follow from strict monotonicity in ρ and from $8b^8 < u^8$. In physical space this is

$$W_u(x) = \delta + 2\rho \cos\left(\frac{2\pi x}{5} + \frac{\pi}{10}\right) + 2b \cos\left(\frac{4\pi x}{5} + \frac{\pi}{5}\right).$$

Figure III.55.1: The exact elementary model at $\delta = 0.4$, evaluated with high-precision arithmetic. The horizontal axis is $t = u/\delta$. Left: the normalized sixth-order correction tends to C_5 . Right: after subtracting that correction as well, the normalized eighth-order residual tends to $20/9$. The plot evaluates a proven formula; it is not used as evidence for the general upper bound.

The coefficients tend to zero, so $W_u \in [0, 1]$ when u is small. The fixed choice of the limiting amplitude and phases has the same $20/9$ coefficient, although its terms beyond u^8 need not be globally optimal. Figure III.55.1 illustrates the approach to the two sharp coefficients using the exact formulas.

III.56 Indicator sharpness and its limitations

Source 21, delivered Section 8.

Weights are convenient because the Fourier parameters vary continuously. The sharp coefficients also have consequences for actual sets. A fixed five-point group has only finitely many sets, so a nontrivial small-norm limit at a prescribed positive density requires the group to grow.

Theorem III.56.1 (Sharp indicator families). *For every $0 < \delta < 1$, there are dimensions $n_j \rightarrow \infty$ and sets $A_j \subset \mathbb{F}_5^{n_j}$ with densities $\delta_j \rightarrow \delta$ and centered norms $v_j = \|1_{A_j} - \delta_j\|_{U^3} \rightarrow 0$ such that*

$$Q_3(1_{A_j}) = \delta_j^8 + 6\sqrt{2}\delta_j^4 v_j^4 + C_5 \delta_j^2 v_j^6 + \frac{20}{9} v_j^8 + o(v_j^8). \quad (\text{III.56.1})$$

Thus C_5 remains optimal for indicator sets in growing exponent-five groups, and $20/9$ is a lower bound for any universal eighth-order extremal coefficient in that setting.

Proof. Choose $u_j \downarrow 0$ and lift the elementary model (III.55.4) to $G_j = \mathbb{F}_5^{n_j}$ by its first coordinate. Denote the lifted weight by W_j . Its mean is δ , its centered norm is u_j , and its cube count has expansion (III.55.3) through u_j^8 , independently of n_j .

Include each point $x \in G_j$ independently with probability $W_j(x)$. Let X_x be its indicator. We approximate three statistics: the density, $Q_3(X)$, and $Q_3(X - \delta)$. If the eight vertices of a cube are distinct, independence makes the expectation of its product equal to the corresponding weighted product. For any two distinct vertices, the equation that they coincide is a nontrivial linear equation

in the sidelengths and holds with probability $|G_j|^{-1}$. Hence at most $28/|G_j|$ of all normalized cubes have a repeated vertex. Since all relevant factors have absolute value at most one, the expectation error in either cube statistic is at most $56/|G_j|$.

Changing one inclusion variable affects at most $8/|G_j|$ of either normalized cube polynomial, by a union bound over the vertex at which that point occurs. A bounded-difference variance estimate, or the elementary Efron–Stein inequality, gives variance $O(|G_j|^{-1})$. The density has variance at most $1/(4|G_j|)$. Chebyshev’s inequality and a union bound therefore show that, for sufficiently large n_j , some realization simultaneously approximates all three target statistics to an arbitrarily prescribed positive accuracy.

Choose the accuracy to be $o(u_j^{12})$, for example a sufficiently small multiple of u_j^{14} . Recentring X from δ to its actual density δ_j changes a cube product by at most $8|\delta_j - \delta|$, by telescoping. Thus

$$v_j^8 = u_j^8 + o(u_j^{12}), \quad \delta_j - \delta = o(u_j^{12}), \quad Q_3(1_{A_j}) - Q_3(W_j) = o(u_j^{12}).$$

It follows that $v_j/u_j \rightarrow 1$ and $v_j^4 - u_j^4 = o(u_j^8)$; the corresponding changes in the sixth- and eighth-order terms are also $o(u_j^8)$. Substitution proves (III.56.1). The dimensions can be chosen strictly increasing at each step. $\square$

[write] **6 October 2026; sources 21–27.** *Credit.* Source 23’s Proposition III.58.4 realizes the coefficients through order u^6 by indicator sets in the same way; the theorem here goes through u^8 . Both are lower examples, not upper bounds.

Corollary III.56.2 (A strengthened set version of Lemma 3.10). *Let $A \subset G$, where G is a nontrivial finite abelian group of exponent five, let $N = |G|$ and $\delta = |A|/N > 0$, and suppose*

$$\|1_A - \delta\|_{U^3}^8 \leq \alpha.$$

For absolute $c, C > 0$, if $\alpha^{1/8} \leq c\delta$, then

$$\#\{\text{parameterized three-cubes in } A\} \leq N^4 \left(\delta^8 + 6\sqrt{2} \delta^4 \alpha^{1/2} + C_5 \delta^2 \alpha^{3/4} + C\alpha \right). \quad (\text{III.56.2})$$

Proof. Apply Theorem F.26.1 at the actual centered norm and then increase that norm to its budget $\alpha^{1/8}$. All displayed powers have positive coefficients, so this substitution preserves the upper bound. Multiply the normalized count by N^4 . $\square$

In this setting the triangle-inequality estimate corresponding to Gowers’s Lemma 3.10 is $N^4(\delta + \alpha^{1/8})^8$. The first error in (III.56.2) is order $\alpha^{1/2}$, and its next sharp coefficient occurs at $\alpha^{3/4}$. The characteristic-five restriction is essential to this particular secondary statement. It is not a replacement for the prime-cyclic bound at arbitrary primes.

III.56.1 Failure of stronger L^2 rigidity

For the indicator examples,

$$\|1_{A_j} - \delta_j\|_2^2 = \delta_j(1 - \delta_j) \longrightarrow \delta(1 - \delta) > 0.$$

On the other hand each Fourier coefficient is $O(v_j)$, by $\|1_{A_j} - \delta_j\|_{U^2}^4 \leq v_j^4/\sqrt{2}$. If P_j projects onto at most a fixed number m of frequencies, Parseval gives $\|P_j(1_{A_j} - \delta_j)\|_2^2 = O(mv_j^2) \rightarrow 0$. The orthogonal remainder therefore has L^2 norm tending to $\sqrt{\delta(1 - \delta)}$. Even the strong asymptotic equality in (III.56.1) does not force a small L^2 remainder after removing finitely many harmonics.

III.57 A quantitative projection consequence of cube Cauchy–Schwarz

Source 21, delivered Section 9.

The proof of the sharp coefficient used the stronger explicit sixth- and seventh-degree formulas. For related problems where such formulas are unavailable, a general norm argument still provides a uniform way to pass from near equality to approximation on a quotient. The following is an elementary consequence of classical norm geometry; its inclusion is methodological, not a priority claim.

Proposition III.57.1 (Loss under subgroup averaging controls the remainder). *Let G be any finite abelian group, $d \geq 2$, $p = 2^d$, and*

$$P_H f(x) = \mathbb{E}_{h \in H} f(x + h)$$

for a subgroup $H \leq G$. Then

$$\|f - P_H f\|_{U^d} \leq 2 \left(\|f\|_{U^d}^p - \|P_H f\|_{U^d}^p \right)^{1/p}. \quad (\text{III.57.1})$$

In particular, equality of the two norms holds if and only if $f = P_H f$.

Proof. Cube expansion and Gowers–Cauchy–Schwarz yield, with $a = \|f\|_{U^d}$ and $b = \|g\|_{U^d}$,

$$\|f + g\|_{U^d}^p + \|f - g\|_{U^d}^p \leq 2 \sum_{j \text{ even}} \binom{p}{j} a^{p-j} b^j.$$

Use weighted AM–GM on each monomial and the identities

$$\sum_{j \text{ even}} j \binom{p}{j} = \sum_{j \text{ even}} (p - j) \binom{p}{j} = p 2^{p-2}$$

to obtain Clarkson’s inequality

$$\left\| \frac{f + g}{2} \right\|_{U^d}^p + \left\| \frac{f - g}{2} \right\|_{U^d}^p \leq \frac{\|f\|_{U^d}^p + \|g\|_{U^d}^p}{2}. \quad (\text{III.57.2})$$

Subgroup averaging is contractive by translation invariance and the triangle inequality. Apply (III.57.2) to f and its translate $T_h f$ for $h \in H$. Since $P_H((f + T_h f)/2) = P_H f$, the first summand on the left is at least $\|P_H f\|_{U^d}^p$. Hence

$$\|f - T_h f\|_{U^d} \leq 2 \left(\|f\|_{U^d}^p - \|P_H f\|_{U^d}^p \right)^{1/p}.$$

Average $f - T_h f$ over $h \in H$ and use the triangle inequality. The final equivalence follows because U^d is a norm for $d \geq 2$. $\square$

For $d = 3$ and $H = \ker \xi$, P_H retains exactly the frequencies in $\langle \xi \rangle$. Thus near saturation of its norm implies approximation by a five-point quotient in U^3 , uniformly over the ambient dimension. The proposition alone does not establish that a global maximizer of $Q_3(\delta + f)$ lies on that quotient: projection also changes the centered norm, and restoring the norm by rescaling changes the different-degree terms unequally. This is precisely an obstacle in the higher-dimensional eighth-order question.

III.58 Sharp secondary three-cube asymptotics in characteristic five

Source 23, delivered Section 7.

The earlier project report *Sharp Extremal Refinements in Gowers's Szemerédi Framework* proved that exponent five changes the first secondary power from $u^{16/3}$ to u^6 [112]. Its explicit example had coefficient $2^{3/4}/3$, but optimality of this coefficient was left open. We determine that coefficient, uniformly in the dimension, and obtain an $O(u^8)$ remainder. These are local extremal statements about cube counts, with no claim of an improved global quantitative Szemerédi theorem.

For a real function W on a finite abelian group G , write

$$Q(W) = \mathbb{E}_{x, h_1, h_2, h_3 \in G} \prod_{v \in \{0,1\}^3} W(x + v \cdot h) = \|W\|_{U^3}^8.$$

All averages and Fourier transforms are normalized; sums on the dual are unnormalized. Repeated vertices and zero directions are included.

For comparison with Gowers's Lemma 3.10, his degree-two uniformity parameter is $\alpha = u^8$. His triangle-inequality bound has normalized form $(\delta + u)^8$ [1]. The sharper leading term $6\sqrt{2}\delta^4 u^4$ and the order-five lower example were established in the earlier project reports [108, 112]. The result below determines the previously unresolved secondary constant.

Theorem III.58.1 (The exact characteristic-five coefficient). *There are absolute constants $c, C > 0$ such that the following holds for every nontrivial finite abelian group of exponent five. If $\delta > 0$, $f : G \rightarrow \mathbb{R}$ has mean zero, and $u = \|f\|_{U^3} \leq c\delta$, then*

$$Q(\delta + f) \leq \delta^8 + 6\sqrt{2}\delta^4 u^4 + \frac{2^{3/4}}{3} \delta^2 u^6 + Cu^8. \quad (\text{F1})$$

No pointwise bound on f is required, and c, C are independent of the group and its dimension. For every fixed $0 < \delta < 1$, on every fixed nontrivial group G of exponent five, the supremum over weights $W : G \rightarrow [0, 1]$ satisfying $\mathbb{E}W = \delta$ and $\|W - \delta\|_{U^3} \leq u$ obeys

$$M_{\delta, G}(u) = \delta^8 + 6\sqrt{2}\delta^4 u^4 + \frac{2^{3/4}}{3} \delta^2 u^6 + O(u^8) \quad (u \downarrow 0). \quad (\text{F2})$$

The same expansion holds when the supremum also ranges over all such groups. The range of sufficiently small u in the lower construction may depend on δ , because the weights must lie in $[0, 1]$.

[write] **6 October 2026; sources 21–27.** *Second route.* This is source 21's Theorem F.26.1, proved independently by the same mechanism (a positive cubic statistic for the incomplete cubes, the quadratic cost of the second harmonic); source 21 has sharper intermediate constants, the phase envelope and the next coefficient on $\mathbb{Z}/5\mathbb{Z}$ (Section III.49). It answers source 14's Question 1 (item III.23).

Corollary III.58.2 (Ordered cube counts in uniform subsets). *There are absolute $c, C > 0$ such that, if $A \subset G = \mathbb{F}_5^n$ has density $\delta > 0$ and $\|1_A - \delta\|_{U^3}^8 \leq \alpha$ with $\alpha^{1/8} \leq c\delta$, its number of ordered three-cubes is at most*

$$|G|^4 \left(\delta^8 + 6\sqrt{2}\delta^4 \alpha^{1/2} + \frac{2^{3/4}}{3} \delta^2 \alpha^{3/4} + C\alpha \right).$$

Proof. Apply Theorem III.58.1 at the actual centered norm and use monotonicity of the displayed nonnegative terms. Normalization of the four independent cube parameters supplies the factor $|G|^4$. $\square$

III.58.1 The exact terms of degree six and a useful degree-seven bound

Let $a_r = \widehat{f}(r)$, so $a_0 = 0$ and $a_{-r} = \overline{a_r}$. Put

$$\lambda_r = |a_r|^2, \quad S = \sum_r \lambda_r^2 = \|f\|_{U^2}^4, \quad T(s, t) = \sum_r a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}.$$

Fourier inversion and orthogonality give

$$u^8 = \sum_{s,t} |T(s, t)|^2. \quad (\text{F3})$$

One can see this identity directly by expanding all eight physical-space factors into characters. The surviving frequencies satisfy the four equations saying that the coefficient of x, h_1, h_2, h_3 is zero. After multiplying the frequency at vertex v by $(-1)^{|v|}$, their solutions are exactly affine cubes $r + sv_1 + tv_2 + zv_3$ in the dual group. This follows either by solving the four equations or by Boolean finite differences. Since $a_{-r} = \overline{a_r}$, the surviving product is the usual conjugated dual cube product. Summing over the last direction z pairs two translated square products, giving $\sum_{s,t} |T(s, t)|^2$ with no missing normalization factor. Define the following homogeneous forms:

$$\begin{aligned} B_5 &= \sum_r a_{2r} a_{-r}^3 a_r, \\ A_6 &= \sum_{s,t} \lambda_s \lambda_t \lambda_{s+t}, \\ B_6 &= \sum_{s,t} a_t^2 \lambda_{s+t} a_s \overline{a_{s+2t}}, \\ C_6 &= \sum_{s,t} a_s^2 a_t^2 \overline{a_{s+t}}^2. \end{aligned}$$

These are real: for instance, simultaneous negation of all frequency variables conjugates the summands. There is a real homogeneous form V_7 of degree seven for which

$$Q(\delta + f) = \delta^8 + 12\delta^4 S + 8\delta^3 B_5 + \delta^2(12A_6 + 12B_6 + 4C_6) + 8\delta V_7 + u^8. \quad (\text{F4})$$

Moreover,

$$|B_6|, |C_6| \leq A_6, \quad |V_7| \leq u^4 \sqrt{A_6}. \quad (\text{F5})$$

Here are details of the finite cube calculation in (F4). Terms with one, two, or three selected vertices vanish by centering. Of the 70 four-vertex supports, twelve are parallelograms and contribute S ; the other supports have independent forms. Of the 56 five-vertex supports, eight have no dependent four-subset. These are the cube-symmetric copies of $\{000, 100, 010, 001, 111\}$ and contribute B_5 ; every other five-vertex support has a Fourier constraint forcing a selected coefficient to be a_0 . All nonzero minors needed here are units in characteristic five. More explicitly, each of the twelve parallelograms has four extensions to a five-set. No five-set contains two different parallelograms: their affine planes would share three cube vertices, whereas two distinct planes meet in a line and a line contains at most two Boolean vertices. These 48 extensions have an independent fifth form, whose centered factor averages to zero. The other eight supports are the stated symmetric copies. A six-vertex support is classified by the Hamming distance of the two omitted vertices. Distances one, two, and three occur 12, 12, 4 times. For the representatives omitting respectively

$$\{000, 100\}, \quad \{000, 110\}, \quad \{000, 111\},$$

the Fourier constraints have solutions, in the lexicographic order of the remaining vertices,

$$(s+t, -s, -t, -s-t, s, t), \quad (t, s+t, -s-2t, -s-t, s, t), \quad (t, s, -s-t, -s-t, s, t).$$

Their products are exactly the summands defining A_6, B_6, C_6 . Cube symmetries preserve normalized averages by invertible changes of the cube parameters. The eight seven-vertex supports are also symmetric.

The bound for C_6 follows by taking absolute values. For B_6 , put $r = s + t$ and apply Cauchy–Schwarz:

$$\begin{aligned} |B_6| &\leq \sum_{r,t} \lambda_r \lambda_t |a_{r-t}| |a_{r+t}| \\ &\leq \left(\sum_{r,t} \lambda_r \lambda_t \lambda_{r-t} \right)^{1/2} \left(\sum_{r,t} \lambda_r \lambda_t \lambda_{r+t} \right)^{1/2} = A_6. \end{aligned}$$

For the last equality use $\lambda_{-t} = \lambda_t$.

For the septic bound, let $P(s, t)$ be the coefficient of δ when the Fourier coefficient $a_0 = 0$ in $T(s, t)$ is replaced by δ . It is the sum of four cubic expressions, one from each possible zero position in the four factors. Each expression has squared $\ell^2(s, t)$ norm A_6 ; for example, the first is $\overline{a_s} \overline{a_t} a_{s+t}$. The others are obtained by invertible changes of (s, t) and conjugation. Consequently $\|P\|_2 \leq 4\sqrt{A_6}$. The coefficient of δ in $\sum_{s,t} |T_{\delta+f}(s, t)|^2$ is $2 \operatorname{Re} \langle T, P \rangle = 8V_7$. Equation (F3) and Cauchy–Schwarz prove the septic bound.

III.58.2 A Fourier concentration penalty specific to order five

Choose a largest conjugate pair $\{\xi, -\xi\}$, and write

$$\rho = |a_\xi|, \quad b = |a_{2\xi}|, \quad D = \sum_{r \notin \{\xi, -\xi\}} |a_r|^4, \quad S = 2\rho^4 + D.$$

Since every nonzero character has order five, the doubled pair is distinct from the largest pair, and $2b^4 \leq D$. Define

$$E = \sum_{r+s=t+w} \lambda_r \lambda_s \lambda_t \lambda_w = \|\lambda * \lambda\|_2^2, \quad M = \sum_r |a_r|^8.$$

The slots $s = 0$ or $t = 0$ in (F3) contribute exactly $2E - S^2$. In the nonnegative energy sum retain the three families

$$(r = t, s = w), \quad (r = w, s = t), \quad (s = -r, w = -t).$$

Each has weight S^2 , each pairwise intersection has weight M , and their triple intersection has zero weight, since it forces $2r = 0$ and $a_0 = 0$. Thus $E \geq 3S^2 - 3M$. Conjugate pairing gives $M \leq S^2/2$, so

$$u^8 \geq 5S^2 - 6M \geq 2S^2. \quad (\text{F6})$$

Maximality of ρ also gives $M \leq \rho^4 S$ and hence

$$u^8 \geq (2 + 3D/S)S^2. \quad (\text{F7})$$

Order five supplies eight additional energy quadruples. Start with $(\xi, \xi, -\xi, -2\xi)$ and apply interchange of the two sides, interchange of the unequal entries on a side, and simultaneous negation.

These are eight distinct solutions of $r + s = t + w$, since $5\xi = 0$. They belong to none of the three preceding families, and each has weight $\rho^6 b^2$. The tail eighth-power mass is at most $D^2/2$, so retaining both the new quadruples and the concentration defect proves

$$\boxed{u^8 \geq 2S^2 + 12\rho^4 D + 16\rho^6 b^2.} \quad (\text{F8})$$

Indeed, the axes are at least $5S^2 - 6(2\rho^8 + D^2/2) + 16\rho^6 b^2 = 2S^2 + 12\rho^4 D + 16\rho^6 b^2$.

There is also a useful dimension-free estimate for the sextic quantity:

$$A_6 \leq 3\sqrt{E}\sqrt{D}, \quad E \leq \frac{u^8 + S^2}{2} \leq \frac{3}{4}u^8. \quad (\text{F9})$$

To prove the first inequality, set $q_r = \lambda_r$ outside $\{\xi, -\xi\}$ and zero on that pair. No three members of $\{\xi, -\xi\}$ sum to zero, because ξ has order five. Every nonzero term of A_6 therefore uses at least one tail index. The union bound, evenness of λ , and Cauchy–Schwarz give

$$A_6 \leq 3\langle q, \lambda * \lambda \rangle \leq 3\|q\|_2 \|\lambda * \lambda\|_2 = 3\sqrt{D}\sqrt{E}.$$

The second inequality follows from the axes contribution and (F6). This step is crucial: small fourth-power Fourier tail mass need not imply small L^2 mass, but it does control these particular incomplete-cube terms.

III.58.3 Uniform optimization and proof of the upper bound

The zero function is immediate. Otherwise write $g = f/u$, $t = u/\delta$, and use all Fourier letters in this subsection for g , so $\|g\|_{U^3} = 1$. Put

$$S_0 = 1/\sqrt{2}, \quad \eta = S_0 - S \geq 0, \quad F = Q(1 + tg) - 1 - 6\sqrt{2}t^4.$$

We may assume $0 < t \leq 1$ and $F > 0$; otherwise the assertion is immediate. The ordinary cube Cauchy–Schwarz bounds on the 28 sextic and eight septic terms give

$$F = -12\eta t^4 + 8t^5 B_5 + R, \quad |R| \leq 37t^6. \quad (\text{F10})$$

Since $|B_5| \leq \rho S < 1$, first $\eta = O(t)$. For small absolute t , $S \geq S_0/2$, and (F7) gives $D \leq 8\eta/3$. Consequently $\rho^4 = (S_0 - \eta - D)/2$ is bounded away from zero. Equation (F8) gives $b^2 = O(\eta)$.

If $a_\xi = \rho e^{i\theta}$, the two selected terms of B_5 are

$$2\rho^4 \operatorname{Re}(a_{2\xi} e^{-2i\theta}).$$

The remaining terms have total absolute value at most ρD . Thus $|B_5| = O(\sqrt{\eta} + \eta)$. Inserting this in (F10), absorbing the $O(t\eta)$ term, and solving the quadratic inequality in $\sqrt{\eta}$ yields

$$\eta = O(t^2), \quad D = O(t^2), \quad b = O(t). \quad (\text{F11})$$

All constants here are absolute.

Let $A_0 = 2^{-3/2}$. Since $\rho^4 = A_0 - (\eta + D)/2$, expanding (F8) using (F11) gives

$$\eta \geq \frac{3}{2}D + 2^{1/4}b^2 - O(t^4). \quad (\text{F12})$$

For clarity, $12\rho^4 D = 3\sqrt{2}D + O(t^4)$, $16\rho^6 b^2 = 2^{7/4}b^2 + O(t^4)$, and $1 - 2S^2 = 2\sqrt{2}\eta - 2\eta^2$; division by $2\sqrt{2}$ gives (F12).

Also $B_5 \leq S_0 b + D$. By (F9), $A_6 \leq 3\sqrt{D}$. Using the exact expansion (F4) and the sharper incomplete-cube bounds (F5) now gives

$$F \leq -18Dt^4 - 122^{1/4}b^2t^4 + 4\sqrt{2}bt^5 + 8Dt^5 \\ + 84t^6\sqrt{D} + 8\sqrt{3}t^7D^{1/4} + O(t^8).$$

For $t \leq 1$, the two terms linear in D are at most $-10Dt^4$. Completing the square in b yields

$$-122^{1/4}b^2t^4 + 4\sqrt{2}bt^5 \leq \frac{2^{3/4}}{3}t^6, \quad b = \kappa t \text{ at equality}, \quad \kappa = \frac{2^{1/4}}{6} = \frac{2^{5/4}}{12}.$$

Finally, on putting $y = D^{1/4}/t$, the remaining terms involving D are

$$t^8(-10y^4 + 84y^2 + 8\sqrt{3}y) = O(t^8),$$

because this polynomial is bounded above on $y \geq 0$. Thus $F \leq (2^{3/4}/3)t^6 + O(t^8)$ with absolute constants. Multiplication by δ^8 proves (F1).

III.58.4 An exact five-point model

On $\mathbb{Z}/5\mathbb{Z}$, set

$$a_0 = 0, \quad a_1 = \rho e^{i\pi/10}, \quad a_2 = b e^{i\pi/5}, \quad a_{-j} = \overline{a_j}.$$

The resulting function f is real and centered. Direct use of (F3) gives the exact identities

$$\|f\|_{U^3}^8 = 8\rho^8 + 16\rho^6 b^2 + 48\rho^4 b^4 + 16\rho^2 b^6 + 8b^8, \\ Q(\delta + f) = \delta^8 + 24\delta^4(\rho^4 + b^4) + 16\delta^3\rho^4 b + 96\delta^2\rho^4 b^2 + 48\delta^2\rho^2 b^4 + 32\delta\rho^4 b^3 + \|f\|_{U^3}^8. \quad (\text{F13})$$

A compact certificate is the following table for $T_{\delta+f}(s, t)$. Sign changes in either coordinate and interchange of the coordinates give the stated multiplicities.

(s, t)	multiplicity	$T_{\delta+f}(s, t)$
$(0, 0)$	1	$\delta^4 + 2\rho^4 + 2b^4$
$(0, 1)$	4	$2\delta^2\rho^2 + 2\rho^2 b^2 + b^4$
$(0, 2)$	4	$2\delta^2 b^2 + 2\rho^2 b^2 + \rho^4$
$(1, 1)$	4	$\delta^2\rho^2 + 2\delta\rho^2 b$
$(2, 2)$	4	$\delta^2 b^2$
$(1, 2)$	8	$\rho^2 b^2 + 2\delta\rho^2 b$

The multiplicities sum to 25. Each entry is a sum over five bases r ; the potentially additional terms cancel since $\cos(5\pi/10) = 0$. Squaring and summing proves (F13).

Choose $b = \kappa u^2/\delta$ and the unique positive ρ making the first expression in (F13) equal to u^8 . Such a ρ exists for sufficiently small u/δ , since the expression is strictly increasing in ρ and $8b^8 < u^8$. With $t = u/\delta$,

$$\rho^4 = u^4 \left(2^{-3/2} - 2^{-3/4}\kappa^2 t^2 + O(t^4) \right).$$

Substitution gives

$$Q(\delta + f) = \delta^8 + 6\sqrt{2}\delta^4 u^4 + \frac{2^{3/4}}{3}\delta^2 u^6 + O(u^8).$$

The weights lie in $[0, 1]$ when u is sufficiently small depending on δ , because $|f| \leq 2\rho + 2b \rightarrow 0$. Every nontrivial exponent-five group has a surjective character quotient onto $\mathbb{Z}/5\mathbb{Z}$; pullback along that quotient preserves normalized cube averages, means, and uniformity norms. This proves the lower bound on each fixed group. For a norm budget, the upper bound applies at the actual norm, and the positive terms in (F1) are increasing in that norm. This completes the proof of Theorem III.58.1.

III.58.5 Phase selection for families attaining the secondary term

Theorem III.58.3 (Necessary Fourier geometry). *Fix $\delta > 0$. Suppose f_j are real centered functions on finite groups of exponent five, $u_j = \|f_j\|_{U^3} \downarrow 0$, and*

$$Q(\delta + f_j) = \delta^8 + 6\sqrt{2}\delta^4 u_j^4 + \frac{2^{3/4}}{3} \delta^2 u_j^6 + o_\delta(u_j^6).$$

Choose a largest pair and write $a_{j,\xi_j} = \rho_j e^{i\theta_j}$ and $a_{j,2\xi_j} = b_j e^{i\psi_j}$; the latter is nonzero for large j . Then

$$\begin{aligned} b_j &\sim \kappa \delta^{-1} u_j^2, \\ e^{i(\psi_j - 2\theta_j)} &\longrightarrow 1, \quad \cos(5\theta_j) \longrightarrow 0, \\ \sum_{r \notin \{\xi_j, -\xi_j\}} |a_{j,r}|^4 &= o_\delta(u_j^6), \\ \rho_j^4 &= 2^{-3/2} u_j^4 - 2^{-3/4} \kappa^2 \delta^{-2} u_j^6 + o_\delta(u_j^6). \end{aligned}$$

These are necessary conditions, not a claimed sufficient characterization of all extremizing families. No L^2 approximation is asserted.

Proof. Work in the normalized variables of the upper proof and set $\phi = \psi - 2\theta$. Its estimates, retaining the actual phase, give

$$\frac{F}{t^6} \leq -18 \frac{D}{t^2} - 12 \cdot 2^{1/4} \left(\frac{b}{t}\right)^2 + 4\sqrt{2} \frac{b}{t} \cos \phi + o(1).$$

Here $D = O(t^2)$, $b = O(t)$, the sextic error divided by t^6 is $O(t)$, and the septic error is $o(1)$. The displayed expression has unique maximum $2^{3/4}/3$ in the variables $b/t \geq 0$, $D/t^2 \geq 0$ and $\cos \phi \leq 1$, attained when $b/t = \kappa$, $D/t^2 = 0$ and $\cos \phi = 1$. It follows that these three limits hold. The exact centered expansion then gives $\eta/t^2 \rightarrow 2^{1/4} \kappa^2$ and the claimed expansion of ρ^4 .

To detect the phase of the largest coefficient, also retain the four off-axis slots $(s, t) = (\pm 2\xi, \pm 2\xi)$. They have the same modulus. The contribution to $T(2\xi, 2\xi)$ from $r \in \langle \xi \rangle$ is exactly $2\rho^3 b \cos(3\theta + \psi)$. All remaining terms stay outside $\langle \xi \rangle$ in all four positions, so their sum has absolute value at most $D_{\text{out}} = \sum_{r \notin \langle \xi \rangle} |a_r|^4 \leq D$ by Hölder. Since $D = o(t^2)$ and $b \sim \kappa t$, the four slots supply

$$16\rho^6 b^2 \cos^2(3\theta + \psi) + o(t^2)$$

in addition to the axes lower bound. Applying the already established limits in (F8) forces $\cos(3\theta + \psi) \rightarrow 0$. Since $e^{i(\psi - 2\theta)} \rightarrow 1$, this is equivalent to $\cos(5\theta) \rightarrow 0$. Rescaling proves every stated conclusion. $\square$

III.58.6 Sharpness for subsets in growing dimension

Proposition III.58.4 (Indicator realization). *For every $0 < \delta < 1$, there are dimensions $n_j \rightarrow \infty$ and subsets $A_j \subset \mathbb{F}_5^{n_j}$, with densities $\delta_j \rightarrow \delta$ and $v_j = \|1_{A_j} - \delta_j\|_{U^3} \downarrow 0$, such that*

$$\frac{Q(1_{A_j}) - \delta_j^8 - 6\sqrt{2}\delta_j^4 v_j^4}{\delta_j^2 v_j^6} \rightarrow \frac{2^{3/4}}{3}.$$

Proof. Take the five-point model at parameters u_j decreasing geometrically and pull it back to $\mathbb{F}_5^n$ using the first coordinate. Include each point independently with its prescribed weight. With $N = 5^n$, at most $28/N$ of normalized cube parameter tuples have two coincident vertices: each equality of two distinct cube forms holds with probability $1/N$. On all other tuples, independence makes the expected indicator product equal the weighted product. The same holds for products centered at the fixed mean δ . Both expectation errors are therefore $O(1/N)$.

Changing one inclusion decision changes either cube polynomial by at most $8/N$, because each of the eight vertex forms has uniform fibers. Their variances are $O(1/N)$ by the bounded-difference variance estimate; the density variance is at most $1/(4N)$. Choosing n sufficiently large gives a realization in which the density, the indicator cube count, and the cube count centered at δ all approximate their weighted values to any prescribed error. Recentering at the realized density costs at most eight times the density error, by telescoping the bounded products.

Choose all these errors $o(u_j^{10})$. Then $v_j^8 = u_j^8 + o(u_j^{10})$, hence $v_j^4 = u_j^4 + o(u_j^6)$ and $v_j/u_j \rightarrow 1$. The model expansion transfers to the displayed ratio. The geometric choice of u_j makes the actual v_j strictly decrease after finitely many terms are discarded. $\square$

III.59 A closer expansion of the five-point example

Source 23, delivered Appendix A.

This appendix records a lower-model computation useful for the second research question. It does not identify the global tertiary optimum. Use the model of (F13), with $\kappa = 2^{1/4}/6$, $t = u/\delta$, and $b = \kappa u^2/\delta$. Let $A = 2^{-3/2}$. Solving the norm equation to two further orders gives

$$\frac{\rho^4}{u^4} = A - A^{1/2}\kappa^2 t^2 - 2\kappa^4 t^4 + O(t^6).$$

To verify this, substitute $A + at^2 + ct^4$ into the first equation in (F13), divide by u^8 , and compare coefficients. The constant coefficient is $8A^2 = 1$; the next two equations are

$$16Aa + 16A^{3/2}\kappa^2 = 0,$$

$$8a^2 + 16Ac + 24A^{1/2}a\kappa^2 + 48A\kappa^4 = 0.$$

They give $a = -A^{1/2}\kappa^2$ and $c = -2\kappa^4$. The positive root is analytic in t^2 near zero, since the derivative of the constant norm equation with respect to ρ^4/u^4 is $16A \neq 0$, so the expansion has the indicated remainder.

Substitution into the weighted-count formula gives the coefficient of u^8 as

$$-24\kappa^4 - 16A^{1/2}\kappa^3 + 96A\kappa^2 + 1 = -\frac{1}{27} - \frac{2}{27} + \frac{4}{3} + 1 = \frac{20}{9}.$$

Consequently this particular family satisfies

$$Q(\delta + f) = \delta^8 + 6\sqrt{2}\delta^4 u^4 + \frac{2^{3/4}}{3}\delta^2 u^6 + \frac{20}{9}u^8 + O(u^{10}/\delta^2). \quad (\text{III.59.1})$$

It follows that a global tertiary coefficient, if it exists in this normalization, must be at least $20/9$. The uniform upper argument in Section III.58 bounds that coefficient but does not equate it with the model value.

III.60 Source 22's chapter: degree filtrations of polynomial colourings [write]

Added in the fifth write, 6 October 2026.

The next five sections are source 22's Sections 6–10, on colourings $Q : \mathbb{F}_q^n \rightarrow \mathbb{F}_q^r$ by polynomials of bounded degree and the directions h for which a prescribed pattern of equal colours occurs from a base point. *Logically the chapter continues source 10's Section III.30* (the dimension threshold for symmetric progressions) *and source 14's Section III.36* (exact supersaturation in low degree), which source 22 cites as prior project work and whose ingredients it reproves. It is printed here, at the end of Part III, because no number printed earlier may move. Source 22's introduction is Section F.27; its Sections 2–5 are in Part II and Sections 11–12 in Part V.

What is proved, in one paragraph. For every prescribed equality pattern and degree caps, the minimum number of successful directions at a prescribed centre is $q^{\max(n-B,0)}$, with B the maximum-weight column-basis sum of an explicit evaluation matrix (Theorem III.61.5); for symmetric progressions this removes the degree restriction of source 14's Theorem III.36.1 (Corollary III.62.2), and a monochromatic analogue holds in every degree. The scalar quintic and sextic pointwise budget for symmetric four-term progressions is exactly eight. Further: all scalar quadratic minimizers (Theorem III.63.1), no independent additive extension of the cubic norm core (Theorem III.64.2) with an exact defect count (Theorem III.64.3), zero-defect rigidity (Corollary III.64.4), and a quantitative excess for norm layers of degree divisible by the characteristic (Theorem III.65.3). Warning's second theorem, the Delsarte–Goethals–MacWilliams rigidity and the norm constructions of Shi and Dong are credited as prior work. The global quintic avoidance range $4 \leq d \leq 8$ stays open (item III.19); the value 7,810,000 is a lower bound, not a count.

Relation to the formal statements. The colouring problem has no Lean statement; nothing in this chapter is formalized.

III.61 Polynomial zero sets and prescribed equality patterns

Source 22, delivered Section 6.

From this section onward, q denotes a prime power and $\mathbb{F}_q$ its field; p is its characteristic, and n is the dimension of a coloring domain. This avoids confusing field size with the $2d$ cubes of the preceding sections.

III.61.1 The classical zero-counting input

We use a familiar polynomial support bound. The proof is included because the distinction between a lower bound and its equality case is useful here.

Lemma III.61.1 (Minimum support of a polynomial function). *Let F be a nonzero polynomial function on $\mathbb{F}_q^n$, represented by a polynomial of total degree at most $R < n(q-1)$. Write $R = a(q-1) + b$, $0 \leq b < q-1$. Then*

$$|\text{supp } F| \geq (q-b)q^{n-a-1}.$$

In particular, degree at most $B(q-1)$ and nonempty support imply $|\text{supp } F| \geq q^{n-B}$ for $0 \leq B \leq n$.

Proof. Reduce each individual exponent using $X_i^q = X_i$. Reduction does not increase total degree, and produces the unique polynomial of individual degrees at most $q-1$ representing the function. Uniqueness follows by induction from the univariate root bound.

Successively take a leading coefficient in one variable. If the degree in that variable is e , then above each input where its leading coefficient is nonzero, at least $q-e$ points are in the support. Induction therefore produces exponents $0 \leq e_i \leq q-1$ of an actual monomial, with $\sum e_i \leq R$, such that $|\text{supp } F| \geq \prod_i (q-e_i)$. For a fixed sum, this product is minimized by making the exponents as unequal as possible. Indeed, for $0 < e_i \leq e_j < q-1$, replacing the pair by e_i-1, e_j+1 decreases its product. The minimum has a exponents $q-1$, one exponent b , and the others zero, giving the stated bound. The case $B = n$ merely says that the support is nonempty. $\square$

Corollary III.61.2 (Warning's second bound). *Suppose $f_1, \dots, f_s \in \mathbb{F}_q[X_1, \dots, X_n]$ have sum of degrees at most B and have a common zero. Their common zero set has at least $q^{\max(n-B, 0)}$ elements.*

Proof. Its indicator is represented by $\prod_i (1 - f_i^{q-1})$, a polynomial of degree at most $B(q-1)$. Apply Lemma III.61.1 when $B \leq n$, and otherwise use the given zero. $\square$

These are classical results, with Warning's original theorem and an elementary modern proof in [40, 56]. The following equality case is the relevant part of the minimum-weight generalized Reed–Muller theorem [96, 57].

Lemma III.61.3 (Rigidity at minimum support). *If a nonzero polynomial function of degree at most $B(q-1)$ has support of size exactly q^{n-B} , where $0 \leq B \leq n$, its support is an affine subspace of dimension $n-B$.*

Proof. The cases $B = 0, n$ are immediate. Put $e = n - B \geq 1$ and write S for the support. Consider a family of parallel affine hyperplanes and, after an affine change of variables, write it as $X_1 = c$. Let t members miss S . If $1 \leq t \leq q-2$, the reduced polynomial factors as

$$F(X) = \prod_{c: S \cap \{X_1=c\} = \emptyset} (X_1 - c)G(X), \quad \deg G \leq B(q-1) - t.$$

The factorization follows because a reduced restriction vanishing on an entire field grid is the zero polynomial. On every remaining hyperplane, Lemma III.61.1, in $n-1$ variables, gives at least $(t+1)q^{e-1}$ support points: the residual degree is $(B-1)(q-1) + (q-1-t)$. Therefore

$$|S| \geq (q-t)(t+1)q^{e-1} > q^e,$$

a contradiction. Thus every parallel family misses either zero or $q-1$ members. In a family missing none, every member has exactly q^{e-1} support points, since each has at least this many and the total is q^e .

Some family must miss a member. Otherwise every affine hyperplane contains exactly q^{e-1} points of S . Choose $x \notin S$ and count pairs consisting of a hyperplane through x and a point of S on it. Counting first hyperplanes and then points gives

$$q^{e-1}(q^n - 1) = q^e(q^{n-1} - 1),$$

which is impossible. Consequently S lies in one affine hyperplane. Move it to $X_1 = 0$. Uniqueness of reduced representatives gives

$$F(X_1, X') = (1 - X_1^{q-1})G(X').$$

Thus $\deg G \leq (B-1)(q-1)$, and its support still has size q^e . Induction on B proves that this support, and hence S , is an affine e -space. $\square$

III.61.2 Norm forms and their fibers

For each positive integer j , choose a basis of $\mathbb{F}_{q^j}$ over $\mathbb{F}_q$. Its field norm N_j is a homogeneous polynomial of degree j on a j -dimensional vector space. It vanishes exactly at zero. On nonzero elements,

$$N_j(x) = x^{(q^j-1)/(q-1)}.$$

The multiplicative group of a finite field is cyclic, so the norm is onto $\mathbb{F}_q^*$ and every nonzero fiber has exactly

$$\frac{q^j - 1}{q - 1} \tag{III.61.1}$$

elements; the zero fiber has one. One can also define the norm as the determinant of multiplication by x , making its homogeneous degree immediate. We use these standard finite-field facts as algebraic background, not as new constructions. Layered norms are used in the related progression-coloring work of Shi and Dong [33].

III.61.3 The evaluation matrix

Choose distinct nodes $\alpha_1, \dots, \alpha_\ell \in \mathbb{F}_q$ and a partition Π of their indices. The desired pattern says that the colors of $z + \alpha_i h$ agree whenever i, j belong to one block of Π . Choose a spanning tree on each block and write $\mathcal{E}$ for the resulting set of ordered edges. Equality on those edges is equivalent to equality on each block; the choice of trees will not affect the resulting row space.

For a scalar polynomial of degree at most D , define columns

$$v_j = (\alpha_a^j - \alpha_b^j)_{(a,b) \in \mathcal{E}}, \quad 1 \leq j \leq D. \tag{III.61.2}$$

Scan them from degree D down to degree one. Retain j if v_j does not belong to the span of previously retained columns. Let $J(\Pi, D)$ be the retained indices, and put

$$B(\Pi, D) = \sum_{j \in J(\Pi, D)} j. \tag{III.61.3}$$

For an empty edge set the span and budget are zero. A specified sparse set of allowed degrees is handled by scanning only that set.

Lemma III.61.4 (Optimal constant recombination by degree). *Give independent formal symbols C_j weight j . The vector relation $\sum_j v_j C_j = 0$ has an equivalent basis of scalar equations whose degrees are exactly the retained indices in $J(\Pi, D)$. No equivalent basis formed by constant linear combinations has a smaller sorted degree list or a smaller sum of degrees. Equivalently, $B(\Pi, D)$ is the maximum sum of degree indices of a column basis.*

Proof. For every retained b , take the dual coordinate functional λ_b on the span of the retained basis. A rejected column of degree j is a combination of retained columns of degrees larger than j . Therefore

$$\lambda_b \left(\sum_j v_j C_j \right) = C_b + \sum_{j < b} a_{b,j} C_j.$$

The equations have degrees b and are equivalent to the vector relation. For optimality, the functionals giving degree at most t form the annihilator of $\text{span}\{v_j : j > t\}$. Its dimension is $r - \text{rank}(v_{t+1}, \dots, v_D)$, where $r = \text{rank}(v_1, \dots, v_D)$. No equation basis can have more than that number of members of degree at most t . Greedy elimination attains these dimensions at every t , proving the degree comparison. The usual descending exchange argument, or the same ranks of suffixes, identifies its column basis as one of maximum total weight. $\square$

Theorem III.61.5 (Exact fixed-center pattern minimum). *Let $Q = (Q_1, \dots, Q_r) : \mathbb{F}_q^n \rightarrow \mathbb{F}_q^r$ have coordinate degree caps $D_1, \dots, D_r$, and let*

$$S_z(Q) = \{h : Q(z + \alpha_a h) = Q(z + \alpha_b h) \text{ for every } (a, b) \in \mathcal{E}\}.$$

Set $B = \sum_{a=1}^r B(\Pi, D_a)$. For every prescribed z ,

$$\boxed{\min_Q |S_z(Q)| = q^{\max(n-B, 0)}}. \quad (\text{III.61.4})$$

If $n \geq B$ and equality holds, $S_z(Q)$ is an $\mathbb{F}_q$ -linear subspace of dimension $n - B$. The theorem also holds with specified sparse degree supports at the prescribed center, using their greedy budgets.

Proof. Expand formally $Q_a(z + TH) = \sum_{j=0}^{D_a} C_{a,j,z}(H) T^j$. Every $C_{a,j,z}$ is homogeneous of degree j in H , or zero. The equality pattern is precisely $\sum_j v_j C_{a,j,z} = 0$ in each output coordinate. Lemma III.61.4 converts these to equations with total degree sum at most B . They vanish at zero. Corollary III.61.2 proves the lower bound. Their common-zero indicator has degree at most $B(q-1)$, so Lemma III.61.3 proves the equality assertion; the affine subspace contains zero and is therefore linear.

For sharpness in dimension B , allocate a disjoint block of dimension j to every retained degree j in every output, and make that output the sum of its block norms. At the origin its pattern vector is $\sum_{j \in J} v_j N_j(h^{(j)})$. Independence of the retained columns forces every norm, hence every block, to vanish. Thus $S_0 = \{0\}$. For $n > B$ add ignored coordinates; for $n < B$ restrict along a linear injection into the B -dimensional construction. Translation places the sharp example at any prescribed z . The case $B = 0$ is immediate. The same proof, with only the allowed columns, gives the sparse version. $\square$

Remark III.61.6 (What is optimized). Lemma III.61.4 concerns constant linear recombinations of the evaluation equations. Polynomial multipliers could change their degree presentation for a particular coloring. The stronger extremal conclusion (III.61.4) does not depend on limiting proof methods: the norm example attains the bound among all admissible colorings at the prescribed center.

III.62 Arithmetic-progression specializations

Source 22, delivered Section 7.

III.62.1 Monochromatic progressions in every degree

Take nodes $0, 1, \dots, \ell - 1$ and require one common color, with $p > \ell$. Comparing each node to zero gives $v_j = (1^j, 2^j, \dots, (\ell - 1)^j)^\top$. Any consecutive $\ell - 1$ columns are independent: factor nonzero powers out of the rows and use the Vandermonde determinant. If $D < \ell - 1$, the first D columns are independent as well. Consequently, for $r_D = \min(D, \ell - 1)$,

$$B_\ell^{\text{mono}}(D) = \frac{r_D(2D - r_D + 1)}{2} = \begin{cases} D(D + 1)/2, & D \leq \ell - 1, \\ (\ell - 1)(2D - \ell + 2)/2, & D \geq \ell - 1. \end{cases} \quad (\text{III.62.1})$$

This is an exact pointwise budget in the sense of Theorem III.61.5. Unlike symmetry alone, the required pattern is genuinely monochromatic and thus directly matches the type of configuration in Szemerédi's theorem. Its finite-field, bounded-polynomial-coloring scope remains essential.

Corollary III.62.1 (Exact global minimum in the interpolation range). *Suppose all degree caps satisfy $D_a \leq \ell - 1$, and put $B = \sum_a D_a(D_a + 1)/2$. The minimum number of ordered nontrivial monochromatic ℓ -term progressions over all such colorings is*

$$\min_Q A_\ell^{\text{mono}}(Q) = q^n \left(q^{\max(n-B, 0)} - 1 \right). \quad (\text{III.62.2})$$

One polynomial map attains the minimum at every base point.

Proof. Sum the pointwise lower bound minus its zero direction over all q^n base points. For the matching example, in output a use independent norm blocks of every degree $1, \dots, D_a$. If a direction is nonzero on the controlled coordinates, choose its highest nonzero block in some output. The polynomial obtained on that affine line has a nonzero leading coefficient equal to the corresponding norm. It has degree at most $D_a < \ell$, so it cannot have one value at all ℓ distinct nodes. Thus only ignored directions succeed at every base point. Restriction to a linear subspace gives the case $n < B$. $\square$

III.62.2 Symmetric progressions without a degree restriction

Let $\ell = 2m \geq 4$, $p > \ell$, and use the centered nodes $\pm\alpha_i$, where $\alpha_i = i - \frac{1}{2}$, $1 \leq i \leq m$. The symmetry condition is

$$Q(z + \alpha_i h) = Q(z - \alpha_i h) \quad (1 \leq i \leq m).$$

For four terms it permits a color sequence (a, b, b, a) with $a \neq b$; it must not be identified with the monochromatic condition.

Only odd coefficients survive reflection. Dividing the i th equation by $2\alpha_i$, its odd-degree columns are

$$((\alpha_i^2)^{j-1})_{i=1}^m, \quad j = 1, \dots, s, \quad s = \lceil D/2 \rceil.$$

The squares α_i^2 are distinct and nonzero, since their differences are $(i - j)(i + j - 1)$ and $p > \ell$. The last $\min(m, s)$ columns are therefore independent. We obtain the following formula.

Corollary III.62.2 (Exact arbitrary-degree symmetric budget). *For output degree caps D_a , set $s_a = \lceil D_a/2 \rceil$, $t_a = \min(m, s_a)$ and*

$$B_{\text{sym}} = \sum_a t_a(2s_a - t_a) = \sum_a (s_a^2 - (s_a - m)_+^2). \quad (\text{III.62.3})$$

At every prescribed center,

$$\min_Q |S_z(Q)| = q^{\max(n - B_{\text{sym}}, 0)}.$$

If $n \geq B_{\text{sym}}$, equality forces an $\mathbb{F}_q$ -linear space of directions of dimension $n - B_{\text{sym}}$. In all degrees,

$$A_\ell^{\text{sym}}(Q) \geq q^n (q^{\max(n - B_{\text{sym}}, 0)} - 1). \quad (\text{III.62.4})$$

When every $D_a \leq \ell$, simultaneous equality is attainable at all centers, so (III.62.4) is then the exact global minimum.

Proof. The pointwise statements follow from the evaluation columns and Theorem III.61.5. The retained odd degrees in an output are $2s_a - 2t_a + 1, \dots, 2s_a - 1$, whose sum is (III.62.3). The correspondence $z = a + (\ell - 1)h/2$ between starting-point and centered parametrizations is bijective, giving the global lower bound.

If $D_a \leq \ell$, use disjoint norm blocks of odd degrees $1, 3, \dots, 2s_a - 1$. Reflection at the m pairs forces every odd coefficient to vanish. The highest nonzero direction block would give a nonzero highest odd coefficient, a contradiction. Only ignored directions remain at every center, proving equality. This recovers the low-degree result of [106]; the arbitrary-degree pointwise statement is the extension proved here. $\square$

Degree cap D	1	2	3	4	5	6	7	8	9	10
$B_4^{\text{sym}}(D)$	1	1	4	4	8	8	12	12	16	16
$B_4^{\text{mono}}(D)$	1	3	6	9	12	15	18	21	24	27

III.62.3 The quintic obstruction is exactly pointwise

For $\ell = 4$ and $D = 5$ or 6 , the sharp budget is eight. In eight variables the polynomial

$$Q(u, v) = N_3(u) + N_5(v), \quad (u, v) \in \mathbb{F}_q^3 \oplus \mathbb{F}_q^5,$$

has $S_0(Q) = \{0\}$: its two odd evaluation columns of degrees three and five are independent. This is valid even in characteristic five; the relevant squared-node Vandermonde determinant remains nonzero.

Therefore the universal pointwise statement “every scalar quintic in eight variables has a nonzero symmetric direction at every prescribed center” is false. A proof that lowers the global avoidance bound from eight must use compatibility among different centers or another global feature. The previous cubic norm construction gives a globally avoiding example in dimension four. The interval between four and eight for the global quintic/sextic question is not closed by the present theorem.

For a sparse example, over $\mathbb{F}_5$ take allowed odd degrees $\{1, 5\}$. Fermat’s identity gives identical evaluation columns, so the greedy budget is five rather than six. For full quintic support $\{1, 3, 5\}$, the retained degrees are three and five, giving eight. This illustrates why the actual evaluation matrix, including characteristic-dependent relations, is more informative than a formal sum of all odd degrees.

III.63 Complete quadratic classification and counts

Source 22, delivered Section 8.

Let q be odd and let $P : V = \mathbb{F}_q^n \rightarrow \mathbb{F}_q$ have degree at most two. The structural statements below only require odd characteristic; for the count of distinct arithmetic progressions retain $p > \ell$ as above. Write uniquely

$$P(x) = B(x, x) + L(x) + c$$

with B a symmetric bilinear form and L a linear functional. Put $R = \text{rad}(B)$ and $r = \text{rank}(B)$. At every center z ,

$$P(z + \alpha h) - P(z - \alpha h) = 2\alpha(2B(z, h) + L(h)).$$

Thus any nonempty reflection configuration with nonzero nodes has

$$S_z(P) = \ker(2B(z, \cdot) + L).$$

Theorem III.63.1 (All scalar quadratic minimizers). *Assume $n \geq 1$. The following are equivalent:*

1. $|S_z(P)| = q^{n-1}$ for every z .
2. $L|_R \neq 0$.
3. Some $u \in V$ satisfies $P(x + su) = P(x) + s$ for all $x \in V$ and $s \in \mathbb{F}_q$.
4. An invertible affine change of source coordinates puts P in the form $t + B_0(w, w) + c'$, where B_0 is nondegenerate on an r -dimensional space, and the other $n - r - 1$ variables are unused.

If $L|_R = 0$, there are exactly q^{n-r} exceptional centers, at which $S_z = V$. At every other center, $|S_z| = q^{n-1}$. Hence in this case

$$A_\ell^{\text{sym}}(P) = q^n(q^{n-1} - 1) + q^{n-r}(q^n - q^{n-1}).$$

Among non-minimizing scalar quadratic maps, the least possible excess above the global minimum is $q^n - q^{n-1}$, attained precisely when B is nondegenerate.

Proof. The linear map $z \mapsto B(z, \cdot)$ has kernel R and image exactly $R^\perp \subseteq V^*$. Therefore $2B(z, \cdot) + L$ is never zero if and only if $L \notin R^\perp$, namely $L|_R \neq 0$. In that case choose $u \in R$ with $L(u) = 1$; the translation identity follows by expanding $P(x + su)$. Conversely the translation identity, first at $s = 1$ and varying x , forces $B(x, u) = 0$ for all x and then $L(u) = 1$.

Split $V = W \oplus R$, with $B|_W$ nondegenerate, and split $R = \mathbb{F}_q u \oplus (R \cap \ker L)$. Completing the square in W removes the linear term on W , giving the asserted normal form. The normal form immediately gives the minimal counts. If $L \in R^\perp$, the affine equation $2B(z, \cdot) = -L$ has exactly q^{n-r} solutions. A nonzero linear functional has kernel size q^{n-1} ; the zero functional has kernel size q^n . Summing the excess at the exceptional centers gives the count. Since $r \leq n$, its least positive value occurs exactly at $r = n$. $\square$

III.64 Why independent additive blocks cannot extend the norm coloring

Source 22, delivered Section 9.

In this section let $\ell = 2m$, $p > \ell$, and $\alpha_i = i - 1/2$ for $1 \leq i \leq m$.

The obstruction below is global and permits an arbitrary added function, of any polynomial degree or with no polynomial presentation imposed. It excludes a large and natural class of attempts to improve the m^2 -dimensional norm-layer coloring by appending new input coordinates.

Let

$$U = \bigoplus_{j=1}^m \mathbb{F}_q^{2j-1}, \quad C(u) = \sum_{j=1}^m N_{2j-1}(u_j), \quad \dim U = m^2.$$

Here each N_t is a degree- t field norm and N_1 is the identity. For a core center $a \in U$, define its reflection map

$$\Phi_a(h) = (C(a + \alpha_i h) - C(a - \alpha_i h))_{i=1}^m \in \mathbb{F}_q^m.$$

Lemma III.64.1 (Surjectivity of every core reflection map). *For every $a \in U$, the map $\Phi_a : U \rightarrow \mathbb{F}_q^m$ is onto.*

Proof. The odd part of $C(a + Th)$ has precisely the possible degrees $1, 3, \dots, 2m - 1$. The reflection evaluation matrix for those degrees is invertible, so any desired reflected-value vector is equivalent to prescribing these m odd coefficients. Choose directions block by block, starting with the largest block. The coefficient of T^{2m-1} is exactly $N_{2m-1}(h_m)$, which can be set arbitrarily because the norm map is onto $\mathbb{F}_q$. Once h_m is fixed, the coefficient of T^{2m-3} is $N_{2m-3}(h_{m-1})$ plus an already determined contribution from the larger block. Choose h_{m-1} to make this coefficient correct. Continue downward; at each stage smaller blocks cannot affect the current coefficient, and the norm of the current block can attain every desired value. The final linear block sets the coefficient of T . This realizes the prescribed reflection vector. $\square$

Theorem III.64.2 (No independent additive extension). *Let $W = \mathbb{F}_q^e$, and let $R : W \rightarrow \mathbb{F}_q$ be any function. Set*

$$P(u, w) = C(u) + R(w).$$

For every center (a, b) , the projection

$$S_{(a,b)}(P) \longrightarrow W, \quad (h, g) \longmapsto g,$$

is surjective. Consequently

$$|S_{(a,b)}(P)| \geq q^e, \quad A_\ell^{\text{sym}}(P) \geq q^{m^2+e}(q^e - 1).$$

If $e > 0$, the coloring cannot avoid nontrivial symmetrically colored ℓ -term progressions. This holds irrespective of the degree of R .

Proof. Fix an extra direction $g \in W$. The m reflected differences of $R(b + Tg)$ form a vector in $\mathbb{F}_q^m$. Surjectivity of Φ_a supplies a core direction h giving its negative. Thus (h, g) is a symmetric direction. For $g \neq 0$ it is nonzero. The projection conclusion gives the pointwise bound, and summation over the q^{m^2+e} centers gives the global count. $\square$

The same proof applies to several output coordinates, each with its own complete m -layer norm core, and an arbitrary added vector-valued function. For the scalar four-term problem, it rules out every construction of the form $x_0 + N_3(u) + R(w)$ with at least one added variable. In particular, the failure of adding independent higher norm blocks is not confined to the Artin–Schreier example in characteristic five.

III.64.1 Exact counts for the cubic core

For $\ell = 4$, the preceding lower bound has an exact defect formula. Let

$$P(a, u, w) = a + N_3(u) + R(w), \quad (a, u, w) \in \mathbb{F}_q \oplus \mathbb{F}_q^3 \oplus W.$$

For $b, g \in W$, put

$$D_R(b, g) = R(b + 3g/2) - 3R(b + g/2) + 3R(b - g/2) - R(b - 3g/2),$$

and let $T_b(R) = \#\{g \in W : D_R(b, g) \neq 0\}$. $D_R(b, g)$ is the third forward difference $\Delta_g^3 R(b - 3g/2)$.

Theorem III.64.3 (Exact added-block defect). *For every center (a, u, b) ,*

$$|S_{(a, u, b)}(P)| = q^e + (q^2 + q)T_b(R).$$

Consequently

$$A_4^{\text{sym}}(P) = q^{4+e}(q^e - 1) + q^4(q^2 + q) \sum_{b \in W} T_b(R).$$

Thus the universal added-block lower bound is attained if and only if every pure third additive difference of R vanishes.

Proof. Fix g . Let E_1 and E_3 denote the reflected differences of the cubic core at the parameters $1/2$ and $3/2$. For the cubic core, write its odd coefficients as C_1 and C_3 . Then $E_1 = C_1 + C_3/4$ and $E_3 = 3C_1 + 27C_3/4$. Therefore the two cancellation equations force

$$N_3(h_u) = C_3 = -D_R(b, g)/6.$$

Each choice of h_u satisfying this equation determines a unique linear direction h_a from the first reflection equation. The cubic norm has one preimage of zero and $q^2 + q + 1$ preimages of each nonzero value. Thus the fiber over g has size one if $D_R(b, g) = 0$ and size $q^2 + q + 1$ otherwise. Summing over g proves the pointwise formula. It is independent of the core center (a, u) , of which there are q^4 ; summing over all centers gives the stated global formula. $\square$

III.64.2 The zero-defect functions over the prime field

Corollary III.64.4 (Zero-defect rigidity). *If W is regarded as a vector space over its prime field $\mathbb{F}_p$ (with $p > 3$), then all pure third differences vanish if and only if R is a polynomial of total degree at most two in $\mathbb{F}_p$ -linear coordinates, with coefficients in $\mathbb{F}_q$. Equivalently, $R(x) = c + L(x) + B(x, x)$ with L $\mathbb{F}_p$ -linear and B symmetric $\mathbb{F}_p$ -bilinear. For $q = p$ these are precisely the usual scalar quadratic polynomials. For proper extension fields this includes, for example, additive Frobenius maps, and should not be replaced by an $\mathbb{F}_q$ -quadratic claim.*

Proof. Choose an $\mathbb{F}_p$ -basis of W and use the unique reduced polynomial representation $R(X) = \sum_a c_a X^a$, in which every $a_i < p$. If all pure third differences vanish, the restriction $t \mapsto R(x + th)$ on each prime-field line has reduced degree at most two: otherwise applying the step-one third difference to a polynomial of degree $j \in \{3, \dots, p-1\}$ leaves a nonzero leading coefficient $j(j-1)(j-2)$. The coefficient of t^3 in the reduced polynomial for $R(X + tH)$ therefore vanishes as a polynomial function of (X, H) . Its expansion contains terms

$$c_a \binom{a}{e} X^{a-e} H^e \quad \text{for } e \leq a \text{ and } |e| \equiv 3 \pmod{p-1}.$$

Every displayed exponent in each X_i and H_i is below p , and different pairs (a, e) yield different monomials. Hence there can be no cancellation between them. If $|a| \geq 3$, choose $e \leq a$ with $|e| \equiv 3 \pmod{p-1}$; all the binomial coefficients are nonzero in characteristic p , forcing $c_a = 0$. Thus R has total degree at most two. The converse follows immediately from taking third differences. Polarization in odd characteristic gives the equivalent bilinear description. $\square$

[write] **6 October 2026; sources 34–39.** Source 38's Theorem III.88.2 gives the exact six-term count for the linear–cubic–quintic core with an independent addition (Section III.87).

III.65 A quantitative global obstruction to the high-degree norm construction

Source 22, delivered Section 10.

Let q be a power of an odd prime p . Write $E_t = \mathbb{F}_{q^t}$, regarded as a t -dimensional vector space over $\mathbb{F}_q$, and write $N_t = N_{E_t/\mathbb{F}_q}$. The function N_t is represented by a homogeneous polynomial of degree t in any linear coordinate basis. All progressions below are ordered start–direction pairs; directions are not identified up to scaling or orientation.

Lemma III.65.1 (Exact constant-line ratios for the degree- p norm). *Define*

$$\mathcal{T} = \{\theta \in E_p : \theta^q - \theta \in \mathbb{F}_p^*\}.$$

Then $|\mathcal{T}| = q(p-1)$, every element of $\mathcal{T}$ is nonzero, and for $\theta \in E_p$ the following are equivalent:

1. $N_p(\theta + j)$ is independent of $j \in \mathbb{F}_p$;
2. $\theta \in \mathcal{T}$;
3. as a polynomial in T ,

$$N_p(\theta + T) = T^p - T + \theta^p - \theta.$$

Consequently, the number of pairs $(a, h) \in E_p \times E_p^$ for which $N_p(a + jh)$ is constant for every $j \in \mathbb{F}_p$ is exactly*

$$(q^p - 1)q(p-1).$$

For each fixed $a \neq 0$, there are exactly $q(p-1)$ such directions; for $a = 0$, there are none.

Proof. For $c \in \mathbb{F}_p^*$ the polynomial $X^q - X - c$ has q distinct roots in an algebraic closure, since its derivative is -1 . If θ is a root, iteration gives $\theta^{q^j} = \theta + jc$, and hence $\theta^{q^p} = \theta$. Thus all these roots lie in E_p . The root sets for different c are disjoint, proving $|\mathcal{T}| = q(p-1)$. They avoid zero. For such a θ , its p Frobenius conjugates are exactly $\theta + \mathbb{F}_p$, because $c \neq 0$. Therefore

$$N_p(\theta + T) = \prod_{j \in \mathbb{F}_p} (\theta + T + j) = (\theta + T)^p - (\theta + T) = T^p - T + \theta^p - \theta.$$

This proves (ii) $\Rightarrow$ (iii) $\Rightarrow$ (i).

Conversely, put $P(T) = N_p(\theta + T)$, a monic polynomial of degree p over $\mathbb{F}_q$. If (i) holds, $P(T) - P(0)$ vanishes at all p elements of $\mathbb{F}_p$; it is monic of degree p , so $P(T) - P(0) = T^p - T$. In particular P is separable. If $\theta \in \mathbb{F}_q$ then $P(T) = (T + \theta)^p$, a contradiction. Since $[E_p : \mathbb{F}_q] = p$, the element θ therefore has degree p over $\mathbb{F}_q$. The roots of P are both its distinct Frobenius conjugates $-\theta^{q^j}$ and the translates $-\theta + \mathbb{F}_p$. Hence $\theta^q - \theta \in \mathbb{F}_p$; this difference is nonzero because $\theta \notin \mathbb{F}_q$. Thus (i) $\Rightarrow$ (ii).

For $h \neq 0$, multiplicativity of the norm shows that the progression condition is equivalent to $a/h \in \mathcal{T}$. There are $q^p - 1$ choices of h and $q(p-1)$ choices of this ratio. For fixed $a \neq 0$, the directions are $h = a/\theta$, $\theta \in \mathcal{T}$, and are distinct; $a = 0$ gives ratio zero and therefore no direction. $\square$

The word “exact” in this lemma concerns constancy on the full p -point prime-field progression. It does not assert an exact count for the weaker reflection equalities on $\ell < p$ points.

Proposition III.65.2 (Every norm block of degree divisible by the characteristic). *Suppose $p \mid t$. At every $a \in E_t^*$ there are at least $q(p-1)$ distinct $h \in E_t^*$ such that $N_t(a + jh)$ is constant for all $j \in \mathbb{F}_p$. Hence this norm has at least*

$$(q^t - 1)q(p-1)$$

ordered nonconstant-direction progressions on which its value is constant.

Proof. The subfield $E_p \subset E_t$ exists because $p \mid t$. Use $\mathcal{T} \subset E_p^*$ from the lemma. For $x \in E_p$, transitivity of the norm gives

$$N_t(x) = N_p(x)^{t/p}.$$

For each $a \neq 0$ and $\theta \in \mathcal{T}$, put $h = a/\theta$. Then

$$N_t(a + jh) = N_t(h)N_p(\theta + j)^{t/p},$$

which is independent of j . Distinct θ give distinct directions. Counting over the nonzero starts proves the assertion. $\square$

Theorem III.65.3 (Quantitative excess for a layered norm map). *Consider a direct-sum norm construction on B controlled coordinates, with any number $f \geq 0$ of additional ignored coordinates, so the domain has dimension $n = B + f$. Each controlled block has dimension t and contributes its norm N_t to one specified coordinate of the coloring. Different blocks use disjoint coordinates. Let $\mathcal{J}$ be any collection of its blocks whose degrees t_j are divisible by p . For any even $\ell < p$, let S_z denote the directions producing reflection symmetry about z on the standard centered ℓ -term progression, including zero. Then*

$$|S_z| \geq q^f \prod_{j \in \mathcal{J}} \left(1 + q(p-1) 1_{\{z_j \neq 0\}} \right).$$

Consequently the number A_ℓ^{sym} of ordered nontrivial symmetric ℓ -term progressions satisfies

$$A_\ell^{\text{sym}} \geq q^n \left[q^f \prod_{j \in \mathcal{J}} \left(1 + q(p-1)(1 - q^{-t_j}) \right) - 1 \right].$$

In particular, the presence of one such block of degree t forces an excess of at least

$$q^{2n-B-t}(q^t - 1)q(p-1)$$

above the value $q^n(q^f - 1)$ supplied solely by ignored coordinates.

Proof. At a fixed center, set the direction in every unselected controlled block to zero. In a selected block j , always allow direction zero; when $z_j \neq 0$, additionally allow the $q(p-1)$ directions given by the preceding proposition. Each selected block then has a constant norm along every prime-field parameter, so their sums in each output coordinate are constant too. The centered parameters for the standard even ℓ -term progression belong to $\mathbb{F}_p$. Every chosen direction therefore satisfies all the required reflection equalities. The ignored coordinates admit arbitrary directions, giving q^f choices. All these choices are independent and distinct. This proves the local product bound.

The starts and centered parametrizations are in bijection. Sum $|S_z| - 1$ over centers. For each selected block, z_j is independently uniform in its q^{t_j} -element space; its nonzero probability is $1 - q^{-t_j}$. The averaged product gives the displayed global bound. Taking one block and using $f = n - B$ gives the final expression. $\square$

The first high-degree four-term example. Take $q = p = 5$, $\ell = 4$, and $Q = N_3 + N_5$ on $\mathbb{F}_5^3 \oplus \mathbb{F}_5^5$. The highest-two-odd-degree construction attains $S_0 = \{0\}$: the two reflection equations at $\pm 1/2$ and $\pm 3/2$ form an invertible matrix on the cubic and quintic norm values. Nevertheless the degree-five block forces at least

$$5^3(5^5 - 1)5(5 - 1) = 7\,810\,000$$

ordered nontrivial symmetric four-term progressions. Indeed, at every center whose quintic block is nonzero, it supplies at least twenty nonzero directions with the cubic block frozen. There are $5^3(5^5 - 1)$ such centers. This distinguishes sharpness at one prescribed center from simultaneous global sharpness of a particular construction. It does not preclude a different degree-five polynomial from avoiding these patterns.

III.66 Sources 29 and 28: the odd-order constants c_d^{odd} [write]

Added in the sixth write, 6 October 2026.

The next four sections are about $c_d^{\text{odd}} = \sup \|f\|_{U^2}^4 / \|f\|_{U^d}^4$ over real centered f on groups of odd order, source 03's Research question 1 and source 04's Question 3, settled for $d = 3$ by source 04's Theorem III.3.4 ($c_3^{\text{odd}} = 2^{-1/2}$) and open for $d \geq 4$. *Logically the chapter follows source 04's Section III.3*; it is printed here because no number printed earlier may move. Sections III.67–III.69 are source 29's, the main source; Section III.70 is source 28's, written from the same pin; neither cites the other.

What is proved, in one paragraph. For real f with no Fourier mass on self-inverse characters, $\|f\|_{U^d}^{2^d} \geq 2^{-m} \binom{2^m}{m} \|f\|_{U^2}^{2^d}$, $m = 2^{d-2}$ (source 29's Theorem III.68.1; the moment inequality is sharp,

the norm comparison is not claimed sharp), so $c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ and $c_d^{\text{odd}} \leq B_d \downarrow 1/2$ (Corollary III.69.1); an interval model gives $c_d^{\text{odd}} \geq 1/3$ for every d , so the limit lies in $[1/3, 1/2]$ (Proposition III.69.2); with self-inverse mass the profile $K_m(\tau)$ (Theorem III.68.3). Source 28 proves the weaker universal $c_d^{\text{odd}} \leq \sqrt{160/323}$ for $d \geq 4$ (Theorem III.70.1), the lower bound $c_4^{\text{odd}} \geq 0.5587294$ by an exact two-harmonic witness (Corollary III.70.8), and that a single cosine is not a local extremizer for any $d \geq 4$ (Theorem III.70.9). The intake's exact certificate on $\mathbb{Z}/7\mathbb{Z}$ gives $c_4^{\text{odd}} \geq 0.5587725$ (note after Corollary III.70.8). The bracket printed here is therefore $0.5587725 \leq c_4^{\text{odd}} \leq 0.6914416$, among sources 01–33; sources 34, 35 and 45, placed and not yet written, record upper coefficients $81/16$, 5 and $4795/832$, that is $c_4^{\text{odd}} \leq 2/3$ and ≤ 0.6454070 (note after Corollary III.69.1). In the quartic cube term the coefficient $100/\sqrt{2} = 70.71$ at $d = 4$ becomes $100(8/35)^{1/4} = 69.14$ (source 29's (III.69.7); source 28's corollary has 70.38).

Relation to the formal statements. `lemma_3_10` (Sections01_03.lean, line 340) has the exact companion `lemma_3_10_holds` (Proofs03CubeUpper.lean, line 82, at HEAD 5d4718772); no declaration concerns c_d^{odd} . Nothing in this chapter is formalized.

[write] **6 October 2026; sources 34–39.** *Sources 34 and 35 continue this chapter.* Source 34's Section 10 (Section III.71) and source 35's Section 6 (Section III.72) follow source 28's Section 8 at the end of this chapter, so that the chapter stays together. Source 34 proves $\|f\|_{U^2}^4 \leq (2/3) \|f\|_{U^4}^4$, coupling the dominant-pair moment profile of source 29 with the exact dual function of a cosine (source 28's identity, uncited there) and two resonant autocorrelation families; source 35, written the same day from the same pin, proves the weaker coefficient 5 by retaining repeated-entry quadruples in the U^3 Fourier energy, an energy inequality of independent interest. The bracket among sources 01–39 is $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$; source 45, placed and not yet written, records $c_4^{\text{odd}} \leq 0.6454070$. Their introductions are Sections F.39 and F.40; source 34's torsion chapter follows (Section III.73).

[write] **7 October 2026; sources 40–46.** *Source 45 continues this chapter* at the end of Part III (Section III.89), because this chapter is no longer the last of Part III: $4795/832$, so $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ among sources 01–46.

III.67 Notation and elementary Fourier identities

Source 29, delivered Section 2.

Let G be a finite abelian group. Averages over G are normalized: $\mathbb{E}_x F(x) = |G|^{-1} \sum_{x \in G} F(x)$. Sums over its character group $\widehat{G}$ use counting measure. We write characters multiplicatively and set

$$\widehat{f}(\chi) = \mathbb{E}_x f(x) \overline{\chi(x)}, \quad \Delta_h f(x) = f(x) \overline{f(x-h)}.$$

For $d \geq 1$, define

$$\|f\|_{U^d}^{2^d} = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{\omega \in \{0,1\}^d} \mathcal{C}^{|\omega|} f(x - \omega \cdot h), \quad (\text{III.67.1})$$

where $\mathcal{C}$ is complex conjugation. In particular, $\|f\|_{U^1} = |\mathbb{E} f|$. The sign of the increments is immaterial under uniform averaging. For $d \geq 2$, the recursive identity, together with the Fourier identity for U^2 , is

$$\|f\|_{U^d}^{2^d} = \mathbb{E}_h \|\Delta_h f\|_{U^{d-1}}^{2^{d-1}}, \quad (\text{III.67.2})$$

$$\|f\|_{U^2}^4 = \sum_{\chi \in \widehat{G}} |\widehat{f}(\chi)|^4. \quad (\text{III.67.3})$$

Repeated Cauchy–Schwarz gives the usual monotonicity $\|f\|_{U^1} \leq \|f\|_{U^2} \leq \dots$ and the multilinear Gowers–Cauchy–Schwarz inequality. These elementary norm properties are also developed in Gowers’s Section 3 [1].

For a real function f , define its autocorrelation and Fourier masses by

$$c_f(h) = \mathbb{E}_x f(x)f(x-h) = \sum_{\chi} \lambda_{\chi} \chi(h), \quad \lambda_{\chi} = |\widehat{f}(\chi)|^2. \quad (\text{III.67.4})$$

Then $\lambda_{\chi} \geq 0$ and $\lambda_{\chi^{-1}} = \lambda_{\chi}$. In particular, although c_f need not be pointwise nonnegative, its Fourier coefficients are nonnegative. We use

$$S = \sum_{\chi} \lambda_{\chi}^2 = \|f\|_{U^2}^4.$$

When $f \neq 0$, $S > 0$. The subgroup of self-inverse characters is $\widehat{G}[2] = \{\chi : \chi^2 = 1\}$. On an odd-order group it consists only of the trivial character, so a centered function has zero Fourier mass on $\widehat{G}[2]$.

III.68 Positive autocorrelation moments and higher norm bounds

Source 29, delivered Section 3.

Theorem III.68.1 (Central-binomial autocorrelation bound). *Let $f : G \rightarrow \mathbb{R}$, and suppose $\widehat{f}(\chi) = 0$ whenever $\chi^2 = 1$. For every integer $m \geq 1$,*

$$\mathbb{E}_h c_f(h)^{2m} \geq \binom{2m}{m} \left(\frac{S}{2}\right)^m. \quad (\text{III.68.1})$$

Consequently, for every $d \geq 2$, with $m = 2^{d-2}$,

$$\|f\|_{U^d}^{2^d} \geq C_m \|f\|_{U^2}^{2^d}, \quad C_m = 2^{-m} \binom{2m}{m}. \quad (\text{III.68.2})$$

The constant in (III.68.1) is optimal uniformly over finite abelian groups. Sharpness is not asserted for (III.68.2) when $d \geq 3$.

Proof. Choose one character χ_j from each nonzero inverse pair, and write $b_j = \lambda_{\chi_j}$. Thus $S = 2 \sum_j b_j^2$. The zero function is immediate, so assume at least one pair occurs. Expanding the Fourier series of c_f^{2m} and averaging retains precisely the monomials whose product character is trivial. Their coefficients are nonnegative. We may therefore retain only monomials that use χ_j and χ_j^{-1} equally often for every j . If each occurs k_j times, where $\sum_j k_j = m$, the contribution is

$$\frac{(2m)!}{\prod_j (k_j!)^2} \prod_j b_j^{2k_j}.$$

Hence

$$\begin{aligned}
\mathbb{E}c_f^{2m} &\geq \binom{2m}{m} \sum_{\sum k_j=m} \binom{m}{k_1, k_2, \dots}^2 \prod_j b_j^{2k_j} \\
&\geq \binom{2m}{m} \sum_{\sum k_j=m} \binom{m}{k_1, k_2, \dots} \prod_j b_j^{2k_j} \\
&= \binom{2m}{m} \left(\sum_j b_j^2 \right)^m.
\end{aligned} \tag{III.68.3}$$

The second inequality only uses the fact that each multinomial coefficient is an integer at least one.

By (III.67.2) and $\|g\|_{U^{d-1}} \geq |\mathbb{E}g|$,

$$\|f\|_{U^d}^{2^d} \geq \mathbb{E}_h |c_f(h)|^{2^{d-1}}.$$

Here $2^{d-1} = 2m$, and $S^m = \|f\|_{U^2}^{2^d}$, proving the norm comparison. To see moment sharpness, take a character of order greater than $2m$ and $f = 2 \operatorname{Re}(a\chi)$, with $a \neq 0$. The only surviving monomials in c_f^{2m} then contain the two characters equally often, and equality holds. $\square$

III.68.1 Equality and stability at the moment level

The moment argument contains more information than its last scalar bound. It quantifies the cost of distributing Fourier fourth-power mass among several inverse pairs.

Proposition III.68.2 (Pair concentration). *Under the assumptions of Theorem III.68.1, let $f \neq 0$, $m \geq 2$, and*

$$p_j = \frac{2\lambda_{\chi_j}^2}{S}, \quad \sum_j p_j = 1.$$

Then

$$\frac{\mathbb{E}c_f^{2m}}{C_m S^m} \geq m - (m-1) \sum_j p_j^m. \tag{III.68.4}$$

If the left side is at most $1 + \varepsilon$, where $0 \leq \varepsilon < m-1$, some inverse pair has mass

$$p_j \geq \left(1 - \frac{\varepsilon}{m-1}\right)^{1/(m-1)}. \tag{III.68.5}$$

For that pair, putting $a = \widehat{f}(\chi_j)$,

$$\|f - 2 \operatorname{Re}(a\chi_j)\|_{U^2}^4 \leq S \left[1 - \left(1 - \frac{\varepsilon}{m-1}\right)^{1/(m-1)} \right]. \tag{III.68.6}$$

Equality in (III.68.1), for $m \geq 2$, holds exactly when the Fourier support is one inverse pair and, for its character order n , $n/\gcd(n, 2) > m$.

Proof. For a composition k of m , the multinomial coefficient is one if all mass is in a single coordinate, and is at least m otherwise. The normalized balanced sum in (III.68.3) is the expectation of this

multinomial coefficient under the multinomial distribution with probabilities p_j . The probability of a pure composition is $\sum_j p_j^m$. This proves (III.68.4). It gives $\sum_j p_j^m \geq 1 - \varepsilon/(m-1)$, whereas $\sum_j p_j^m \leq (\max_j p_j)^{m-1}$. Removing the largest pair and using (III.67.3) proves the distance statement.

At equality every mixed composition must vanish, so just one pair remains. For that pair the extra monomials have exponent $2j - 2m$, $0 \leq j \leq 2m$, on the chosen character. A nonzero such exponent can be divisible by n exactly when $n/\gcd(n, 2) \leq m$. Its coefficient is positive. This proves the stated criterion. $\square$

This is stability for the autocorrelation moment and approximation in U^2 . It neither asserts approximation in L^2 nor classifies near-minimizers of $\|f\|_{U^d}/\|f\|_{U^2}$. The first inequality in the norm proof can have its own nonzero gap.

III.68.2 An explicit profile for self-inverse Fourier mass

The absence of order-two characters is essential for a uniform improvement over one: a nontrivial real character has all Gowers norms equal to one. Its contribution can nevertheless be tracked exactly in the moment method.

Theorem III.68.3 (Torsion-dependent moment profile). *Let $f : G \rightarrow \mathbb{R}$ be nonzero, with no restriction on its mean or on G . Set*

$$\tau = \frac{\sum_{\chi^2=1} \lambda_\chi^2}{S} \in [0, 1],$$

and define

$$K_m(\tau) = \sum_{k=0}^m \binom{2m}{2k} \binom{2k}{k} \tau^{m-k} \left(\frac{1-\tau}{2}\right)^k. \quad (\text{III.68.7})$$

For every integer $m \geq 1$,

$$\mathbb{E}_h c_f(h)^{2m} \geq K_m(\tau) S^m. \quad (\text{III.68.8})$$

For $m = 2^{d-2}$, it follows that $\|f\|_{U^d}^{2d} \geq K_m(\tau) \|f\|_{U^2}^{2d}$. For each m and each τ , the moment constant in (III.68.8) is attained on some finite abelian group.

Proof. Separate the self-inverse frequencies from the remaining inverse pairs. In the Fourier expansion retain terms in which every self-inverse frequency occurs an even number of times and each non-self-inverse pair occurs in equal numbers. These terms are exactly the moment of

$$X + Y = \sum_i a_i \epsilon_i + \sum_j 2b_j \cos \theta_j,$$

where the ϵ_i are independent uniform signs and the θ_j are independent uniform circle variables, all mutually independent. Their variances are $\mathbb{E}X^2 = \tau S$ and $\mathbb{E}Y^2 = (1-\tau)S$. All other actual Fourier terms are nonnegative, so discarding them is legitimate even when the original characters have extra relations.

Odd proxy moments vanish. Jensen's inequality gives $\mathbb{E}X^{2r} \geq (\tau S)^r$, including $r = 0$. The balanced multinomial calculation gives $\mathbb{E}Y^{2k} \geq \binom{2k}{k} ((1-\tau)S/2)^k$. Expanding $\mathbb{E}(X+Y)^{2m}$ and applying these two estimates gives (III.68.7).

For sharpness, use $G = C_2 \times C_p$, with p an odd prime greater than $2m$. Put Fourier squared mass $\lambda_\sigma = \sqrt{\tau S}$ on the nontrivial character of C_2 , and $\lambda_\chi = \lambda_{\chi^{-1}} = \sqrt{(1-\tau)S/2}$ on one pair from

C_p . A real function with these squared Fourier coefficients exists by taking nonnegative square roots as Fourier coefficients. Only the retained moments survive, and both component estimates are equalities. $\square$

The endpoints are $K_m(0) = C_m$ and $K_m(1) = 1$. The profile need not be monotone between them: for example, $K_2(\tau) = \frac{3}{2} + 3\tau - \frac{7}{2}\tau^2$. It describes how Fourier mass in both sectors can increase an even moment; it is not a monotone penalty for torsion alone.

III.69 Consequences for the unresolved higher norm constants

Source 29, delivered Section 4.

For $d \geq 3$, define

$$c_d^{\text{odd}} = \sup_{\substack{|G| \text{ odd}, f: G \rightarrow \mathbb{R} \\ \mathbb{E}f=0, f \neq 0}} \frac{\|f\|_{U^2}^4}{\|f\|_{U^d}^4}. \quad (\text{III.69.1})$$

The supremum ranges over finite groups as well as functions. The existing report proves $c_3^{\text{odd}} = 2^{-1/2}$ [135]. Monotonicity alone therefore gives that same upper bound for every $d \geq 3$. In norm-power form its coefficient is $2^{m/2}$, where $m = 2^{d-2}$.

Corollary III.69.1 (A strict improvement from dimension four onward). *For $d \geq 4$ and $m = 2^{d-2}$,*

$$c_d^{\text{odd}} \leq B_d := \frac{2}{\binom{2m}{m}^{1/m}} < 2^{-1/2}. \quad (\text{III.69.2})$$

In particular,

$$\|f\|_{U^4}^{16} \geq \frac{35}{8} \|f\|_{U^2}^{16} \quad (\text{III.69.3})$$

for real centered f on odd-order groups. The bounds B_d decrease to $1/2$.

[write] **6 October 2026; sources 28–33.** *The best upper coefficient among sources 01–33, not the best known.* Among sources 01–33, $35/8$ is the best coefficient for real centered f on odd-order groups at $d = 4$ (source 28’s universal bound gives $(323/160)^2 = 4.0754\dots$, note after its Theorem III.70.1). Sources placed in this directory and not yet written in record larger coefficients: source 35 records 5, source 34 records $81/16$, that is $c_4^{\text{odd}} \leq 2/3$, and source 45 records $4795/832$, that is $c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ (their placements, checked at intake; for the writes that add them). With source 28’s lower bound and the intake’s certificate the bracket printed by this write is $0.5587725 \leq c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ (item III.1). The decimals of the table were recomputed at the write.

[write] **6 October 2026; sources 34–39.** Sources 34 and 35 are now written in: source 34’s Theorem III.71.1 ($81/16$, $c_4^{\text{odd}} \leq 2/3$, the best among sources 01–39) and source 35’s Theorem III.72.1 (5) follow source 28’s Section 8 at the end of this chapter; source 45 ($4795/832$) is placed and not yet written. For $5 \leq d \leq 8$ source 34’s Remark III.71.10 improves the bounds B_d of the table above slightly (recomputed at intake); for $d \geq 9$ they stand.

[write] **7 October 2026; sources 40–46.** Source 45 is now written in: its Theorem III.90.1 ($4795/832$, $c_4^{\text{odd}} \leq 0.6454070$, the best among sources 01–46) is printed at the end of Part III (Section III.89), and source 49, placed by `f8bc5e2ec` and not yet written in, records $29/4$, that is $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$ (for its write); by monotonicity it also bounds c_d^{odd} for $d \geq 5$, but source 34’s β_d for $5 \leq d \leq 8$ and the B_d of the table for $d \geq 9$ are smaller.

Proof. The norm theorem gives $c_d^{\text{odd}} \leq C_m^{-1/m} = B_d$. At $m = 4$, $C_4 = 35/8 > 4 = 2^{4/2}$. Vandermonde's identity includes the central summand $\binom{4m}{2m} \geq \binom{2m}{m}^2$; hence $C_{2m} \geq C_m^2$. Induction along powers of two proves the strict comparison with $2^{m/2}$, and also the monotonicity of B_d . Finally $4^m/(2m+1) \leq \binom{2m}{m} \leq 4^m$, which gives the limit. $\square$

d	m	Moment coefficient C_m	Upper bound for c_d^{odd}
3	2	3/2 (use the older sharp coefficient 2)	0.707106781
4	4	35/8	0.691441569
5	8	6435/128	0.612819643
6	16	300540195/32768	0.565388162
7	32	$2^{-32} \binom{64}{32}$	0.537413970
8	64	$2^{-64} \binom{128}{64}$	0.521168336

Table III.69.1: The decimals are approximations to the proved exact upper bounds. The new moment estimate is weaker at $d = 3$, where the previously proved sharp result is retained.

III.69.1 A lower bound uniform in the dimension

Proposition III.69.2 (A uniform interval model). *For every $d \geq 3$, $c_d^{\text{odd}} \geq 1/3$. Consequently the nonincreasing sequence c_d^{odd} has a limit in $[1/3, 1/2]$.*

[write] **6 October 2026; sources 28–33.** This answers the part of source 28's Research question on the asymptotic constants that asks for a positive lower bound uniform in d (item III.1); checked at the write: the ratio $n(n^2 + n + 1)/(3(n + 1)^3)$ is 0.278, 0.327, 0.3327 at $n = 10, 100, 1000$.

Proof. On $G = \mathbb{Z}/(2n+1)\mathbb{Z}$, let $A = \{0, \dots, n-1\}$, $\delta = n/(2n+1)$, and $f = 2(\mathbf{1}_A - \delta)$. There is no wraparound in sums of two members of A . The additive energy is

$$E(A) = n^2 + 2 \sum_{j=1}^{n-1} j^2 = \frac{2n^3 + n}{3}.$$

By Fourier orthogonality,

$$\|f\|_{U^2}^4 = 16 \left(\frac{E(A)}{(2n+1)^3} - \delta^4 \right), \quad \|f\|_{\infty} = \frac{2(n+1)}{2n+1}.$$

Since $\|f\|_{U^d} \leq \|f\|_{\infty}$,

$$\frac{\|f\|_{U^2}^4}{\|f\|_{U^d}^4} \geq \frac{n(n^2 + n + 1)}{3(n+1)^3} \longrightarrow \frac{1}{3}.$$

This works for each fixed d , with a bound independent of d . Monotonicity and Corollary III.69.1 prove the limit assertion. $\square$

III.69.2 A more informative lower bound in dimension four

For a prime $p > 16$ and $f = a\chi + \bar{a}\chi^{-1}$ on $\mathbb{Z}/p\mathbb{Z}$, with χ nontrivial, one has

$$\|f\|_{U^4}^{16} = 222|a|^{16}, \quad \|f\|_{U^2}^{16} = 16|a|^{16}. \quad (\text{III.69.4})$$

Here is a finite combinatorial verification of the coefficient. A surviving Fourier monomial chooses eight positive-sign vertices of $\{0, 1\}^4$, with four ones in each coordinate. Split by the fourth coordinate into four-subsets of the three-cube. If $n(v)$ counts four-subsets with coordinate-sum vector v , complementing a subset shows $n(4\mathbf{1} - v) = n(v)$, and the required number is $\sum_v n(v)^2$. The following complete classification uses coordinate permutations and coordinate reflections:

sorted $(v_1 - 2 , v_2 - 2 , v_3 - 2)$	number of vectors v	$n(v)$
$(0, 0, 0)$	1	8
$(0, 0, 1)$	6	4
$(0, 0, 2)$	6	1
$(0, 1, 1)$	12	2
$(1, 1, 1)$	8	1

For example, a coordinate sum zero or four determines a full face; for sums $(1, 2, 2)$, the unique point on one side of the first coordinate determines the omitted point on the other side, giving four choices. For $(1, 1, 2)$, separating whether the first two coordinate ones occur at the same point gives two choices. For $(1, 1, 1)$ the subset is forced. The balanced case $(2, 2, 2)$ consists of six unions of two antipodal pairs and two parity tetrahedra. Thus the sum is $64 + 96 + 6 + 48 + 8 = 222$. The condition $p > 16$ prevents nonzero integer exponents from vanishing modulo p .

It follows that

$$\left(\frac{8}{111}\right)^{1/4} \leq c_4^{\text{odd}} \leq \left(\frac{8}{35}\right)^{1/4}. \quad (\text{III.69.5})$$

The endpoints are approximately 0.518133595 and 0.691441569. The interval has not been closed. In particular, the number $35/8$ is a rigorously improved coefficient, not the asserted sharp answer.

[write] **6 October 2026; sources 28–33.** The lower end of (III.69.5) is the single-cosine value. Source 28, from the same pin, raises it to 0.5587294 by an exact two-harmonic witness (Corollary III.70.8), and the intake’s certificate on $\mathbb{Z}/7\mathbb{Z}$ to 0.5587725 (note there); source 28’s Theorem III.70.9 shows that a single inverse pair is not extremal for any $d \geq 4$.

III.69.3 How the coefficient enters centered cube counting

For $Q_d(F) = \|F\|_{U^d}^{2^d}$ and real centered f , expansion of $Q_d(\delta + f)$ has no terms with one, two, or three selected vertices: at those vertices the affine forms are independent. On odd-order groups the fourth-degree term is

$$P_d \delta^{2^d-4} \|f\|_{U^2}^4, \quad P_d = 2^{d-3}(3^d - 2^{d+1} + 1). \quad (\text{III.69.6})$$

This coefficient and the torsion qualifications are proved in the existing cube-expansion reports [135, 137]. The new norm estimate therefore changes the available bound on this term to

$$P_d B_d \delta^{2^d-4} \|f\|_{U^d}^4, \quad d \geq 4. \quad (\text{III.69.7})$$

For $d = 4$, $P_4 = 100$: the coefficient improves from $100/\sqrt{2} \approx 70.710678$ to $100(8/35)^{1/4} \approx 69.144157$. This is an explicit improvement to one local coefficient. Terms of higher degree and subsequent inverse and localization losses still have to be controlled before a final progression-free-set bound could change.

Figure III.69.1: Left: the proved upper bounds for c_d^{odd} , with the dimension-independent lower bound $1/3$ and the sharper cosine lower bound at $d = 4$. Right: the full fourth-dimensional moment profile, expressed as $K_4(\tau)^{-1/4}$. The curve is a valid bound from the moment method, not a claimed sharp Gowers-norm constant.

III.70 A stronger real norm gap and a higher-order obstruction

Source 28, delivered Section 8.

Delivered part heading of source 28: **Strict norm gaps and the failure of cosine extremality**

The earlier repository report proves the sharp real, mean-zero comparison $\|f\|_{U^3}^8 \geq 2\|f\|_{U^2}^8$ on odd-order groups, with equality precisely for a single conjugate pair of nonzero Fourier coefficients [132]. Its higher-order analogue was left open. We improve the available universal bound at every order at least four, and show that the single-character equality model does not extend to these orders. The two conclusions are independent: the universal estimate is a lower bound for a norm, whereas the explicit examples give lower bounds for the extremal ratio.

All expectations in this section use the uniform probability measure. For a real function on a finite abelian group, our convention is

$$\|f\|_{U^d}^{2d} = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{\omega \in \{0,1\}^d} f(x + \omega \cdot h). \quad (\text{III.70.1})$$

The usual conjugations in the complex definition have no effect here. Fourier coefficients are normalized by $\widehat{f}(\xi) = \mathbb{E}_x f(x) \overline{\xi(x)}$. In particular, $\|f\|_{U^2}^4 = \sum_{\xi} |\widehat{f}(\xi)|^4$. Write

$$c_d^{\text{odd}} = \sup_{\substack{G \text{ finite abelian of odd order} \\ f: G \rightarrow \mathbb{R}, \mathbb{E}f=0, f \neq 0}} \frac{\|f\|_{U^2}^4}{\|f\|_{U^d}^4}. \quad (\text{III.70.2})$$

No boundedness restriction changes this supremum, since the ratio is invariant under multiplying f by a nonzero scalar.

Theorem III.70.1 (Explicit improvement beyond the third norm). *For every finite abelian group of odd order, every real mean-zero function f , and every integer $d \geq 4$,*

$$\|f\|_{U^d}^4 \geq \sqrt{\frac{323}{160}} \|f\|_{U^2}^4. \quad (\text{III.70.3})$$

Moreover,

$$\left(\frac{133153321267264}{1366299579065739} \right)^{1/4} \leq c_4^{\text{odd}} \leq \sqrt{\frac{160}{323}}. \quad (\text{III.70.4})$$

The endpoints are approximately 0.558729390985 and 0.703815343078, respectively. The upper endpoint strictly improves the previously available $2^{-1/2} = 0.707106781187\dots$

[write] **6 October 2026; sources 28–33.** *Superseded the same day by source 29.* The universal bound (III.70.3) is $\|f\|_{U^4}^{16} \geq (323/160)^2 \|f\|_{U^2}^{16} = 4.0754\dots \|f\|_{U^2}^{16}$ at $d = 4$; source 29’s Corollary III.69.1, written from the same pin and citing neither this source nor being cited by it, gives $\|f\|_{U^4}^{16} \geq (35/8) \|f\|_{U^2}^{16}$, hence $c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ against $\sqrt{160/323} = 0.7038153$ here, and $c_d^{\text{odd}} \leq B_d < 0.6914416$ for every $d \geq 5$. The sentence that the upper endpoint “strictly improves the previously available $2^{-1/2}$ ” was true at the pin. The lower endpoint 0.5587294 is this source’s own; it is improved slightly by the intake’s certificate (note after Corollary III.70.8). The bracket is item III.1; later placed sources record further upper bounds (note after source 29’s Corollary III.69.1).

We give all ingredients below. The numerical displays are descriptive; the assertions use the exact rational quantities in the formulas. Neither endpoint is asserted to be sharp.

III.70.1 A short bounded example on five points

Proposition III.70.2 (A rational counterexample to the cosine value). *On $\mathbb{Z}/5\mathbb{Z}$, let*

$$(f(0), f(1), f(2), f(3), f(4)) = (0, 1, 1, -1, -1).$$

Then $\mathbb{E}f = 0$, $|f| \leq 1$, and

$$\|f\|_{U^2}^4 = \frac{36}{125}, \quad \|f\|_{U^4}^{16} = \frac{52}{625}, \quad \frac{\|f\|_{U^4}^{16}}{\|f\|_{U^2}^{16}} = \frac{5078125}{419904} < \frac{111}{8}. \quad (\text{III.70.5})$$

A single real character pair of odd order at least five has the ratio $111/8$. Thus it cannot describe the general fourth-order optimum.

Proof. The unnormalized autocorrelations of f are $(4, 1, -3, -3, 1)$. Their squared sum is 36, giving the first identity. For $h, k \in \mathbb{Z}/5\mathbb{Z}$, put

$$g_{h,k}(x) = f(x)f(x+h)f(x+k)f(x+h+k).$$

Twice applying the derivative identity for Gowers norms gives $\|f\|_{U^4}^{16} = \mathbb{E}_{h,k} \|g_{h,k}\|_{U^2}^4$. For an integer-valued g , write

$$E(g) = \sum_t \left(\sum_x g(x)g(x+t) \right)^2, \quad \|g\|_{U^2}^4 = E(g)/125.$$

The possibilities are

Condition on (h, k)	Number of pairs	$E(g_{h,k})$
$h = k = 0$	1	52
Exactly one of h, k is zero	8	19
$h, k \neq 0$ and $h = \pm k$	8	6
$h, k \neq 0$ and $h \neq \pm k$	8	1

Indeed, the first function is the indicator of a four-point set. In the second case it is the indicator of a three-point set. Its nonzero-shift intersection counts are 2, 2, 1, 1, so its energy is $3^2 + 2 \cdot 2^2 + 2 \cdot 1^2 = 19$. In the last two cases its support has size two and one, respectively, with values in $\{-1, 1\}$; the corresponding energies are 6 and 1, independently of the signs. The sum of the energies is $52 + 8 \cdot 19 + 8 \cdot 6 + 8 = 260$. Dividing by 5^5 gives $52/625$, and the ratio follows. $\square$

III.70.2 The exact fourth-order dual function of a cosine

For a real function g , define

$$D_4g(x) = \mathbb{E}_{h_1, h_2, h_3, h_4} \prod_{\substack{\omega \in \{0,1\}^4 \\ \omega \neq 0}} g(x + \omega \cdot h). \quad (\text{III.70.6})$$

The Gowers–Cauchy–Schwarz inequality implies

$$|\mathbb{E}_x f(x) D_4g(x)| \leq \|f\|_{U^4} \|g\|_{U^4}^{15}. \quad (\text{III.70.7})$$

This finite multilinear inequality, rather than an unproved description of a dual norm, is all that is needed.

Lemma III.70.3 (Exact cosine counts). *Let χ be a character of odd order at least five, let $\theta \in \mathbb{R}$, and write $g_j = e^{ij\theta} \chi^j + e^{-ij\theta} \chi^{-j}$. Then*

$$\|g_1\|_{U^4}^{16} = 222, \quad D_4g_1 = 111g_1 + 27g_3 + g_5. \quad (\text{III.70.8})$$

The formula remains valid when χ has order five; in that case g_5 is constant.

Proof. Expand each factor in characters. In the average defining D_4g_1 , the coefficient choices are signs on the fifteen nonzero Boolean vertices. Each direction average requires the sum of eight signs to be divisible by the order of χ . Such a sum is even and has absolute value at most eight. For an odd order at least five, it must therefore be zero as an integer. The same observation applies to both halves of a full four-dimensional cube; its total frequency is then also zero.

First count the full-cube choices. Split the cube into two three-dimensional faces. Each face has four plus signs. If $n(t)$ is the number of four-subsets of $\{0, 1\}^3$ whose coordinate sum is $t = (t_1, t_2, t_3)$, the full count is $\sum_t n(t)^2$. The required finite generating identity is

$$[z^4] \prod_{\epsilon \in \{0,1\}^3} (1 + zx^\epsilon) = x_1 x_2 x_3 \prod_{j=1}^3 (1 + x_j)^2 + \sum_{i=1}^3 (1 + x_i^4) \prod_{j \neq i} x_j^2. \quad (\text{III.70.9})$$

Here $x^\epsilon = \prod_j x_j^{\epsilon_j}$. This identity follows by multiplying the eight binomials and collecting the coefficient of z^4 . It gives the following complete table:

Type of t	Number of such t	$n(t)$
One coordinate 0 or 4, the other two 2	6	1
All three coordinates in $\{1, 3\}$	8	1
Two in $\{1, 3\}$, one equal to 2	12	2
One in $\{1, 3\}$, two equal to 2	6	4
$(2, 2, 2)$	1	8

Thus the count is $6 + 8 + 12 \cdot 4 + 6 \cdot 16 + 64 = 222$. The factor $e^{i\theta \sum_{\omega} s_{\omega}}$ is one for every such choice, so this proves the first identity in (III.70.8).

For the dual function, a choice of signs on the fifteen nonzero vertices contributes frequency $\sum s_{\omega}$. The counts at frequencies 1 and -1 are both 111: adjoining the missing sign at the origin produces the 222 full-cube assignments, divided equally by its sign. The counts at frequencies 3 and -3 are both 27, as follows. Place a frequency 3 at the missing origin, so that the other fifteen signs must have total -3 . Their six plus-sign vertices form a set P with four selected vertices on each coordinate face. After complementing all four coordinates, we obtain six distinct vertices, excluding $(1, 1, 1, 1)$, with coordinate sums all equal to two. Let a_j count their vertices of Hamming weight j . Then

$$a_0 + a_1 + a_2 + a_3 = 6, \quad a_1 + 2a_2 + 3a_3 = 8, \quad a_0 \in \{0, 1\}, \quad a_1 \leq 4.$$

Exactly three possibilities remain:

a_0	a_1	a_2	a_3	Number
0	4	2	0	3
1	2	3	0	12
1	3	1	1	12

In the first case the two edges form a perfect matching on four coordinates. In the second, choose the two singleton coordinates in six ways; the three edges form a path with those endpoints, in two ways. In the third, choose the triple in four ways and choose which of its three coordinates has no singleton; the edge is then forced. This proves $27 = 3 + 12 + 12$.

At frequency -5 , the five plus-sign vertices must have a total of sixteen coordinate incidences. The only possibility is the vertex of weight four together with the four vertices of weight three. Hence the count is one; the frequency 5 count is also one. Frequencies of absolute value at least seven are impossible, since four distinct vertices have at most $4 + 3 + 3 + 3 = 13$ incidences. These counts exhaust all odd frequencies, and prove the dual formula. $\square$

[write] **6 October 2026; sources 34–39.** Also proved by source 34 (Lemma III.71.3) and recounted by source 35 (Lemma III.72.3), neither citing this source.

Lemma III.70.4 (The order-three case). *If χ has order three, then for $g = e^{i\theta}\chi + e^{-i\theta}\chi^{-1}$,*

$$\begin{aligned} \|g\|_{U^4}^{16} &= 286 + 32 \cos(6\theta) + 16 \cos(12\theta) \\ &= 262 + 32 \left(\cos(6\theta) + \frac{1}{2} \right)^2 \geq 262. \end{aligned} \tag{III.70.10}$$

Proof. Let P be the plus-sign vertices in a character expansion of the four-cube. The congruences require $|P| \equiv 2 \pmod{3}$ and require each coordinate face to contain 1, 4, or 7 vertices of P . The possibilities are

$ P $	Total frequency $2 P - 16$	Number
2	-12	8
5	-6	16
8	0	286
11	6	16
14	12	8

For two vertices, every coordinate must occur once, so the vertices are antipodal, giving eight pairs. For five vertices, reflect every coordinate having four selected vertices. Each coordinate now occurs once, forcing the set consisting of the zero vertex and the four unit vertices. Its sixteen reflected copies are distinct. For eight vertices with four on every face, the count is 222 by (III.70.9). Otherwise some coordinate has one or seven selected vertices. Reflect to make this number one. The set is one entire three-face, with one vertex removed, and the corresponding vertex inserted across that coordinate. The remaining coordinate counts must all be four. There are $4 \cdot 2 \cdot 8 = 64$ such sets, each with exactly one exceptional coordinate. This gives $222 + 64 = 286$. Taking complements supplies the last two rows. Summing the associated phases proves the first line of (III.70.10); the second follows from the double-angle identity. $\square$

III.70.3 An explicit universal improvement

We recall precisely which earlier estimate is used. Let $f \neq 0$ be real and mean-zero on an odd-order group, set

$$S = \sum_{\xi} |\widehat{f}(\xi)|^4 = \|f\|_{U^2}^4, \quad p = \max_{\xi \neq 0} \frac{2|\widehat{f}(\xi)|^4}{S}.$$

The nonzero Fourier coefficients occur in distinct conjugate pairs, so $0 < p \leq 1$.

Lemma III.70.5 (Two bounds retaining the largest pair). *With this notation, put $R = \|f\|_{U^4}^{16}/S^4$. Then*

$$R \geq (5 - 3p)^2. \quad (\text{III.70.11})$$

If a maximizing character has order at least five, also

$$R \geq \frac{111}{8} \left[p^{1/4} - \frac{28}{111}(1-p)^{1/4} \right]_+^{16}, \quad (\text{III.70.12})$$

where $[t]_+ = \max(t, 0)$. If it has order three, then

$$R \geq \frac{131}{8} p^4. \quad (\text{III.70.13})$$

Proof. The prior real U^2 – U^3 argument retains the stronger intermediate inequality

$$\|f\|_{U^3}^8 \geq 5S^2 - 6M, \quad M = \sum_{\xi} |\widehat{f}(\xi)|^8.$$

For completeness, write $\lambda_{\xi} = |\widehat{f}(\xi)|^2$. Writing $a_r = \widehat{f}(r)$, the exact Fourier identity is

$$\|f\|_{U^3}^8 = \sum_{s,t} \left| \sum_r a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t} \right|^2.$$

Retaining its two coordinate axes gives $\|f\|_{U^3}^8 \geq 2E(\lambda) - S^2$. In the additive energy $E(\lambda)$, retain the union of $r = t, s = w$; $r = w, s = t$; and $s = -r, w = -t$. Each contributes S^2 , each pairwise intersection contributes M , and their triple intersection has zero weight because the group has odd order and $\hat{f}(0) = 0$. Thus $E(\lambda) \geq 3S^2 - 3M$, proving the displayed estimate. If p_j are the normalized conjugate-pair fourth-power masses, then $2M/S^2 = \sum_j p_j^2 \leq \max_j p_j = p$. Consequently $\|f\|_{U^3}^8 \geq (5 - 3p)S^2$. Norm monotonicity $\|f\|_{U^4} \geq \|f\|_{U^3}$ proves (III.70.11).

Choose a maximizing character χ and write $\hat{f}(\chi) = ae^{i\theta}$, where $a = (pS/2)^{1/4}$. If its order is at least five, apply (III.70.7) to the function g_1 in Lemma III.70.3. The frequencies $\chi^{\pm 3}$ and $\chi^{\pm 5}$ do not coincide with the maximizing pair. A trivial fifth power contributes zero because f is centered. Every remaining coefficient has modulus at most $((1 - p)S/2)^{1/4}$. Therefore

$$\mathbb{E}fD_4g_1 \geq 222(pS/2)^{1/4} - 56((1 - p)S/2)^{1/4}.$$

Since $\|g_1\|_{U^4}^{16} = 222$, inequality (III.70.7), followed by taking the sixteenth power and dividing by S^4 , gives (III.70.12).

If χ has order three, average f over translates by $\ker \chi$. This operation does not increase a Gowers norm, by its triangle inequality and translation invariance. The quotient has three points, and the centered averaged function is exactly $a(e^{i\theta}\chi + e^{-i\theta}\chi^{-1})$. Lemma III.70.4 gives $\|f\|_{U^4}^{16} \geq 262a^{16} = (131/8)p^4S^4$. $\square$

Upper bound in Theorem III.70.1. The zero function is immediate. Otherwise use Lemma III.70.5 and split at $p_0 = 159/160$. If $p \leq p_0$, then

$$R \geq (5 - 3p_0)^2 = (323/160)^2.$$

If $p > p_0$ and the maximizing character has order three,

$$R \geq (131/8)(159/160)^4 > (323/160)^2.$$

In the remaining case use the exact rational comparisons

$$(599/600)^4 < 159/160, \quad 1/160 < (9/32)^4.$$

They imply

$$p^{1/4} - \frac{28}{111}(1 - p)^{1/4} > \frac{599}{600} - \frac{28}{111} \frac{9}{32} = \frac{5147}{5550}.$$

Finally,

$$\frac{111}{8} \left(\frac{5147}{5550} \right)^{16} > \left(\frac{323}{160} \right)^2.$$

For example, the last comparison is the integer inequality $111 \cdot 3200 \cdot 5147^{16} > 104329 \cdot 5550^{16}$. Thus $R \geq (323/160)^2$ in every case, which is (III.70.3) for $d = 4$. Norm monotonicity extends it to all $d \geq 4$. Rearranging proves the upper bound for c_4^{odd} . $\square$

Corollary III.70.6 (A smaller local quartic cube coefficient). *Let $d \geq 4$, $q = 2^d$, $\delta \geq 0$, and let f be real and centered on an odd-order group. Put $u = \|f\|_{U^d}$ and*

$$P_d = 2^{d-3}(3^d - 2^{d+1} + 1).$$

The exact quartic expansion established in the earlier repository report [132] now gives

$$\left| \mathbb{E}_{x,h} \prod_{\omega \in \{0,1\}^d} (\delta + f(x + \omega \cdot h)) - \delta^q \right| \leq P_d \sqrt{\frac{160}{323}} \delta^{q-4} u^4 + \sum_{r=5}^q \binom{q}{r} \delta^{q-r} u^r. \quad (\text{III.70.14})$$

For $d = 4$, the available leading coefficient decreases from $100/\sqrt{2}$ to $100\sqrt{160/323}$, approximately 70.3815343.

Proof. The existing exact quartic term is $P_d \delta^{q-4} \|f\|_{U^2}^4$. Substitute (III.70.3). The higher support terms retain their original Gowers–Cauchy–Schwarz bounds. $\square$

III.70.4 An exact two-harmonic family and a stronger lower bound

Let χ have order greater than 24, and set

$$f_b = \chi + \chi^{-1} + b(\chi^3 + \chi^{-3}), \quad b \in \mathbb{R}. \quad (\text{III.70.15})$$

These functions are real and centered. Orthogonality immediately gives

$$\|f_b\|_{U^2}^4 = 2(1 + b^4). \quad (\text{III.70.16})$$

Proposition III.70.7 (Exact fourth-norm polynomial). *For (III.70.15),*

$$\|f_b\|_{U^4}^{16} = P(b) = \sum_{j=0}^{16} c_j b^j, \quad (\text{III.70.17})$$

where the coefficients are

j	c_j	j	c_j
0	222	9	28320
1	864	10	24160
2	4080	11	4256
3	9120	12	5920
4	25640	13	0
5	31808	14	0
6	55120	15	0
7	49280	16	222
8	52360		

In particular, if $R_4(b) = \|f_b\|_{U^4}^{16} / \|f_b\|_{U^2}^{16}$, then

$$R_4(0) = \frac{111}{8}, \quad R'_4(0) = 54 > 0. \quad (\text{III.70.18})$$

Proof. A Fourier choice attaches $s_\omega \in \{-3, -1, 1, 3\}$ to each four-cube vertex and has weight $b^{\#\{\omega: |s_\omega|=3\}}$. Orthogonality requires

$$\sum_{\omega} s_{\omega} = 0, \quad \sum_{\omega} \omega_i s_{\omega} = 0 \quad (1 \leq i \leq 4),$$

initially as congruences modulo the character order. Each half-cube sum has absolute value at most 24. The total and first-coordinate congruences imply that both first-coordinate half sums are zero integers; the other coordinate sums are also zero integers. Thus the order assumption removes every congruence alias.

Here is a finite generating identity for all the displayed coefficients, so their calculation can be reproduced without enumerating 4^{16} full cubes. For $v \in \mathbb{Z}^3$, let

$$F_v(b) = [z^0 y^v] \prod_{\epsilon \in \{0,1\}^3} (zy^\epsilon + z^{-1}y^{-\epsilon} + bz^3y^{3\epsilon} + bz^{-3}y^{-3\epsilon}). \quad (\text{III.70.19})$$

The expressions are Laurent polynomials. Splitting the four-cube into its two three-faces gives the exact identity

$$P(b) = \sum_{v \in \mathbb{Z}^3} F_v(b) F_{-v}(b) = \sum_{v \in \mathbb{Z}^3} F_v(b)^2. \quad (\text{III.70.20})$$

Only $v \in [-12, 12]^3$ can occur, and $F_{-v} = F_v$ by negating all frequency choices. Multiplication of the eight four-term factors in (III.70.19), followed by (III.70.20), gives the table. This is an exact finite coefficient identity; the supplied verifier uses integer counts to reproduce every entry.

The first two coefficients also have the independent counts already proved above: $c_0 = 222$, and $c_1 = 16 \cdot 2 \cdot 27 = 864$, because there are sixteen positions for the unique third harmonic, two choices of its sign, and twenty-seven completions. Formula (III.70.16) gives $R_4(b) = P(b)/(16(1+b^4)^4)$, proving (III.70.18). $\square$

Corollary III.70.8 (Explicit improved witness). *For any character of order greater than 24, put*

$$F = 7(\chi + \chi^{-1}) - (\chi^3 + \chi^{-3}).$$

Then

$$\|F\|_{U^2}^4 = 4804, \quad \|F\|_{U^4}^{16} = 5465198316262956, \quad (\text{III.70.21})$$

so

$$\frac{\|F\|_{U^4}^{16}}{\|F\|_{U^2}^{16}} = \frac{1366299579065739}{133153321267264} = 10.2611002569 \dots < \frac{111}{8}. \quad (\text{III.70.22})$$

The rescaled witness $F/16$ is bounded by one in absolute value. Consequently (III.70.22) proves the lower bound in Theorem III.70.1; one may take $G = \mathbb{Z}/29\mathbb{Z}$.

Proof. Substitute $b = -1/7$ in Proposition III.70.7 and multiply by the appropriate powers of seven. The bound $|F| \leq 16$ is immediate from the triangle inequality. Both normalized ratios are unchanged by rescaling. $\square$

[write] **6 October 2026; sources 28–33.** *A better witness, from the intake* (a review result, credited to the batch-121 intake, not to any source; recomputed at the write in exact integer arithmetic). On $\mathbb{Z}/7\mathbb{Z}$ the centered integer function $f = (181, 1000, -780, -932, 989, 540, -998)$ has

$$\frac{\|f\|_{U^4}^{16}}{\|f\|_{U^2}^{16}} = \frac{73456939652364023667491495159266974387074638671313075}{7160989329808722083386562416397488648766840301198728} = 10.2579317 \dots,$$

below the ratio $10.2611003 \dots$ of the witness here, so $c_4^{\text{odd}} \geq 0.5587725$ (exactly: the ratio is at most 0.5587725^{-4}). The group has order $7 < 24$, so congruence aliases occur; that is allowed, because c_4^{odd} is a supremum over all groups of odd order. Hence the two-harmonic witness is not optimal. The intake's

numerical optimization over centered functions on $\mathbb{Z}/N\mathbb{Z}$, $N = 5, \dots, 13$, found ratios down to about 10.25714 ($c_4^{\text{odd}} \gtrsim 0.558783$); that is evidence only.

[write] **6 October 2026; sources 34–39.** Source 34’s Proposition III.71.7, written the same day, reproduces this example (the same polynomial and witness) without citing this source; it is credited here and there.

For comparison, on $\mathbb{Z}/7\mathbb{Z}$ the same expression has $\|F\|_{U^2}^4 = 4804$ but $\|F\|_{U^4}^{16} = 5465448865508028$. Its ratio is $1366362216377007/133153321267264$, approximately 10.2615706719. This difference is a useful check on the characteristic hypothesis: the generic polynomial must not be substituted at a small character order. The verifier reproduces this second value by a modular coefficient expansion and, independently, by direct cube summation in $\mathbb{Q}[t]/(t^3 + t^2 - 2t - 1)$ with $t = \zeta_7 + \zeta_7^{-1}$.

III.70.5 The obstruction persists in every higher dimension

Theorem III.70.9 (Single characters are not local extremizers for $d \geq 4$). *Let $d \geq 4$ and let χ have order greater than $3 \cdot 2^{d-1}$. For*

$$f_{b,\theta} = e^{i\theta}\chi + e^{-i\theta}\chi^{-1} + b(e^{3i\theta}\chi^3 + e^{-3i\theta}\chi^{-3}),$$

the derivative at $b = 0$ of

$$R_d(b) = \frac{\|f_{b,\theta}\|_{U^d}^{2^d}}{\|f_{b,\theta}\|_{U^2}^{2^d}} \quad (\text{III.70.23})$$

is strictly positive. Hence every sufficiently small negative b strictly increases $\|f_{b,\theta}\|_{U^2}^4 / \|f_{b,\theta}\|_{U^d}^4$. In particular, a nonzero single real character pair of such order is not a local maximizer for the higher-order extremal problem.

Proof. Let $C_{d,j}$ count assignments $s : \{0, 1\}^d \rightarrow \{-3, -1, 1, 3\}$ having exactly j third harmonics and satisfying the integer equations

$$\sum_{\omega} s_{\omega} = 0, \quad \sum_{\omega} \omega_i s_{\omega} = 0 \quad (1 \leq i \leq d). \quad (\text{III.70.24})$$

The same half-cube argument as above shows that the character-order hypothesis turns all orthogonality congruences into these integer equations. The phase factor is then $e^{i\theta} \sum_{\omega} s_{\omega} = 1$. Thus

$$\|f_{b,\theta}\|_{U^d}^{2^d} = \sum_j C_{d,j} b^j, \quad R_d(b) = \frac{\sum_j C_{d,j} b^j}{[2(1 + b^4)]^{2^{d-2}}}.$$

All $C_{d,j}$ are nonnegative integers, and $C_{4,1} = 864$. There are pure-sign solutions in every dimension at least two, for example $s_{\omega} = (-1)^{\omega_1 + \dots + \omega_d}$, so $C_{d,0} > 0$. Place a solution with one third harmonic on one d -face and an independent pure-sign solution on the other. Their separate moment conditions imply all the $(d+1)$ -dimensional conditions. Either face can contain the unique third harmonic, and the resulting assignments are distinct. Therefore

$$C_{d+1,1} \geq 2C_{d,1}C_{d,0} > 0. \quad (\text{III.70.25})$$

It follows that $R'_d(0) = C_{d,1}/2^{2^{d-2}} > 0$. The desired inverse ratio is $R_d(b)^{-1/2^{d-2}}$, which decreases strictly with $R_d(b)$, proving the assertion. $\square$

[write] **6 October 2026; sources 28–33.** *Answers two questions.* Together with Proposition III.70.2 and the witness above, this theorem answers, for $d \geq 4$, the sub-question of source 03’s Research question V.14.1 whether the odd-order constant is attained by real parts of characters: no (for $d = 3$ it is, by source 04’s Theorem III.3.4). It also answers the second sentence of source 29’s Question V.117.1 (“Is a single Fourier inverse pair extremal?”): no. Item III.1.

[write] **6 October 2026; sources 34–39.** At $d = 4$ source 34 gives a global form: every function supported on one inverse pair of a character of odd order at least five has ratio at most $(8/111)^{1/4}$, below the witness above (Theorem III.71.1 and the note there).

[write] **7 October 2026; sources 40–46.** Source 45 also re-derives the single-pair non-extremality at $d = 4$ (its Section III.90, with the dual identity and order three), without citing this source or source 34.

III.70.6 What is settled and what remains open

The proved bound (III.70.3) improves the prior general comparison for every $d \geq 4$. The exact examples give a stronger lower bound for the fourth-order constant, and Theorem III.70.9 rules out extending the third-order single-character equality model to higher order in general. These conclusions do not identify the sharp value of c_4^{odd} , establish that two harmonics suffice at an optimum, or classify maximizing sequences. The recurrence (III.70.25) proves the sign of a first variation; it does not determine an optimal higher-dimensional constant.

A natural next problem is to optimize the two complementary bounds in Lemma III.70.5, retaining the separate fourth-power masses at χ^3 and χ^5 . A more substantial improvement would use dual functions of a two-harmonic trial function instead of a cosine, together with compatible concentration estimates. Another precise question is whether the global fourth-order supremum is attained on a finite cyclic group or requires a limiting spectral profile. Any such investigation must keep small-order aliases separate from integer frequency relations.

The exact quartic-count consequence (III.70.14) is local. It does not by itself improve a final Szemerédi bound. The supplied standard-library program verifies the finite generating identities, the two explicit finite-group examples, the rational comparisons in the universal estimate, and a finite set of the constructive higher-dimensional certificates. The general proofs are those above; no numerical optimization or proof-assistant verification is claimed as a substitute.

III.71 A stronger fourth-dimensional norm comparison

Source 34, delivered Section 10.

The torsion analysis and the analytic norm comparison address different losses in a centered cube expansion. We now improve the analytic coefficient. Throughout this section, G is a finite abelian group of odd order, physical averages are normalized, and Fourier sums use counting measure. In this section we also use additive notation for frequency labels: $-\xi$ denotes ξ^{-1} and $j\chi$ denotes χ^j . For real, centered, nonzero f , recall

$$c_d^{\text{odd}} = \sup_{G,f} \frac{\|f\|_{U^2}^4}{\|f\|_{U^d}^4}. \quad (\text{III.71.1})$$

The merged repository report proves $c_3^{\text{odd}} = 2^{-1/2}$, with equality precisely for one conjugate Fourier pair [155]. The subsequently received moment manuscript already improves the fourth-dimensional

Figure III.70.1: The exact polynomial ratio $R_4(b)$ in the two-harmonic family. The marked point is the rational certificate $b = -1/7$. The curve illustrates the proved local improvement over $b = 0$; it is not a computation of the global extremal constant.

bracket to

$$(8/111)^{1/4} \leq c_4^{\text{odd}} \leq (8/35)^{1/4}, \quad (\text{III.71.2})$$

whose endpoints are approximately 0.518133595 and 0.691441569 [156]. That later manuscript is the relevant baseline for the following improvement.

Theorem III.71.1 (Improved fourth-dimensional bracket). *Every real centered function on every finite abelian group of odd order satisfies*

$$\|f\|_{U^2}^4 \leq \frac{2}{3} \|f\|_{U^4}^4. \quad (\text{III.71.3})$$

More precisely,

$$\frac{4804}{5465198316262956^{1/4}} \leq c_4^{\text{odd}} \leq \frac{2}{3}. \quad (\text{III.71.4})$$

The lower endpoint is approximately 0.558729391. It is attained as a lower-bound certificate by a function with two conjugate Fourier pairs on $\mathbb{Z}/29\mathbb{Z}$. In contrast, every function supported on one conjugate Fourier pair has ratio at most $(8/111)^{1/4}$.

[write] **6 October 2026; sources 34–39.** Where this stands (checked at the write). In source 29's normalization $\|f\|_{U^4}^{16} \geq C \|f\|_{U^2}^{16}$ the theorem is $C = (3/2)^4 = 81/16$, so $c_4^{\text{odd}} = \sup C^{-1/4}$ -bound $\leq 2/3$; source 29 has $C = 35/8$ (0.6914416), source 35, written the same day from the same pin and not cited here, $C = 5$ ($5^{-1/4} = 0.6687403$; Section III.72), and source 28 $(323/160)^2$. So $2/3$ is the best upper bound among sources 01–39. It is not the best known: source 45, placed in this directory by **2dfe46f44** and not yet written in, records $C = 4795/832$, that is $c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ (its placement, checked at intake; for the write that adds it). The lower endpoint here is source 28's witness (0.5587294, Corollary III.70.8), improved by the batch-121 intake's exact certificate on $\mathbb{Z}/7\mathbb{Z}$ to 0.5587725 (note there). Among sources 01–39 the bracket is therefore $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$ (item III.1). The statement that one-pair functions have ratio at most $(8/111)^{1/4} = 2/222^{1/4}$ is the global form, at $d = 4$ and every odd order at least five, of source 28's non-extremality theorem; for order three see Lemma III.71.4.

[write] **7 October 2026; sources 40–46.** *Superseded by source 45* (written the same day, now printed in Section III.89): its Theorem III.90.1 has the coefficient $4795/832 = 5.7632212 > 81/16$, so $c_4^{\text{odd}} \leq 0.6454070$ and the bracket among sources 01–46 is $0.5587725 \leq c_4^{\text{odd}} \leq 0.6454070$. The statement “best among sources 01–39” above stays true for those sources. Source 45 also re-derives the single-pair results of this section without citing it (note in Section F.50).

The theorem improves both endpoints of the audited bracket. In particular, the one-pair extremizers in dimension three cease to be extremizers in dimension four. Neither endpoint in (III.71.4) is asserted to be the optimum.

III.71.1 Retaining the dominant-pair moment profile

Write $a_\xi = \widehat{f}(\xi)$, so $a_{-\xi} = \overline{a_\xi}$ and $a_0 = 0$. Set

$$S = \sum_{\xi} |a_\xi|^4 = \|f\|_{U^2}^4, \quad p_j = \frac{2|a_{\xi_j}|^4}{S}, \quad p = \max_j p_j,$$

where one ξ_j is chosen from each nonzero inverse pair. Thus $\sum_j p_j = 1$. The incoming moment argument [156] begins with the positive Fourier expansion of the autocorrelation

$$c_f(h) = \mathbb{E}_x f(x)f(x-h) = \sum_{\xi} |a_\xi|^2 \xi(h).$$

We reproduce that argument and retain the additional information needed to combine it with a dual-function estimate.

Lemma III.71.2 (A profile for a specified Fourier pair). *For $m \geq 1$, put*

$$C_m = 2^{-m} \binom{2m}{m}, \quad H_m(p) = \sum_{k=0}^m \binom{m}{k}^2 p^k (1-p)^{m-k}.$$

For any selected pair of mass p , one has

$$\mathbb{E}_h c_f(h)^{2m} \geq C_m S^m H_m(p). \quad (\text{III.71.5})$$

Consequently, when $m = 2^{d-2}$,

$$\frac{\|f\|_{U^d}^4}{S} \geq (C_m H_m(p))^{1/m}. \quad (\text{III.71.6})$$

For $m = 4$ this gives

$$\frac{\|f\|_{U^4}^4}{S} \geq A(p) := \left[\frac{35}{8} \{1 + 12p(1-p) + 6p^2(1-p)^2\} \right]^{1/4}. \quad (\text{III.71.7})$$

If the largest pair has $p \leq 1/2$, one additionally has

$$\frac{\|f\|_{U^4}^4}{S} \geq (1015/64)^{1/4}. \quad (\text{III.71.8})$$

Proof. Put $b_j = |a_{\xi_j}|^2$, so $S = 2 \sum_j b_j^2$. In the Fourier expansion of c_f^{2m} , every coefficient is nonnegative. Retain only monomials using each ξ_j and $-\xi_j$ equally often. Writing their common multiplicity as k_j gives

$$\mathbb{E} c_f^{2m} \geq C_m S^m \sum_{\sum_j k_j = m} \left(\binom{m}{k_1, k_2, \dots} \right)^2 \prod_j p_j^{k_j}. \quad (\text{III.71.9})$$

This is the positive balanced-monomial step of [156]. Group its terms according to the multiplicity k of the specified pair. The remaining multinomial coefficient is an integer at least one, so its square is at least itself. The multinomial theorem therefore bounds the contribution of the other pairs below by $(1 - p)^{m-k}$. This proves (III.71.5).

The recursive norm identity and monotonicity give

$$\|f\|_{U^d}^{2^d} = \mathbb{E}_h \|f(\cdot)f(\cdot - h)\|_{U^{d-1}}^{2^{d-1}} \geq \mathbb{E}_h |c_f(h)|^{2^{d-1}}.$$

Since $2^{d-1} = 2m$ and $S^m = \|f\|_{U^2}^{2^d}$, this proves (III.71.6). Direct expansion gives $H_4(p) = 1 + 12p(1 - p) + 6p^2(1 - p)^2$.

For the last claim, interpret the normalized balanced sum in (III.71.9) as the expected multinomial coefficient under the multinomial distribution of four trials with probabilities p_j . That coefficient is one for a pure composition and at least four for every mixed composition. Hence the sum is at least $4 - 3 \sum_j p_j^4$. Because $\sum_j p_j^4 \leq p^3 \sum_j p_j \leq 1/8$, the lower bound is $29/8$. Multiplication by $C_4 = 35/8$ proves (III.71.8). $\square$

Thus near the old moment endpoint, almost all Fourier fourth-power mass lies in one pair. The next step uses information that the moment estimate alone discarded: a one-pair function has a substantially larger fourth Gowers norm than that endpoint permits.

III.71.2 The exact fourth dual function of a real character

For real h , define

$$\mathcal{D}_4 h(x) = \mathbb{E}_{t_1, t_2, t_3, t_4} \prod_{\substack{v \in \{0,1\}^4 \\ v \neq 0}} h(x + v \cdot t).$$

The Gowers–Cauchy–Schwarz inequality supplies the dual certificate

$$|\mathbb{E} f \mathcal{D}_4 h| \leq \|f\|_{U^4} \|h\|_{U^4}^{15}, \quad \mathbb{E} h \mathcal{D}_4 h = \|h\|_{U^4}^{16}. \quad (\text{III.71.10})$$

The general use of a dual function is standard. The useful input here is its exact value on a real character, including the two additional harmonics.

Lemma III.71.3 (The fifteen-vertex dual polynomial). *Let χ have odd order at least five, let $\theta \in \mathbb{R}$, and put*

$$\phi_j = e^{ij\theta} \chi^j + e^{-ij\theta} \chi^{-j}.$$

Then

$$\mathcal{D}_4 \phi_1 = 111\phi_1 + 27\phi_3 + \phi_5, \quad \|\phi_1\|_{U^4}^{16} = 222. \quad (\text{III.71.11})$$

These identities hold for arbitrary θ , including when the character order is five or seven.

Proof. Expand the fifteen factors into their two character terms. For each coordinate, orthogonality requires a sum of eight signs to vanish modulo the order of χ . This sum is even and has absolute value at most eight. Since that order is odd and at least five, the sum must vanish as an integer.

The positive-sign subset T of the fifteen nonorigin vertices therefore has exactly four ones in every coordinate. If $|T| = k$, its output harmonic is $2k - 15$. The complete count is

k	5	6	7	8	9	10
$\#T$	1	27	111	111	27	1.

(III.71.12)

Here is an elementary verification. Replace each selected vertex by its set of zero coordinates, a proper subset of $\{1, 2, 3, 4\}$. For five selected vertices each coordinate must occur once among these zero sets. The only five distinct sets with total size four are the empty set and the four singletons, giving one choice.

For six selected vertices every coordinate has degree two. If the empty set is absent, the four singleton sets and a perfect matching are forced, giving three choices. If it is present, either the three pair sets form a Hamilton path, with singleton sets at the two endpoints (twelve choices), or there are one triple, one pair, and three singletons. In the latter case the vertex without a singleton belongs to both the pair and triple, and the other endpoint of the pair is the omitted vertex of the triple. There are $4 \cdot 3 = 12$ choices. The total is 27.

For seven selected vertices every coordinate has degree three. Let $z \in \{0, 1\}$ record the empty set, and let u, e, t be the numbers of singleton, pair, and triple sets. The complete list is

z	t	u	e	number
0	0	2	5	6
0	1	3	3	$4 + 24$
0	2	4	1	6
1	0	0	6	1
1	1	1	4	$12 + 12$
1	2	2	2	$18 + 24$
1	3	3	0	4

To verify completeness, the degree and cardinality equations give $e = 5 + z - 2t$ and $u = 2 - 2z + t$. If T_0 is the set of vertices omitted by the triples and U_0 is the set of singleton vertices, the graph formed by the pairs must have degree $3 - t + \mathbf{1}_{T_0}(v) - \mathbf{1}_{U_0}(v)$ at v . The rows count, respectively: a missing edge in K_4 ; a star or a Hamilton path with prescribed internal vertices; a prescribed edge; K_4 ; a four-cycle or the complement of a two-edge path; a perfect matching or a two-edge path; and equal sets $T_0 = U_0$. The entries sum to 111.

Complementation within all fifteen vertices preserves the four coordinate counts and exchanges k with $15 - k$. Sizes at most four are impossible: four distinct vertices cannot all have a one in every coordinate. This proves (III.71.12), hence the dual identity. Finally, character orthogonality in $\mathbb{E}\phi_1\mathcal{D}_4\phi_1$ leaves just 222. In orders five and seven the third and fifth harmonics still do not overlap the first; in order five ϕ_5 is constant, which causes no change. $\square$

[write] **6 October 2026; sources 34–39.** The identity and the value 222 are also source 28's Lemma III.70.3, proved there by a face-splitting count; source 35's Lemma III.72.3 recounts them by a third decomposition. All three sources were written on the same day; none cites another for this identity.

The order-three case requires its own calculation, since additional sign sums can vanish modulo three.

Lemma III.71.4 (The order-three endpoint). *For a character χ of order three and $\phi = e^{i\theta}\chi + e^{-i\theta}\chi^{-1}$, let $r = 2\cos(3\theta)$. Then*

$$\|\phi\|_{U^4}^{16} = 270 - 16r^2 + 8r^4 = 262 + 8(r^2 - 1)^2 \geq 262. \quad (\text{III.71.13})$$

If $\hat{f}(\chi) = \rho e^{i\theta}$, then $\|f\|_{U^4} \geq \rho\|\phi\|_{U^4}$.

Proof. The three values a, b, c of ϕ satisfy $a + b + c = 0$, $ab + bc + ca = -3$, and $abc = r$. Flipping cube coordinates shows that the average associated with a step vector depends only on its number

of nonzero coordinates. Their multiplicities are 1, 8, 24, 32, 16. Consequently, after also averaging the basepoint,

$$243\|\phi\|_{U^4}^{16} = \sum a^{16} + 8 \sum (ab)^8 + 24r^4 \sum a^4 + 32r^4 \sum (ab)^2 + 16r^5 \sum a,$$

where each sum has three cyclic terms. Newton recurrences give

$$\sum a^4 = 18, \quad \sum (ab)^2 = 9, \quad \sum a^{16} = 13122 + 11664r^2 + 360r^4,$$

and $\sum (ab)^8 = 6561 - 1944r^2 + 108r^4$. Substitution proves (III.71.13).

Conditional expectation onto the quotient defined by χ is averaging over translations in its kernel, hence is a contraction for the U^4 norm. Since f is centered, this conditional expectation is exactly $\rho\phi$. This proves the last claim. $\square$

III.71.3 Coupling the moment and dual certificates

Proposition III.71.5 (A second lower bound from the largest pair). *Put*

$$K = \frac{222^{1/4}}{2}, \quad b = \frac{82^{3/4}}{111}, \quad B(p) = K[p^{1/4} - b(1-p)^{1/4}]_+^4,$$

where $[x]_+ = \max(x, 0)$. On every odd-order group,

$$\frac{\|f\|_{U^4}^4}{S} \geq B(p). \quad (\text{III.71.14})$$

Proof. Choose a largest pair and write $a_\chi = \rho e^{i\theta}$, where $\rho = (pS/2)^{1/4}$. If its order is at least five, Lemma III.71.3 and centering give

$$\mathbb{E}f\mathcal{D}_4\phi_1 \geq 222\rho - 54|a_{3\chi}| - 2|a_{5\chi}|.$$

The nonzero pairs $\{\pm 3\chi\}$ and $\{\pm 5\chi\}$ are distinct from each other and from $\{\pm\chi\}$. If $5\chi = 0$, its coefficient vanishes. Hölder therefore yields

$$\begin{aligned} 54|a_{3\chi}| + 2|a_{5\chi}| &\leq (54^{4/3} + 2^{4/3})^{3/4}(|a_{3\chi}|^4 + |a_{5\chi}|^4)^{1/4} \\ &\leq 2 \cdot 82^{3/4} (S(1-p)/2)^{1/4}. \end{aligned}$$

Apply (III.71.10), using $\|\phi_1\|_{U^4}^{16} = 222$, and raise to the fourth power. This gives precisely (III.71.14).

If the selected character has order three, Lemma III.71.4 instead gives

$$\frac{\|f\|_{U^4}^4}{S} \geq \frac{262^{1/4}}{2} p \geq Kp \geq B(p).$$

Thus no group-exponent restriction has been omitted. $\square$

The two separate profiles already improve the incoming bound, but their interaction gives a larger gain. The third and fifth harmonics that weaken the dual certificate also force additional *positive* monomials in the autocorrelation moment.

Lemma III.71.6 (The resonance cost of the dual error). *Suppose the selected character χ has odd order at least five. Define*

$$q_3 = \frac{2|a_{3\chi}|^4}{S}, \quad q_5 = \frac{2|a_{5\chi}|^4}{S}, \quad L = 27q_3^{1/4} + q_5^{1/4},$$

with $q_5 = 0$ when $5\chi = 0$. Then, writing $R = \|f\|_{U^4}^4/S$, one has simultaneously

$$R \geq K[p^{1/4} - L/111]_+^4, \quad (\text{III.71.15})$$

$$R^4 \geq \frac{35}{8}H_4(p) + p^{7/2}(21\sqrt{q_3} + 7\sqrt{q_5}) \geq \frac{35}{8}H_4(p) + \frac{7}{244}p^{7/2}L^2. \quad (\text{III.71.16})$$

Proof. The first inequality is the proof of Proposition III.71.5 before applying Hölder to the two unwanted harmonics. For the second, return to the expansion of c_f^8 . In addition to all pair-balanced monomials retained in Lemma III.71.2, retain those containing one 3χ , two χ , and five $-\chi$, and their inverses. Their total contribution is

$$2 \frac{8!}{5!2!} |a_\chi|^{14} |a_{3\chi}|^2 = 336 |a_\chi|^{14} |a_{3\chi}|^2.$$

Likewise, the monomials containing one 5χ , one χ , and six $-\chi$, together with their inverses, contribute $112 |a_\chi|^{14} |a_{5\chi}|^2$. These are valid zero-sum frequency tuples by the integer relations $3 + 2 - 5 = 0$ and $5 + 1 - 6 = 0$. They are disjoint from the pair-balanced monomials and from each other: each uses exactly one occurrence from a different nonzero pair. In order five the second family has zero coefficient; in order seven the pairs remain distinct. Any further modular relations only add nonnegative terms.

Divide by S^4 and use $|a_\chi|^{14} |a_{j\chi}|^2 = (S/2)^4 p^{7/2} \sqrt{q_j}$. The moment lower bound for R^4 follows. Finally, weighted Cauchy–Schwarz gives

$$(27q_3^{1/4} + q_5^{1/4})^2 \leq \left(\frac{27^2}{21} + \frac{1}{7} \right) (21\sqrt{q_3} + 7\sqrt{q_5}) = \frac{244}{7} (21\sqrt{q_3} + 7\sqrt{q_5}),$$

which proves the last inequality. $\square$

Proof of the upper bound in Theorem III.71.1. The zero function is immediate, so suppose $S > 0$ and put $R = \|f\|_{U^4}^4/S$. If $p \leq 1/2$, (III.71.8) gives $R > 3/2$. On $[1/2, 1]$, A is decreasing, and for $p_0 = 49/50$ exact arithmetic gives

$$A(p_0)^4 - \frac{81}{16} = \frac{1757921}{5000000} > 0. \quad (\text{III.71.17})$$

Hence $1/2 \leq p \leq p_0$ also implies $R > 3/2$.

It remains to consider $p \geq p_0$. If the selected character has order three, Lemma III.71.4 gives $R \geq Kp > (193/100)(49/50) > 3/2$. Suppose instead that its order is at least five and, towards a contradiction, $R \leq 3/2$. The following rational comparisons are elementary:

$$p^{1/4} > \frac{99}{100}, \quad K > \frac{193}{100}, \quad \left(\frac{3}{2K} \right)^{1/4} < \frac{47}{50}.$$

Indeed $(99/100)^4 < 49/50$, $(193/100)^4 < 222/16$, and $(47/50)^4 > 150/193$. By (III.71.15), these comparisons force

$$\frac{L}{111} > \frac{99}{100} - \frac{47}{50} = \frac{1}{20}, \quad L > \frac{111}{20}.$$

Since $H_4(p) \geq 1$ and $p^{7/2} \geq p^4 \geq (49/50)^4$, (III.71.16) now yields

$$\begin{aligned} R^4 - \frac{81}{16} &> \frac{35}{8} + \frac{7}{244} \left(\frac{49}{50}\right)^4 \left(\frac{111}{20}\right)^2 - \frac{81}{16} \\ &= \frac{77821791847}{610000000000} > 0, \end{aligned} \quad (\text{III.71.18})$$

contradicting $R \leq 3/2$. Thus $R > 3/2$ for nonzero f , which proves the stated uniform inequality. $\square$

III.71.4 An explicit two-pair improvement and the variational obstruction

Proposition III.71.7 (An exact two-harmonic polynomial). *On $\mathbb{Z}/29\mathbb{Z}$, let $\chi(x) = e^{2\pi ix/29}$ and*

$$f_t = \chi + \chi^{-1} + t(\chi^3 + \chi^{-3}), \quad t \in \mathbb{R}.$$

Then $\|f_t\|_{U^2}^4 = 2(1 + t^4)$ and

$$\begin{aligned} P(t) := \|f_t\|_{U^4}^{16} &= 222 + 864t + 4080t^2 + 9120t^3 + 25640t^4 \\ &\quad + 31808t^5 + 55120t^6 + 49280t^7 + 52360t^8 \\ &\quad + 28320t^9 + 24160t^{10} + 4256t^{11} + 5920t^{12} + 222t^{16}. \end{aligned} \quad (\text{III.71.19})$$

In particular $7^{16}P(-1/7) = 5465198316262956$, which proves the lower bound in (III.71.4).

Proof. The U^2 identity is Fourier orthogonality. For the second identity, split the four-cube into its two three-dimensional faces. An expanded term assigns a frequency in $\{-3, -1, 1, 3\}$ to each vertex. Orthogonality in the fourth step and the basepoint requires the total frequency on each face to be zero. These and all remaining coordinate conditions hold over the integers: each relevant sum has eight terms and absolute value at most $24 < 29$.

For $v \in \{0, 1\}^3$ assign a frequency r_v , and define

$$A_m(t) = \sum_{\substack{r_v \in \{-3, -1, 1, 3\} \\ \sum_v r_v = 0, \sum_v r_v v = m}} t^{\#\{v: |r_v|=3\}}, \quad m \in \mathbb{Z}^3.$$

The exact finite identity is

$$P(t) = \sum_{m \in \mathbb{Z}^3} A_m(t) A_{-m}(t). \quad (\text{III.71.20})$$

It supplies a short exhaustive integer certificate for (III.71.19): enumerate the 4^8 assignments on one face, discard those with nonzero total, and group the others by their three integer moments and their count of frequencies of absolute value three. Multiplying opposite-moment polynomials gives the coefficients displayed in (III.71.19). The accompanying standard-library verification program implements exactly this finite sum, using integers and rational arithmetic only. Thus the polynomial certificate requires neither sampling nor numerical optimization.

Finally,

$$\frac{\|f_{-1/7}\|_{U^2}^4}{\|f_{-1/7}\|_{U^4}^4} = \frac{2(1 + 7^{-4})}{P(-1/7)^{1/4}} = \frac{4804}{5465198316262956^{1/4}}.$$

$\square$

[write] **6 October 2026; sources 34–39.** *This is source 28’s example* (Corollary III.70.8): the same functions on $\mathbb{Z}/29\mathbb{Z}$, the same polynomial and the same witness $7^{16}P(-1/7) = 5465198316262956$. The intake found that the best member of the family, at $t \approx -0.145611$, gives 0.5587462, and the batch-121 intake’s certificate on $\mathbb{Z}/7\mathbb{Z}$ gives 0.5587725 (note after source 28’s corollary); neither is claimed by a source as optimal.

The full polynomial is useful for an explicit certificate, but the failure of one-pair extremality follows already from the dual function. At $t = 0$, its third harmonic gives $P'(0) = 16 \cdot 2 \cdot 27 = 864 > 0$, whereas $\frac{d}{dt}\|f_t\|_{U^2}^4|_{t=0} = 0$. Therefore small negative t strictly increases the ratio. This mechanism persists for arbitrary initial phase and every character order at least five: the third harmonic lies outside the original pair and is nonzero.

To compare with every one-pair model, if $f = \rho(e^{i\theta}\chi + e^{-i\theta}\chi^{-1})$ then $\|f\|_{U^2}^4 = 2\rho^4$. For character order at least five, Lemma III.71.3 gives ratio $2/222^{1/4}$; for order three, Lemma III.71.4 gives ratio at most $2/262^{1/4}$, which is smaller. Thus the two-pair certificate exceeds every one-pair model on every finite odd-order group.

Remark III.71.8 (What a genuine optimizer must satisfy). On a fixed finite group, minimize $\|f\|_{U^4}^{16}$ subject to $\|f\|_{U^2}^4 = 1$ and $\mathbb{E}f = 0$. A minimizer exists by finite-dimensional compactness. The Lagrange-multiplier equation is

$$\mathcal{D}_4 f = \lambda \mathcal{D}_2 f + \mu, \quad \widehat{\mathcal{D}_2 f}(\xi) = |a_\xi|^2 a_\xi,$$

for real constants λ, μ . The extra third harmonic in (III.71.11) prevents a one-pair function of character order at least five from satisfying this equation. Order three is an exception to that stationarity statement, since its centered function space already consists of one Fourier pair.

III.71.5 The resulting fourth-dimensional cube coefficient

Proposition III.81.2, recalling the established odd-order centered expansion [155, 156], gives

$$Q_4(\delta + f) = \delta^{16} + 100\delta^{12}\|f\|_{U^2}^4 + R, \quad |R| \leq \sum_{j=5}^{16} \binom{16}{j} \delta^{16-j} \|f\|_{U^4}^j,$$

for $\delta \geq 0$. The theorem therefore gives the following direct refinement of the coefficient used at Lemma 3.10.

Corollary III.71.9 (A smaller leading coefficient). *Let $u = \|f\|_{U^4}$. Under the preceding hypotheses,*

$$Q_4(\delta + f) \leq \delta^{16} + \frac{200}{3}\delta^{12}u^4 + \sum_{j=5}^{16} \binom{16}{j} \delta^{16-j} u^j. \quad (\text{III.71.21})$$

The coefficient $200/3 \approx 66.666667$ replaces the audited incoming coefficient $100(8/35)^{1/4} \approx 69.144157$.

[write] **6 October 2026; sources 34–39.** The leading coefficient at $d = 4$ is now $200/3 = 66.667$ (against $100 \cdot 5^{-1/4} = 66.874$ for source 35, $100(8/35)^{1/4} = 69.144$ for source 29, 70.382 for source 28 and $100/\sqrt{2} = 70.711$ from source 04’s comparison); recomputed at the write.

If $u^{16} \leq \alpha$, the leading correction in (III.71.21) is $(200/3)\delta^{12}\alpha^{1/4}$ and the remaining terms have powers $\alpha^{j/16}$, $j \geq 5$. The two-pair example implies that the optimal universal leading coefficient is at least $100 \cdot 4804/5465198316262956^{1/4} \approx 55.872939$: scale that fixed example to zero amplitude while keeping a positive density fixed. At sufficiently small amplitude it also gives a weight in $[0, 1]$. This is a local counting improvement; the subsequent density-increment losses have not been recomputed.

Remark III.71.10 (The same coupling in a few higher dimensions). For $m = 2^{d-2}$, Lemma III.71.2 and monotonicity $\|f\|_{U^d} \geq \|f\|_{U^4}$ combine the profiles $(C_m H_m(p))^{1/m}$ and $B(p)$. The identity

$$H_m(p) = \sum_{j=0}^{\lfloor m/2 \rfloor} \binom{m}{2j} \binom{2j}{j} \{p(1-p)\}^j$$

follows by extracting the coefficient of z^m in $(\sqrt{p(1-p)} + z + \sqrt{p(1-p)}z^2)^m$; it shows that the first profile decreases on $[1/2, 1]$. When $p \leq 1/2$, the balanced-composition argument gives the stronger bound

$$\frac{\|f\|_{U^d}^4}{S} \geq [C_m \{m - (m-1)2^{-(m-1)}\}]^{1/m}.$$

For $m = 4, 8, 16, 32, 64$, this last bound exceeds K , while $C_m^{1/m} < K$. Both comparisons become rational inequalities after raising to the m th power; the accompanying certificate checks them exactly. For each $d \in \{5, 6, 7, 8\}$, let p_d be the unique point of $[1/2, 1]$ satisfying

$$(C_m H_m(p_d))^{1/m} = B(p_d), \quad \beta_d = (C_m H_m(p_d))^{-1/m}.$$

The decreasing and increasing profiles meet once: their endpoint order is opposite, and the diffuse branch is stronger than K . Their maximum is at least their common value at p_d , proving $c_d^{\text{odd}} \leq \beta_d$. The following are rounded approximations to these exact implicit bounds:

d	incoming moment bound	coupled bound
5	0.612819643	0.609912380
6	0.565388162	0.564904412
7	0.537413970	0.537382843
8	0.5211683364	0.5211682954

These are consequences of the same two proved profiles, not applications of the weaker uniform bound $2/3$. The fourth dual certificate alone does not improve the incoming moment bound in dimensions $d \geq 9$.

[write] **6 October 2026; sources 34–39.** Recomputed at intake by bisection: the four coupled bounds and the four bounds of source 29 are reproduced to the printed digits; the gain over source 29's B_d is about $3 \cdot 10^{-3}$ at $d = 5$ and $4 \cdot 10^{-8}$ at $d = 8$, and none for $d \geq 9$, as stated. So for $5 \leq d \leq 8$ the best upper bounds among sources 01–39 are the β_d here; for $d \geq 9$ they are source 29's B_d (Corollary III.69.1).

III.72 A stronger gap between real centered uniformity norms

Source 35, delivered Section 6.

Delivered part heading of source 35: A stronger real fourth-order uniformity gap

We use normalized counting measure on a finite abelian group G : $\mathbb{E}_x u(x) = |G|^{-1} \sum_{x \in G} u(x)$. Let $\mathcal{C}$ denote complex conjugation, so $\mathcal{C}z = \bar{z}$. For $f : G \rightarrow \mathbb{C}$, the normalized Gowers quantity is

$$\|f\|_{U^d(G)}^{2^d} = \mathbb{E}_{x, h_1, \dots, h_d \in G} \prod_{\omega \in \{0,1\}^d} \mathcal{C}^{|\omega|} f(x + \omega \cdot h), \quad \omega \cdot h = \sum_{i=1}^d \omega_i h_i. \quad (\text{III.72.1})$$

This defines a norm for $d \geq 2$; at $d = 1$ it is the seminorm $|\mathbb{E}f|$. For a character $\xi \in \widehat{G}$, our Fourier normalization is

$$\widehat{f}(\xi) = \mathbb{E}_{x \in G} f(x) \overline{\xi(x)}. \quad (\text{III.72.2})$$

We suppress G in the norm subscript when the ambient group is fixed. For real functions the conjugations in (III.72.1) have no effect.

The original Gowers inequalities compare successive uniformity norms by monotonicity [1]. Realness and centering permit a strict comparison on odd-order groups. The earlier research compilation proves

$$\|f\|_{U^3}^8 \geq 2 \|f\|_{U^2}^8$$

for real mean-zero functions, with equality precisely for a single conjugate Fourier pair [159]. The subsequent manuscript *Logarithmic Selection, Local Freiman Models, and Higher Uniformity* shows that this equality model does not persist at order four, and obtains

$$\|f\|_{U^d}^4 \geq \sqrt{\frac{323}{160}} \|f\|_{U^2}^4 \quad (d \geq 4)$$

[162]. More recently, the positive-autocorrelation moment argument of [163] gives the stronger fourth-order bound

$$\|f\|_{U^4}^{16} \geq \frac{35}{8} \|f\|_{U^2}^{16}.$$

We increase its coefficient from $35/8$ to 5 . The additional information is a positive term counting three-term progressions in the Fourier amplitude distribution. Its third-harmonic specialization controls the principal negative direction in the fourth-order dual function of a cosine.

Theorem III.72.1 (A stronger real centered fourth-order norm gap). *Let G be a finite abelian group of odd order, and let $f : G \rightarrow \mathbb{R}$ have mean zero. Then*

$$\|f\|_{U^4}^{16} \geq 5 \|f\|_{U^2}^{16}. \quad (\text{III.72.3})$$

In fact (III.72.3) is strict for nonzero f . Consequently, for every integer $d \geq 4$,

$$\|f\|_{U^d}^4 \geq 5^{1/4} \|f\|_{U^2}^4. \quad (\text{III.72.4})$$

The constant 5 is not asserted to be optimal. The improvement over the strongest inspected prior estimates is at $d = 4$.

[write] 6 October 2026; sources 34–39. *Superseded the same day by source 34.* Source 34’s Theorem III.71.1, written from the same pin and not cited here, gives the coefficient $81/16 = 5.0625 > 5$, that is $c_4^{\text{odd}} \leq 2/3$ against $5^{-1/4} = 0.6687403$ here; source 45 (placed, not yet written) records $4795/832$. The statement that 5 improves “the strongest inspected U^4 coefficient $35/8$ ” was true at the pin. The energy inequality of Theorem III.72.2 is a separate result that source 34 does not contain. The intake re-derived the proof and recomputed every rational comparison of the scalar certificate exactly.

Define the extremal constants

$$c_d^{\text{odd}} = \sup_{\substack{G \text{ finite abelian, } |G| \text{ odd} \\ f: G \rightarrow \mathbb{R}, \mathbb{E}f=0, f \neq 0}} \frac{\|f\|_{U^2}^4}{\|f\|_{U^d}^4}. \quad (\text{III.72.5})$$

The new fourth-order bound gives

$$c_4^{\text{odd}} \leq 5^{-1/4} = 0.668740304976 \dots, \quad (\text{III.72.6})$$

improving $(8/35)^{1/4} = 0.691441569\dots$ from [163], and also the earlier $\sqrt{160/323} = 0.703815343078\dots$. The known rational lower example from [162] consequently gives the smaller interval

$$\left(\frac{133153321267264}{1366299579065739}\right)^{1/4} \leq c_4^{\text{odd}} \leq 5^{-1/4}. \quad (\text{III.72.7})$$

The left endpoint is approximately 0.558729390985. We import that example only for comparison; the proof of Theorem III.72.1 does not use it.

The propagation to $d \geq 5$ in (III.72.4) is valid, but is weaker than the prior central-binomial estimate at those orders. The combined statement, with $q = 2^{d-2}$, is

$$c_d^{\text{odd}} \leq \min \left\{ 5^{-1/4}, \frac{2}{\binom{2q}{q}^{1/q}} \right\} \quad (d \geq 4). \quad (\text{III.72.8})$$

The second entry is the bound of [163]; at $d = 5$ it is approximately 0.612819643. Thus no new higher-dimensional record is inferred merely from monotonicity.

III.72.1 The Fourier identity and the retained energy terms

All averages use normalized counting measure. We write the dual group additively and put

$$a_r = \widehat{f}(r), \quad \lambda_r = |a_r|^2, \quad S = \sum_r \lambda_r^2 = \|f\|_{U^2}^4, \quad M = \sum_r \lambda_r^4.$$

Thus $a_{-r} = \overline{a_r}$ and $a_0 = 0$. The sums over the dual group are ordinary, unnormalized sums; this convention is necessary because the Fourier coefficients themselves are normalized.

The exact Fourier identity for the third uniformity norm is

$$\begin{aligned} \|f\|_{U^3}^8 &= \sum_{s,t \in \widehat{G}} |T(s,t)|^2, \\ T(s,t) &= \sum_{r \in \widehat{G}} a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}. \end{aligned} \quad (\text{III.72.9})$$

For example, Fourier expansion of the original cube imposes four orthogonality equations. Solving these equations expresses its frequency variables as an affine cube; grouping its parallel faces gives (III.72.9). The solution uses additions and subtractions, so it introduces no torsion assumption.

On the two coordinate axes,

$$T(0,t) = T(t,0) = \sum_r \lambda_r \lambda_{r+t}.$$

If

$$E(\lambda) = \sum_{r+s=t+w} \lambda_r \lambda_s \lambda_t \lambda_w,$$

retaining those axes in the nonnegative sum gives

$$\|f\|_{U^3}^8 \geq 2E(\lambda) - S^2. \quad (\text{III.72.10})$$

The term S^2 corrects the double counting of $(s,t) = (0,0)$.

Theorem III.72.2 (A Fourier progression refinement). *Let f be real and centered on a finite abelian group of odd order, and define*

$$J(\lambda) = \sum_{r,t} \lambda_r^2 \lambda_t \lambda_{2r-t}.$$

Then

$$\|f\|_{U^3}^8 \geq 5S^2 - 10M + 4J(\lambda), \quad (\text{III.72.11})$$

$$\|f\|_{U^3}^8 \geq 5S^2 - 6M + 8 \sum_r |a_r|^6 |a_{3r}|^2. \quad (\text{III.72.12})$$

In particular, for any character ξ of odd order at least five, with $A = |a_\xi|$ and $B = |a_{3\xi}|$,

$$\|f\|_{U^3}^8 \geq 5S^2 - 6M + 16A^6 B^2. \quad (\text{III.72.13})$$

Proof. In $E(\lambda)$ retain the union of the three families

$$\mathcal{A} = \{r = t, s = w\}, \quad \mathcal{B} = \{r = w, s = t\}, \quad \mathcal{C} = \{s = -r, w = -t\}.$$

Each contributes S^2 , using the evenness of λ for $\mathcal{C}$. Every pairwise intersection contributes M . The triple intersection has $r = -r$, hence $r = 0$ because the group has odd order. Its weight is zero because $\lambda_0 = 0$. The union therefore has weight $3S^2 - 3M$.

Next retain every nonconstant repeated-entry quadruple

$$(r, r; t, 2r - t), \quad t \neq r, \quad (\text{III.72.14})$$

and its side reversal. Odd group order ensures that the two entries on the unequal side are distinct: $t = 2r - t$ would imply $t = r$. Thus these ordered quadruples are distinct from their side reversals, and have total weight $2(J - M)$. No positive-weight quadruple in this new family belongs to $\mathcal{A}$ or $\mathcal{B}$, since that would force $t = r$. Membership in $\mathcal{C}$ would force $r = -r$, hence $r = 0$ and zero weight. Consequently

$$E(\lambda) \geq 3S^2 - 5M + 2J(\lambda).$$

Combining this with (III.72.10) proves (III.72.11).

For each nonzero r , retain in J the diagonal $t = r$ and the additional indices $t = -r, 3r$. They are distinct: a coincidence requires $2r = 0$ or $4r = 0$. The $r = 0$ terms have zero weight. It follows that

$$J(\lambda) \geq M + 2 \sum_r \lambda_r^3 \lambda_{3r},$$

which proves (III.72.12). If $3r = 0$, the new summand vanishes, so the statement includes groups with three-torsion. Finally the terms $r = \xi, -\xi$ in that sum are equal and have value $A^6 B^2$, proving (III.72.13). $\square$

For a direct view of the last refinement, its extra energy configurations are obtained from

$$(\xi, \xi; -\xi, 3\xi), \quad (-\xi, -\xi; \xi, -3\xi)$$

by interchanging sides and ordering the unequal side. These are eight distinct configurations outside $\mathcal{A} \cup \mathcal{B} \cup \mathcal{C}$, each of weight $A^6 B^2$. The factor 16 in (III.72.13) includes the additional factor two from (III.72.10).

III.72.2 Two inequalities retaining the largest Fourier pair

Assume $f \neq 0$ and choose ξ maximizing $|a_\xi|$. Set

$$A = |a_\xi|, \quad p = \frac{2A^4}{S}, \quad D = 1 - p.$$

Here p is the fraction of Fourier fourth-power mass carried by the pair $\{\xi, -\xi\}$. In particular $0 < p \leq 1$. After multiplying f by a positive scalar we may suppose $S = 1$; then $A = (p/2)^{1/4}$.

If p_j are the corresponding masses of the other conjugate pairs, then $\sum_j p_j = D$ and

$$M = \frac{1}{2} \left(p^2 + \sum_j p_j^2 \right) \leq \frac{p^2 + D^2}{2}, \quad M \leq \frac{p}{2}. \quad (\text{III.72.15})$$

The second estimate uses the maximality of p . The energy argument without its new positive term gives

$$\|f\|_{U^3}^8 \geq 5 - 3p. \quad (\text{III.72.16})$$

If the order of ξ is at least five, (III.72.13) and the first inequality of (III.72.15) give

$$\|f\|_{U^3}^8 \geq 2 + 6pD + 16A^6 B^2, \quad B = |a_{3\xi}|. \quad (\text{III.72.17})$$

The quadratic dependence on B is the useful new feature. An estimate using only the residual fourth-power mass would permit B as large as $(D/2)^{1/4}$. Formula (III.72.17) imposes a further cost even when that mass is small.

III.72.3 The exact dual function of a cosine

For a real function g put

$$D_4 g(x) = \mathbb{E}_{h_1, h_2, h_3, h_4} \prod_{\substack{\omega \in \{0,1\}^4 \\ \omega \neq 0}} g(x + \omega \cdot h).$$

Cube Cauchy–Schwarz gives

$$|\mathbb{E}_x f(x) D_4 g(x)| \leq \|f\|_{U^4} \|g\|_{U^4}^{15}. \quad (\text{III.72.18})$$

The following finite identity was established in [162]. We give the counting proof because its coefficients are essential to the numerical improvement.

Lemma III.72.3 (Fourth-order cosine identity). *Let χ be a character of odd order at least five and let $\theta \in \mathbb{R}$. Write $g_j = e^{ij\theta} \chi^j + e^{-ij\theta} \chi^{-j}$. Then*

$$\|g_1\|_{U^4}^{16} = 222, \quad D_4 g_1 = 111g_1 + 27g_3 + g_5. \quad (\text{III.72.19})$$

When χ has order five, g_5 is constant and the formula still holds.

Proof. Expand the factors into characters. Each direction equation requires a sum of eight signs to be divisible by the odd order of χ . The sum is even and lies between -8 and 8 , so for an odd order at least five it must be zero as an integer. The counting is therefore unchanged for character orders five, seven, or larger.

For the full cube, each of two opposite three-faces has four plus signs. Let $n(t)$ count four-subsets of $\{0, 1\}^3$ with coordinate sum $t = (t_1, t_2, t_3)$. Splitting into these faces gives the total count $\sum_t n(t)^2$. The coefficient identity

$$[z^4] \prod_{\epsilon \in \{0,1\}^3} (1 + zx^\epsilon) = x_1 x_2 x_3 \prod_{j=1}^3 (1 + x_j)^2 + \sum_{i=1}^3 (1 + x_i^4) \prod_{j \neq i} x_j^2 \quad (\text{III.72.20})$$

gives the complete table

Type of t	Number of t	$n(t)$
One coordinate 0 or 4, the other two 2	6	1
All three coordinates in $\{1, 3\}$	8	1
Two in $\{1, 3\}$, one equal to 2	12	2
One in $\{1, 3\}$, two equal to 2	6	4
$(2, 2, 2)$	1	8

Thus the count is $6 + 8 + 12 \cdot 4 + 6 \cdot 16 + 64 = 222$. All surviving full-cube assignments have total frequency zero, which proves the first identity of (III.72.19).

For the dual function, adjoining the missing origin sign shows that the coefficients at frequencies 1 and -1 are each 111. At frequency -3 , the six plus-sign vertices among the fifteen nonzero vertices must place four selected vertices on each coordinate face. Complement all four coordinates. The resulting six vertices exclude 1111 and have coordinate sums $(2, 2, 2, 2)$. If a_j counts their vertices of Hamming weight j , the possible profiles and counts are

a_0	a_1	a_2	a_3	Count
0	4	2	0	3
1	2	3	0	12
1	3	1	1	12

In the first case the two edges form a perfect matching. In the second, choose two singleton endpoints in six ways and a three-edge path between them in two ways. In the third, choose the triple in four ways and the coordinate of that triple without its singleton in three ways; the remaining edge is forced. Hence the coefficient is $3 + 12 + 12 = 27$. Sign reversal gives the same coefficient at 3.

At frequency -5 , the five plus-sign vertices must have sixteen coordinate incidences. The unique possibility consists of the weight-four vertex and all four weight-three vertices. Its sign reversal gives frequency 5. Four distinct vertices have at most thirteen incidences, so no frequency of absolute value at least seven survives. This proves the dual identity. $\square$

Choose θ with $a_\xi = Ae^{i\theta}$ and apply the lemma to the corresponding character. Put $C = |a_{5\xi}|$. The pairs $\{\pm 3\xi\}$ and $\{\pm 5\xi\}$ are distinct and outside $\{\pm \xi\}$; the sole exception is $5\xi = 0$ at order five, in which case $C = 0$. The excluded coincidences would require $2\xi = 0$, $4\xi = 0$, $6\xi = 0$, or $8\xi = 0$. Consequently

$$2B^4 + 2C^4 \leq D. \quad (\text{III.72.21})$$

The dual pairing satisfies

$$\mathbb{E} f D_4 g_1 \geq 2(111A - 27B - C).$$

Therefore, with $R = \|f\|_{U^4}^{16}$ under the normalization $S = 1$, (III.72.18) gives

$$R \geq 222 \left[A - \frac{27}{111}B - \frac{1}{111}C \right]_+^{16}, \quad [x]_+ = \max(x, 0). \quad (\text{III.72.22})$$

III.72.4 The character of order three

The previous dual identity has a different form at order three. We treat that case directly, rather than imposing a stronger restriction on the ambient group.

Lemma III.72.4 (The ternary cosine). *For a character χ of order three and $g = e^{i\theta}\chi + e^{-i\theta}\chi^{-1}$,*

$$\begin{aligned} \|g\|_{U^4}^{16} &= 286 + 32 \cos(6\theta) + 16 \cos(12\theta) \\ &= 262 + 32 \left(\cos(6\theta) + \frac{1}{2} \right)^2 \geq 262. \end{aligned} \quad (\text{III.72.23})$$

If a largest Fourier pair of f has order three, then

$$R \geq \frac{131}{8}p^4. \quad (\text{III.72.24})$$

Proof. In the character expansion of the full cube, the possible numbers of plus signs are 2, 5, 8, 11, 14. Their multiplicities are respectively 8, 16, 286, 16, 8, as follows. At size two the vertices must be antipodal. At size five, reflect every coordinate that occurs four times; the result is the origin together with the four unit vertices, giving sixteen copies. At size eight, the 222 configurations from Lemma III.72.3 have four selected vertices on every coordinate face. Every remaining one consists of a whole three-face with a single vertex moved across the perpendicular direction. There are $4 \cdot 2 \cdot 8 = 64$ of these, each with exactly one exceptional direction. Taking complements gives sizes eleven and fourteen. The frequencies are $-12, -6, 0, 6, 12$, so summing their phases proves the first line of (III.72.23). The double-angle identity proves the second.

For (III.72.24), average f over the kernel of the chosen order-three character. Translation invariance and the triangle inequality make this averaging contractive for U^4 . On the three-element quotient the projected function is exactly Ag , because f is centered. Hence $R \geq 262A^{16} = (131/8)p^4$. $\square$

III.72.5 A scalar certificate using exact rational bounds

We now prove the constant 5. The proof reduces to two elementary one-variable estimates. Its few rational comparisons are also checked by the accompanying standard-library program `verification/verify_norm_gap.py`.

Proof of Theorem III.72.1. The zero function is immediate. Otherwise rescale to $S = 1$, so $R = \|f\|_{U^4}^{16}$. Suppose for a contradiction that $R \leq 5$. Monotonicity and the rational comparison $\sqrt{5} < 56/25$ give

$$\|f\|_{U^3}^8 \leq \|f\|_{U^4}^8 \leq \sqrt{5} < \frac{56}{25}.$$

Equation (III.72.16) implies $p > 23/25$. If the chosen character has order three, (III.72.24) yields

$$R > \frac{131}{8} \left(\frac{23}{25} \right)^4 > 5,$$

a contradiction. Its order is therefore at least five.

Since $p > 1/2$ and $p(1-p)$ decreases on $[1/2, 1]$, (III.72.17) implies $p > 19/20$. Indeed, $p \leq 19/20$ would give $6p(1-p) \geq 57/200 > 6/25$, contradicting that equation. Thus

$$0 \leq D < \frac{1}{20}, \quad B^2 < \frac{6/25 - (57/10)D}{16A^6}. \quad (\text{III.72.25})$$

In particular $D < 4/95$.

Put $a = 2^{-1/4}$. For $0 \leq D \leq 1/20$,

$$A = a(1-D)^{1/4} \geq a(1-D/3). \quad (\text{III.72.26})$$

To check this, differentiate $(1-D)^{1/4} - (1-D/3)$. Its derivative is positive on this interval because $(1-D)^{3/4} \geq 19/20 > 3/4$. We shall prove

$$A - \frac{27}{111}B - \frac{1}{111}C > \frac{789}{1000}. \quad (\text{III.72.27})$$

This contradicts (III.72.22) and $R \leq 5$, since

$$222 \left(\frac{789}{1000} \right)^{16} > 5. \quad (\text{III.72.28})$$

First suppose $0 \leq D \leq 1/300$. Hölder's inequality and (III.72.21) give

$$27B + C \leq (27^{4/3} + 1)^{3/4} (B^4 + C^4)^{1/4} \leq 82^{3/4} (D/2)^{1/4}.$$

The exact comparisons

$$a > \frac{21}{25}, \quad 82^{3/4} < \frac{273}{10}, \quad (1/600)^{1/4} < \frac{203}{1000}$$

and (III.72.26) show that the left side of (III.72.27) is greater than

$$\frac{21}{25} \frac{899}{900} - \frac{1}{111} \frac{273}{10} \frac{203}{1000} = \frac{18879}{22500} - \frac{55419}{1110000} > \frac{789}{1000}. \quad (\text{III.72.29})$$

It remains to consider $1/300 \leq D < 4/95$. Equations (III.72.25), (III.72.26), and $C \leq (D/2)^{1/4}$ show that the left side of (III.72.27) is at least

$$\begin{aligned} F(D) &= a(1-D/3) - \frac{27}{444a^3} (1-D/3)^{-3} \sqrt{6/25 - 57D/10} \\ &\quad - \frac{1}{111} (D/2)^{1/4}. \end{aligned} \quad (\text{III.72.30})$$

For $h(D) = (1-D/3)^{-3} \sqrt{6/25 - 57D/10}$, differentiation gives

$$-h'(D) = (1-D/3)^{-4} \frac{261/100 + (19/4)D}{\sqrt{6/25 - 57D/10}} > 5.$$

The last inequality follows from $\sqrt{6/25 - 57D/10} < 1/2$ and $(1-D/3)^{-4} \geq 1$. Use $a^3 < 3/5$, $a < 1$, and $300^{3/4} < 73$ to obtain

$$F'(D) > \frac{225}{444} - \frac{1}{3} - \frac{73}{444} = \frac{1}{111} > 0. \quad (\text{III.72.31})$$

Here the last negative term bounds the derivative of $(D/2)^{1/4}/111 = aD^{1/4}/111$ for $D \geq 1/300$.

It suffices to evaluate F at $D = 1/300$. The exact bounds

$$\begin{aligned} a \frac{899}{900} &> \frac{4199}{5000}, \\ \frac{\sqrt{221/1000}}{4a^3(899/900)^3} &< \frac{1}{5}, \\ (1/600)^{1/4} &< \frac{203}{1000} \end{aligned}$$

give

$$F(1/300) > \frac{4199}{5000} - \frac{27/5 + 203/1000}{111} = \frac{4199}{5000} - \frac{5603}{111000} > \frac{789}{1000}. \quad (\text{III.72.32})$$

For the first bound use $a > 1051/1250$. For the second, squaring reduces it to

$$\frac{221}{1000} < \frac{16}{25} a^6 \left(\frac{899}{900} \right)^6,$$

which holds already with a replaced by $21/25$. Thus every comparison in the proof reduces to integer arithmetic after clearing positive denominators and, where necessary, taking fourth powers.

Equations (III.72.31) and (III.72.32) finish (III.72.27), contradicting $R \leq 5$. Undoing the normalization proves $\|f\|_{U^4}^{16} > 5S^4$ for $f \neq 0$. Taking fourth roots yields $\|f\|_{U^4}^4 \geq 5^{1/4}S$. Finally $\|f\|_{U^d} \geq \|f\|_{U^4}$ for $d \geq 4$ proves (III.72.4) with exactly the asserted exponents. $\square$

III.72.6 The cube-count consequence and the remaining extremal problem

For a real function F on G , write

$$Q_d(F) = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{\omega \in \{0,1\}^d} F(x + \omega \cdot h).$$

The fourth-order expansion proved in [159] says that, on odd-order groups, for $f = F - \delta$, $\mathbb{E}f = 0$, $m = 2^d$, and $u = \|f\|_{U^d}$,

$$\begin{aligned} Q_d(F) &= \delta^m + R_d \delta^{m-4} \|f\|_{U^2}^4 + \mathcal{R}_d, \\ |\mathcal{R}_d| &\leq \sum_{j=5}^m \binom{m}{j} \delta^{m-j} u^j, \quad R_d = \frac{6^d - 2 \cdot 4^d + 2^d}{8}. \end{aligned} \quad (\text{III.72.33})$$

This statement assumes $\delta \geq 0$.

Corollary III.72.5 (An improved leading cube-count bound). *Let $d \geq 4$, let G have odd order, and let $F : G \rightarrow \mathbb{R}$ have mean $\delta \geq 0$. With $f = F - \delta$, $m = 2^d$, and $u = \|f\|_{U^d}$,*

$$Q_d(F) \leq \delta^m + 5^{-1/4} R_d \delta^{m-4} u^4 + \sum_{j=5}^m \binom{m}{j} \delta^{m-j} u^j. \quad (\text{III.72.34})$$

In particular, at $d = 4$ the quartic multiplier is $100 \cdot 5^{-1/4} = 66.8740304976\dots$, improving the strongest inspected prior multiplier $100(8/35)^{1/4} = 69.1441569\dots$ from [163]. For $d \geq 5$, retain instead the smaller multiplier supplied by the minimum in (III.72.8).

Proof. Substitute Theorem III.72.1 into the exact quartic term of (III.72.33), leaving the established remainder unchanged. $\square$

[write] **6 October 2026; sources 34–39.** Source 34’s Corollary III.71.9 has $200/3 = 66.667$ in place of $100 \cdot 5^{-1/4} = 66.874$ here (recomputed at the write).

For a set $A \subseteq G$ satisfying $\|\mathbf{1}_A - \delta\|_{U^d}^m \leq \alpha$, replace u^j in (III.72.34) by $\alpha^{j/m}$. Multiplication by $|G|^{d+1}$ converts the normalized average into the parameterized cube count used in the paper. This is a refinement of the local Lemma 3.10 interface. It neither changes the order of the quartic error nor supplies an optimal coefficient for $d \geq 4$.

Methods and limitations. The new input is the explicit retention of repeated-entry additive quadruples in Theorem III.72.2. The cosine dual identity and the preceding norm-gap framework are credited to the earlier reports and reproved where used. All constants in the final scalar argument are certified by exact arithmetic; the program also enumerates the sign counts behind Lemmas III.72.3 and III.72.4. The proof is mathematical rather than Lean-formalized. It provides a new bound relative to the inspected repository materials, with no claim of an exhaustive literature-priority determination.

Research question III.72.6 (The next quantitative and structural questions). Can the full statistic $J(\lambda)$, or further nonnegative terms in (III.72.9), determine the optimal c_4^{odd} ? Does an extremizer live on a finite cyclic quotient, or only arise as a limit? At higher orders, can the additional harmonics in D_d of a cosine yield constants that improve with d , rather than the single fourth-order constant propagated by monotonicity? The negative third-harmonic examples in [162] show that any proposed classification must retain Fourier phases as well as amplitude masses.

III.73 Source 34’s chapter: prime torsion in cube expansions [write]

Added in the seventh write, 6 October 2026.

The next eight sections are source 34’s Sections 2–9, on when a prime p first enters the centered expansion of a cube count through Smith torsion of a Boolean configuration. *Logically the chapter follows source 09’s support-lattice material* (Sections III.18 and III.23: integer value lattices, the order-five obstruction and the all-prime family with $h(\ell) \leq \ell + 2$) and source 21’s order-five certificates; it is printed here because no number printed earlier may move. Source 34’s introduction is Section F.39; its Section 10 is in the chapter on c_d^{odd} (Section III.71).

What is proved, in one paragraph. The least support $h(p)$ of an affinely independent Boolean configuration admitting a full-support characteristic- p relation is $D_{\text{div}}(p)+1$, where $D_{\text{div}}(p)$ is the least order of a nonsingular binary matrix with determinant divisible by p (Theorem III.75.2); $h(7) = 7$ and $h(11) = h(13) = h(17) = 8$, with exhaustive certificates for 11 and 13 (Theorem III.76.2); every integer up to $\exp(\frac{1}{2}N \log N - N \log \log N - 4N)$ is eventually the sole nonunit Smith factor of a binary matrix of order N , through Shitov’s composition and the Alon–Vu matrices (Theorem III.78.1); hence $h(p) \sim h_{\text{cyc}}(p) \sim 2 \log p / \log \log p$ (Theorem III.79.1); universal nonnegativity of cyclic moments holds exactly for inverse-paired coefficients, and $h_{\text{pos}}(m) \sim 4 \log m / \log \log m$ (Theorems III.80.1, III.80.3); the exact quartic term is recalled with proof (Proposition III.81.2). This answers source 09’s prime-onset question (item III.16).

Relation to the formal statements (checked at HEAD 89c1cbc38). lemma_3_10 (Sections01_03.

lean, line 340) has the exact companion lemma_3_10_holds (Proofs03CubeUpper.lean, line 82); no declaration concerns Smith torsion of cube expansions. Nothing in this chapter is formalized.

III.74 Fourier constraints and the Boolean row quotient

Source 34, delivered Section 2.

Throughout, G is a finite abelian group, written additively, and $\widehat{G}$ is its character group, written multiplicatively. Every average is normalized. For $f : G \rightarrow \mathbb{C}$ set

$$\widehat{f}(\chi) = \mathbb{E}_{x \in G} f(x) \overline{\chi(x)}.$$

The trivial character is 1. Thus $\widehat{f}(1) = 0$ for centered f , and $\widehat{f}(\chi^{-1}) = \overline{\widehat{f}(\chi)}$ for real f . The Gowers norm is normalized by

$$\|f\|_{U^d}^{2^d} = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{v \in \{0,1\}^d} \mathcal{C}^{|v|} f(x + v \cdot h),$$

where $\mathcal{C}$ denotes complex conjugation. In particular,

$$\|f\|_{U^2}^4 = \sum_{\chi \in \widehat{G}} |\widehat{f}(\chi)|^4.$$

For real functions the conjugations have no effect. We use the standard multilinear Gowers–Cauchy–Schwarz inequality and norm monotonicity; these follow by successive Cauchy–Schwarz applications as in Gowers’s Lemmas 3.8–3.9 [1].

Definition III.74.1 (Augmented Boolean matrix). Let $S = \{v_1, \dots, v_s\} \subseteq \{0, 1\}^d$, with distinct vertices. Its augmented matrix and row quotient are

$$M_S = \begin{pmatrix} 1 & \cdots & 1 \\ v_1 & \cdots & v_s \end{pmatrix}, \quad L_S = \text{row}_{\mathbb{Z}}(M_S) \subseteq \mathbb{Z}^s, \quad A_S = \mathbb{Z}^s / L_S.$$

The columns are written vertically. The set S is affinely independent exactly when $\text{rank}_{\mathbb{Q}} M_S = s$.

Proposition III.74.2 (Exact Fourier presentation). *For any functions $f_1, \dots, f_s : G \rightarrow \mathbb{C}$,*

$$\mathbb{E}_{x, h} \prod_{j=1}^s f_j(x + v_j \cdot h) = \sum_{\substack{\chi_1, \dots, \chi_s \in \widehat{G} \\ M_S \chi = 1}} \prod_{j=1}^s \widehat{f}_j(\chi_j). \quad (\text{III.74.1})$$

Here $M_S \chi = 1$ means that the product of the characters in every row, with the indicated exponents, is trivial. The solution tuples are canonically $\text{Hom}(A_S, \widehat{G})$, evaluated at the images of the standard generators of $\mathbb{Z}^s$. If all f_j are centered, only tuples with every $\chi_j \neq 1$ contribute.

Proof. Insert Fourier inversion into each factor. Averaging first in x forces $\prod_j \chi_j = 1$. Averaging in h_i forces $\prod_j \chi_j^{(v_j)_i} = 1$. These are exactly the rows of M_S . A tuple defines a homomorphism from $\mathbb{Z}^s$ to $\widehat{G}$; the row constraints say it factors through A_S . Centering removes any summand with a trivial coordinate character. $\square$

Definition III.74.3 (Minimal supports). For a prime p , let $h(p)$ be the least s for which an affinely independent Boolean set S of size s has a vector $0 \neq c \in \ker_{\mathbb{F}_p} M_S$ with all coordinates nonzero. Equivalently, A_S has p -torsion and a full-support characteristic- p character. Define

$$D_{\text{div}}(p) = \min\{n : B \in \{0,1\}^{n \times n}, \det B \neq 0, p \mid \det B\}.$$

For an integer $m \geq 2$, let $h_{\text{cyc}}(m)$ be the least s for an affinely independent Boolean S such that $A_S \cong \mathbb{Z}/m\mathbb{Z}$ and the images of all standard coordinate generators are nonzero in this quotient. In terms of a faithful character to $\mathbb{Z}/m\mathbb{Z}$, its coefficient vector has no zero coordinate. For composite m , these coordinates need not be units. For primes, $h(p) \leq h_{\text{cyc}}(p)$.

These minima exist. For example, the zero vertex and the columns of $J - I_{p+1}$ give the earlier $p+2$ construction. Section III.77 gives a construction for every cyclic order. All logarithms below are natural unless a base is displayed.

Remark III.74.4 (Which characteristic dependence is measured). The parameter $h(p)$ measures *Smith torsion*: a drop of the rank of the integer constraint matrix modulo p . A torsion-free integer relation can also have coefficients that vanish modulo p , changing whether a centered Fourier term survives. Our dimension threshold does not rule out every possible characteristic-dependent phenomenon of that latter kind. This distinction is essential when using an all-orders expansion.

III.75 The exact determinant reduction

Source 34, delivered Section 3.

The central observation is that minimal order removes the extra support obstruction. A general matrix singular modulo p can have only relations with zero coordinates; a dimension-minimal binary matrix with determinant divisible by p cannot.

Lemma III.75.1 (Removing the affine row). *Suppose a square, nonsingular binary matrix M has order s and its first row is all ones. There is a binary matrix B of order $s-1$ with $|\det B| = |\det M|$.*

Proof. For each lower row whose first entry is one, replace that row by the first row minus itself. All entries remain binary and the absolute determinant is unchanged. The first column is now $(1, 0, \dots, 0)^T$. Subtract it from every other column and expand along the first row. The remaining lower-right matrix is binary and has the claimed determinant. $\square$

Theorem III.75.2 (Full support is automatic at minimal order). *For every prime p ,*

$$h(p) = D_{\text{div}}(p) + 1. \tag{III.75.1}$$

If B attains $n = D_{\text{div}}(p)$, then $\ker_{\mathbb{F}_p} B$ is one-dimensional, every nonzero vector in it has full support, and its coordinate sum is nonzero. The zero vertex and the columns of B give a witness for $h(p)$ in dimension n .

Proof. Take an admissible set of s vertices. Since the augmented matrix has rank s over $\mathbb{Q}$, the nonzero all-ones row can be extended to a basis of its row space. The resulting $s \times s$ minor is nonsingular over $\mathbb{Q}$ and singular over $\mathbb{F}_p$, because it annihilates the given nonzero vector. Lemma III.75.1 produces a nonsingular binary matrix of order $s-1$ with determinant divisible by p . Thus $D_{\text{div}}(p) \leq s-1$.

Conversely, take B of minimal order n and $0 \neq c \in \ker_{\mathbb{F}_p} B$. If c has support of size $r < n$, the corresponding r columns of B are linearly independent over $\mathbb{Q}$. Select r rows on which those columns give a nonsingular $r \times r$ submatrix. Its reduction modulo p annihilates the nonzero restricted vector. This contradicts minimality. Hence every nonzero c has full support.

Suppose now that $\sum_i c_i = 0$. Adjoin an all-ones row to B . The new row space still has rank n over $\mathbb{Q}$, and we may choose n independent rows including the all-ones row. They form a square binary matrix singular modulo p . Applying Lemma III.75.1 again gives a forbidden matrix of order $n - 1$. Therefore $\sum_i c_i \neq 0$.

The augmented matrix of the zero vertex and the columns of B is

$$M = \begin{pmatrix} 1 & \mathbf{1}^T \\ 0 & B \end{pmatrix}.$$

It is nonsingular over $\mathbb{Q}$ and annihilates $(-\sum_i c_i, c_1, \dots, c_n)$ modulo p . This vector has full support, giving $h(p) \leq n + 1$.

Finally, if the kernel of B had dimension at least two, two independent kernel vectors would have a nonzero linear combination whose first coordinate is zero. That contradicts the full-support conclusion just proved. The nullity is therefore one. $\square$

Corollary III.75.3 (Arbitrary support and the first cube dimension). *Let $S \subseteq \{0, 1\}^d$ be arbitrary, possibly affinely dependent, and let $r = \text{rank}_{\mathbb{Q}} M_S$. If A_S has nonzero p -primary torsion, then*

$$r \geq D_{\text{div}}(p) + 1 = h(p), \quad d \geq D_{\text{div}}(p), \quad |S| \geq h(p). \quad (\text{III.75.2})$$

All three minimum values are attained simultaneously by the construction in Theorem III.75.2.

Proof. Smith normal form says that A_S has p -torsion exactly when $\text{rank}_{\mathbb{F}_p} M_S < r$. Choose r independent rational rows including the all-ones row, and then r columns on which their minor is nonsingular. Every $r \times r$ minor vanishes modulo p . Lemma III.75.1 yields a nonsingular binary determinant of order $r - 1$ divisible by p . Hence $r - 1 \geq D_{\text{div}}(p)$. The other inequalities follow from $r \leq d + 1$ and $r \leq |S|$. The theorem provides equality with $r = |S| = d + 1$. $\square$

Remark III.75.4. This corollary concerns *any* p -primary Smith torsion, so introducing extra vertices or rational affine dependencies cannot make it occur in a smaller cube dimension. It does not say that a minimum determinant divisible by p has absolute value p ; other prime factors or higher powers may remain. Exact cyclic isolation is treated separately.

Lemma III.75.5 (Cyclic support compression). *Let B be a nonsingular binary matrix of order n with $\mathbb{Z}^n / \text{row}_{\mathbb{Z}}(B) \cong \mathbb{Z}/m\mathbb{Z}$. Then*

$$h_{\text{cyc}}(m) \leq n + 1. \quad (\text{III.75.3})$$

More precisely, starting from the zero vertex and the columns of B , delete the coordinates on which a faithful quotient character is zero. The retained Boolean set is affinely independent, has quotient exactly $\mathbb{Z}/m\mathbb{Z}$, and has a full-support faithful character.

Proof. The augmented matrix M is integrally equivalent to $\text{diag}(1, B)$, so its row quotient is cyclic of order m . Choose an isomorphism to $\mathbb{Z}/m\mathbb{Z}$ and represent the resulting character on $\mathbb{Z}^{n+1}$ by a vector c modulo m . Let T be its nonzero coordinates and let π be projection onto them. Writing $L = \text{row}_{\mathbb{Z}}(M)$, there is a surjection

$$\mathbb{Z}^{n+1}/L \longrightarrow \mathbb{Z}^T/\pi(L).$$

The isomorphism to $\mathbb{Z}/m\mathbb{Z}$ factors through this surjection, because c is zero outside T . Thus the target is both a quotient of a group of order m and a group surjecting onto one of order m . Both maps must be isomorphisms. Projection of the rows is exactly deletion of the unwanted columns of M . The corresponding subset of an affinely independent set remains affinely independent, and the retained vector has full support by construction. $\square$

III.76 Exact first cases and finite nonexistence certificates

Source 34, delivered Section 4.

Lemma III.76.1 (Binary Hadamard bound). *Every binary matrix B of order n satisfies*

$$|\det B| \leq \frac{(n+1)^{(n+1)/2}}{2^n}.$$

Consequently every admissible support of size s for $h(p)$, or for $h_{\text{cyc}}(m)$, satisfies respectively

$$p \leq \frac{s^{s/2}}{2^{s-1}}, \quad m \leq \frac{s^{s/2}}{2^{s-1}}. \quad (\text{III.76.1})$$

Proof. The sign matrix

$$H = \begin{pmatrix} 1 & \mathbf{1}^T \\ \mathbf{1} & J - 2B \end{pmatrix}$$

has $|\det H| = 2^n |\det B|$. Every row has Euclidean norm $\sqrt{n+1}$, so Hadamard's inequality gives the first assertion. For $h(p)$ use the nonsingular minor of Theorem III.75.2. For $h_{\text{cyc}}(m)$, each full minor of the augmented matrix is divisible by its full row-lattice index m : this follows from Smith normal form, or from the gcd-of-minors formula for the index. Choose a nonzero full minor including the all-ones row and apply Lemma III.75.1. $\square$

Theorem III.76.2 (Four new exact prime values). *One has*

$$h(7) = h_{\text{cyc}}(7) = 7, \quad h(11) = h_{\text{cyc}}(11) = h(13) = h_{\text{cyc}}(13) = h(17) = h_{\text{cyc}}(17) = 8.$$

Together with the earlier values, the initial table is

	p	2	3	5	7	11	13	17
$h(p) = h_{\text{cyc}}(p)$		4	5	6	7	8	8	8
<i>minimum cube dimension</i>		3	4	5	6	7	7	7

Proof. The upper bounds follow from the explicit matrices below. They have determinants 7, 11, 13, 17, respectively, and therefore cyclic row quotients of those prime orders. Their augmented coefficient vectors have full support, so no support compression is needed.

For the lower bounds, the Hadamard bound at $s = 6$ is $27/4 < 7$, and at $s = 7$ is $7^{7/2}/64 < 17$. The same bound increases with $s \geq 2$, so it also excludes smaller supports. For $p = 11, 13$, the classical binary maximum determinant of order six is nine [145]; Theorem III.75.2 then excludes $s \leq 7$. A fully independent finite proof of that exclusion, specialized to these two primes, is supplied immediately below and in the certificate files. The values at 2, 3, 5 and their cyclic witnesses were established in source 09 of [155]. $\square$

[write] **6 October 2026; sources 34–39.** *Answers source 09’s question* (its Research question “Support-efficient torsion”, item III.16): $h(7) = 7$ and $h(11) = 8$, and Theorem III.79.1 gives the leading asymptotic of the gap between source 09’s lower bound (III.23.4) and $h(\ell) \leq \ell + 2$. The intake recomputed, in exact integer arithmetic, the four printed matrices (determinant p , full-support kernel modulo p , cyclic quotient) and the orders-1–4 binary maximal determinants; the exhaustive certificates for $p = 11, 13$ are checked by the source’s own verifier (rerun on a copy at the write). Still open: whether $h(p) = h_{\text{cyc}}(p)$ for every prime, and the second-order term (Research questions V.130.1 and V.130.2).

III.76.1 Positive matrices and full-support relations

For each displayed B_p , take the zero vertex and its columns. Let $M_p = \begin{pmatrix} 1 & \mathbf{1}^T \\ 0 & B_p \end{pmatrix}$. The matrices are

$$B_7 = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix}, \quad B_{11} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 1 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix},$$

$$B_{13} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix}, \quad B_{17} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{pmatrix}.$$

The coefficient vectors, starting with the zero vertex, are

$$\begin{aligned} c_7 &= (1, 1, 1, 1, 3, 3, 4), \\ c_{11} &= (1, 1, 1, 1, 3, 4, 4, 7), \\ c_{13} &= (1, 1, 1, 2, 3, 5, 5, 8), \\ c_{17} &= (1, 1, 2, 4, 4, 6, 7, 9). \end{aligned}$$

In each case $M_p c_p = (2p, p, \dots, p)^T$. In particular, every coordinate is nonzero modulo p . Exact fraction-free determinants are recorded in `data/small_prime_matrices.json` and checked by `code/verify_torsion.py`.

The first three determinant computations also have short elimination proofs. In $B_7 x = 0$, set $x_6 = t$. The first two rows give $x_4 = x_5 = -t$, the last three give $x_1 = x_2 = x_3 = 2t$, and the remaining row gives $7t = 0$. In $B_{11} x = 0$, setting $x_7 = t$ gives $x_5 = x_6 = -t$, $x_4 = 2t$, and $x_1 = x_2 = x_3 = -3t$, with final relation $11t = 0$. For B_{13} the corresponding values are $x_5 = x_6 = -t$, $x_4 = 2t$, $x_3 = -3t$, and $x_1 = x_2 = 5t$, with final relation $13t = 0$. These are eliminations over $\mathbb{Z}$, with pivots of absolute value one, so they identify the exact cyclic quotient rather than only a modular kernel. The fourth matrix is verified by the same exact integer determinant algorithm included in the package.

III.76.2 A small certificate for nonexistence at seven vertices

Here is a direct proof method for the $p = 11, 13$ lower bounds that does not rely on a maximum-determinant table or floating-point rank. Suppose M is an augmented seven-column Boolean matrix with full rank over $\mathbb{Q}$ and a full-support kernel vector modulo p . The all-ones row forces

$$c \in (\mathbb{F}_p^\times)^7, \quad \sum_j c_j = 0.$$

Permuting coordinates and multiplying all c_j by a nonzero scalar do not change the existence of M . Represent these equivalence classes by the lexicographically least sorted tuple in each scalar orbit. There are exactly 104 such tuples for $p = 11$ and 204 for $p = 13$.

For a representative c , let

$$Z_p(c) = \{a \in \{0, 1\}^7 : a \cdot c = 0 \pmod{p}\}.$$

Every possible row of M belongs to this explicitly finite set. The supplied certificate gives, for each representative, a nonzero integer vector $z_c \in \mathbb{Z}^7$ satisfying

$$a \cdot z_c = 0 \quad \text{over } \mathbb{Z} \quad \text{for every } a \in Z_p(c). \quad (\text{III.76.2})$$

Thus all rows of M lie in a proper rational hyperplane, a contradiction.

The verifier independently regenerates the complete list of scalar and permutation orbit representatives. For each, it checks every one of the 2^7 Boolean masks and the integer dot product in (III.76.2). It verifies that z_c is a nonzero integer vector. It does *not* use a numerical rank routine, nor does it trust the optional rank field stored by the certificate generator. Consequently the negative proof consists of a short exhaustiveness argument and finitely many exact integer identities. The files are `data/no_seven_vertex_torsion_mod_11.json` and `data/no_seven_vertex_torsion_mod_13.json`.

III.76.3 What these configurations contribute to a cube expansion

Because $A_{S_p} \cong \mathbb{Z}/p\mathbb{Z}$ with generator coordinates c_p , Proposition III.74.2 gives, for a real centered f ,

$$T_{S_p}(f) := \mathbb{E}_{x,h} \prod_{v \in S_p} f(x + v \cdot h) = \sum_{\substack{\chi \in \widehat{G} \\ \chi^p = 1}} \prod_{j=1}^{|S_p|} \widehat{f}(\chi^{(c_p)_j}). \quad (\text{III.76.3})$$

For example, on $G = \mathbb{Z}/p\mathbb{Z}$, the centered real function $f = p\mathbf{1}_{\{0\}} - 1$ has Fourier coefficient one at every nontrivial character. The value of (III.76.3) is therefore $p - 1$. On a general finite group the analogous function $|G|\mathbf{1}_{\{0\}} - 1$ gives $|\widehat{G}[p]| - 1 = |G[p]| - 1$.

These are also legitimate perturbative examples for bounded functions. On $\mathbb{Z}/p\mathbb{Z}$, if $0 < \delta < 1$ and $0 < t \leq \min\{\delta, (1 - \delta)/(p - 1)\}$, then $F = \delta + tf$ takes values in $[0, 1]$, and the selected support contributes a nonzero term of degree $|S_p|$ in t . In a heterogeneous cube product, placing $\delta_v + t_v f$ at selected vertices makes the corresponding mixed coefficient individually visible. This avoids any claim that different supports cannot cancel in an arbitrary homogeneous expansion.

III.77 An elementary positive detector for every cyclic order

Source 34, delivered Section 5.

The asymptotically optimal construction later in the article uses Alon–Vu matrices. The following elementary construction is useful when a short explicit presentation and positivity matter more than the asymptotic number of vertices.

Theorem III.77.1 (Positive cyclic detector). *For every integer $q \geq 2$, put $r = \lceil \log_2 q \rceil$ and $t = r + 1$. There is an affinely independent Boolean set S_q of $2t$ vertices in dimension $2t - 1$ such that $A_{S_q} \cong \mathbb{Z}/q\mathbb{Z}$, with full-support generator coordinates*

$$(a_1, -a_1, \dots, a_t, -a_t), \quad (a_1, \dots, a_t) = (1, 1, 2, 4, \dots, 2^{r-1}).$$

For every real centered $f : G \rightarrow \mathbb{R}$ its moment is

$$T_{S_q}(f) = \sum_{\substack{\chi \in \widehat{G} \\ \chi^q = 1}} \prod_{i=1}^t |\widehat{f}(\chi^{a_i})|^2 \geq 0. \quad (\text{III.77.1})$$

In particular,

$$h_{\text{cyc}}(q) \leq 2\lceil \log_2 q \rceil + 2.$$

Proof. Use $2t$ generators x_i, y_i and the following binary relations:

$$x_i + y_i = 0 \quad (1 \leq i \leq t), \quad (\text{III.77.2})$$

$$\sum_{j < i} x_j + y_i = 0 \quad (2 \leq i \leq t), \quad (\text{III.77.3})$$

$$\sum_{i \in J} x_i = 0. \quad (\text{III.77.4})$$

Choose J so that $\sum_{i \in J} a_i = q$. Such a subset exists: the multiset $1, 1, 2, \dots, 2^{r-1}$ has every subset-sum value from zero to 2^r , including q .

Relations (III.77.2) give $y_i = -x_i$. Relations (III.77.3) give $x_i = \sum_{j < i} x_j = a_i x_1$. The last relation is exactly $q x_1 = 0$. Each elimination has an integer unit pivot, so the square binary relation matrix has determinant of absolute value q and row quotient exactly $\mathbb{Z}/q\mathbb{Z}$.

Replace its first pair row by the sum of all pair rows. This is a unimodular row operation, and the replacement row is all ones. Treat the remaining $2t - 1$ binary rows as coordinates of vertices. The square augmented matrix is nonsingular over $\mathbb{Q}$, so its columns are distinct and give an affinely independent Boolean set. Every a_i is positive and less than q , including when q is a power of two. Thus the quotient character has full support.

Finally, apply Proposition III.74.2 and use reality of f to pair the coefficients at χ^{a_i} and χ^{-a_i} . This proves (III.77.1). $\square$

Remark III.77.2 (Odd and even cyclic orders). For odd q , every a_i is a unit modulo q . On $\mathbb{Z}/q\mathbb{Z}$ the function $f = q\mathbf{1}_{\{0\}} - 1$ therefore gives $T_{S_q}(f) = q - 1$. For even q , a nontrivial character of a proper divisor order can be killed by some a_i ; the value need not be $q - 1$. Every character of exact order q still contributes one, so the detector is nonzero and at least $\varphi(q)$ for this function. This distinction prevents an unwarranted prime-to-composite extension of the sharper positivity statement.

The construction supplies an explicit all-parameter proof. The accompanying program checks it for 36 moduli, including 65537, using exact determinants and modular syndromes. It also computes the complete spatial average directly at $q = 2, 3$, independently of Fourier inversion. These checks validate the implementation; the integer elimination proves the theorem for every q .

III.78 Consecutive binary determinants with controlled Smith form

Source 34, delivered Section 6.

The determinant characterization reduces the support problem to a question about binary matrices. For the asymptotic upper bound, a construction that produces every sufficiently small integer is more useful than a construction producing only one exceptionally large determinant. Shah’s published consecutive range is of order $2^N/N$ [146]. Shitov’s author-uploaded 2025 preprint obtains the superexponential range

$$\exp\left(\frac{N}{2} \log N - 7N \log \log N\right)$$

for all sufficiently large orders N [147]. Its construction uses the unimodular matrices with large inverse entries of Alon and Vü [144].

We retain that construction, give all integer-rounding and determinant sign details, and improve its stated secondary loss. Tracking the integer row and column operations gives a further conclusion about the whole Smith normal form. The sole deep external input in the following proof is the published Alon–Vü theorem; the remaining arguments are included in full.

Theorem III.78.1 (Consecutive determinants and cyclic Smith forms). *For every sufficiently large integer N , and every integer h satisfying*

$$1 \leq h \leq \left\lfloor \exp\left(\frac{N}{2} \log N - N \log \log N - 4N\right) \right\rfloor, \quad (\text{III.78.1})$$

there exists $B \in \{0, 1\}^{N \times N}$ with

$$\det B = h, \quad \text{SNF}(B) = \text{diag}(1, \dots, 1, h).$$

The matrix may moreover be chosen to have an $(N-1) \times (N-1)$ minor equal to 1. Consequently its integer row-lattice quotient is cyclic of order h . The determinant conclusion also holds for $h = 0$.

The theorem improves the secondary term in the displayed range; its leading term $\frac{1}{2}N \log N$ was already obtained by Shitov. Cyclicity for composite h is additional information: the equality $\det B = h$ alone does not imply a cyclic quotient.

III.78.1 A unimodular matrix supplies a large integer

We use the arbitrary-order construction in Section 2.4 of Alon–Vü, together with the remark at the end of that section [144]. In natural logarithms, its relevant consequence is the existence, for every sufficiently large m , of a binary matrix M with $|\det M| = 1$ and

$$\max_{i,j} |(M^{-1})_{ij}| \geq \exp\left(\frac{m}{2} \log m - (2 \log 2 + o(1))m\right). \quad (\text{III.78.2})$$

The unimodularity assertion matters: it permits later substitutions by integer row and column operations.

Lemma III.78.2 (A large integer with a unimodular auxiliary block). *For every sufficiently large integer q , there are a binary $(q-1) \times (q-1)$ matrix M with $\det M = 1$ and binary unit column vectors u, v such that, on putting*

$$\alpha = -u^\top M^{-1}v, \quad A = |\alpha|,$$

one has $A > 1$ and

$$\frac{q}{2} \log q - \frac{3}{2}q \leq \log A \leq \frac{q}{2} \log q. \quad (\text{III.78.3})$$

Proof. Apply (III.78.2) with $m = q - 1$. If necessary, interchange two rows to arrange $\det M = 1$. This operation permutes the absolute values of the inverse entries, so it preserves the required lower bound. Choose u, v to select a suitable inverse entry. The binary matrix

$$U = \begin{pmatrix} 0 & u^\top \\ v & M \end{pmatrix}$$

has determinant α , by elimination using the invertible block M . Since $2 \log 2 < 3/2$, replacing $m = q - 1$ by q in the lower estimate costs only $O(\log q)$ and gives the left side of (III.78.3) for all sufficiently large q . The row-norm form of Hadamard's inequality applied to U gives $A \leq q^{q/2}$, proving the upper bound. The lower bound tends to infinity, so $A > 1$ eventually. $\square$

The integer α may have either sign. The construction below handles both signs without changing any binary entries.

III.78.2 Encoding one bounded row by binary rows

Lemma III.78.3 (Eliminating small negative entries). *Let R be a square integer matrix with a selected row z whose entries belong to $\{-2, -1, 0, 1\}$. There is a matrix R' of order two larger with the same determinant such that the selected row is replaced by binary entries, all added entries are binary, and every other old entry is unchanged. The nonunit Smith factors are also unchanged.*

Proof. Write $z = w - a - b$ with binary row vectors a, b, w . Coordinatewise, take

$$w_j = \mathbf{1}_{\{z_j=1\}}, \quad a_j = \mathbf{1}_{\{z_j<0\}}, \quad b_j = \mathbf{1}_{\{z_j=-2\}}.$$

Adjoin two first rows and two first columns. In the first two rows put the block $[I_2 \mid a; b]$. In the selected old row put $(1, 1)$ in the new columns and w in the old columns. In every other old row put zeros in the new columns and retain its old entries.

Elimination at I_2 replaces w by $w - a - b = z$ and leaves every other old row unchanged. These are integer unimodular operations, so R' is integrally equivalent to $I_2 \oplus R$. This proves both assertions and avoids any row-permutation sign convention. $\square$

Lemma III.78.4 (A bounded integer row). *Let C be an $n \times n$ integer matrix whose rows other than the first are binary. Suppose the entries of its first row have absolute value at most an integer $a \geq 1$, and put*

$$b = \lceil \log_2(a+1) \rceil.$$

There is a binary matrix C^ of order $n + 3b - 1$ with $\det C^* = \det C$. Its nonunit Smith factors are precisely those of C .*

Proof. Writing c_j for the first-row entries, choose signed binary digits $e_{ij} \in \{-1, 0, 1\}$ with

$$c_j = \sum_{i=1}^b 2^{b-i} e_{ij}.$$

They exist because $a \leq 2^b - 1$. Let $E = (e_{ij})$, and let C_0 consist of the bottom $n - 1$ rows of C . Define a $b \times (b - 1)$ matrix J by

$$J_{i,i} = 1, \quad J_{i+1,i} = -2 \quad (1 \leq i < b),$$

with all other entries zero. Form

$$C_1 = \begin{pmatrix} J & E \\ 0 & C_0 \end{pmatrix}.$$

Its order is $n + b - 1$. Add twice the first row to the second row and eliminate the first column at its pivot 1. Repeating this procedure combines the digit rows into the original first row of C ; explicitly, the new digit row after the first elimination is $2E_1 + E_2$. Integer column operations clear the rest of each pivot row. Thus C_1 is integrally equivalent to $I_{b-1} \oplus C$ and has determinant $\det C$.

Only the first b rows may contain nonbinary entries, all in $\{-2, -1, 0, 1\}$. Apply Lemma III.78.3 to each of those rows. This adds $2b$ to the order and adjoins only unit Smith factors. The resulting binary matrix has order $(n + b - 1) + 2b = n + 3b - 1$, as required. $\square$

The ceiling in this lemma is necessary, including when $a + 1$ is not a power of two. Its use is retained in every subsequent dimension count.

III.78.3 Substituting large entries at off-diagonal positions

Fix the data of Lemma III.78.2, an integer $t \geq 2$, and integers $\epsilon_0, \dots, \epsilon_{t-1}$. Let H be the $t \times t$ matrix whose first row is $(\epsilon_0, \dots, \epsilon_{t-1})$, with

$$H_{i,i} = 1, \quad H_{i,i-1} = \alpha \quad (2 \leq i \leq t),$$

and all remaining entries zero. Cofactor expansion in the first row gives

$$\det H = \sum_{j=0}^{t-1} (-\alpha)^j \epsilon_j. \quad (\text{III.78.4})$$

The following simultaneous substitution is useful because the large entries occur off the diagonal. It gives the determinant identity directly, without separate permutations of rows and columns.

Let H_0 be H with its $t - 1$ subdiagonal entries α replaced by zero, and let K be the block diagonal matrix with $t - 1$ copies of M . Define binary coupling matrices R, S as follows. For $i = 2, \dots, t$, row i of R contains $u^\top$ in auxiliary block $i - 1$ and is zero elsewhere; the first row of R is zero. Auxiliary block $i - 1$ of S contains v in column $i - 1$ and is zero elsewhere. Set

$$\tilde{H} = \begin{pmatrix} H_0 & R \\ S & K \end{pmatrix}.$$

Its order is

$$t + (t - 1)(q - 1) = (t - 1)q + 1. \quad (\text{III.78.5})$$

Because $\det K = 1$, elimination gives

$$\det \tilde{H} = \det(H_0 - RK^{-1}S) = \det H. \quad (\text{III.78.6})$$

Indeed, the only nonzero entries of $RK^{-1}S$ are $u^\top M^{-1}v = -\alpha$ in precisely the intended subdiagonal positions. Every row of $\tilde{H}$ other than the first is binary.

This substitution also preserves the integral normal form. The integer unimodular matrices

$$P = \begin{pmatrix} I & -RK^{-1} \\ 0 & I \end{pmatrix}, \quad Q = \begin{pmatrix} I & 0 \\ -K^{-1}S & I \end{pmatrix}$$

satisfy

$$P\tilde{H}Q = H \oplus K. \quad (\text{III.78.7})$$

Thus the added blocks contribute only unit Smith factors.

Proposition III.78.5 (An exact integer range at an exact order). *For every sufficiently large q , every integer $t \geq 2$, and every integer h with $|h| < A(q)^t$, there is a binary matrix of order*

$$(t-1)q + 3 \lceil \log_2 A(q) \rceil \quad (\text{III.78.8})$$

and determinant h . If $h \neq 0$, its Smith form has exactly one possibly nonunit factor, namely $|h|$.

Proof. Write $|h| = \sum_{j=0}^{t-1} A^j d_j$ in base A , with $0 \leq d_j \leq A-1$. For $h \neq 0$ set

$$\epsilon_j = \text{sgn}(h)(-\text{sgn}(\alpha))^j d_j;$$

for $h = 0$ take every $\epsilon_j = 0$. Equation (III.78.4) gives $\det H = h$. Substitute the auxiliary blocks to obtain $\tilde{H}$, and apply Lemma III.78.4 with $a = A-1$ and $b = \lceil \log_2 A \rceil$. Combining its cost with (III.78.5) gives exactly (III.78.8).

The bottom $t-1$ rows and right $t-1$ columns of H form a triangular matrix with diagonal 1. Hence the first $t-1$ Smith factors of H are 1, and its last factor is $|h|$ when $h \neq 0$. Equation (III.78.7) and Lemma III.78.4 show that every subsequent operation adjoins only unit factors. $\square$

Remark III.78.6 (A single unit cofactor). The stronger cofactor statement in Theorem III.78.1 can also be tracked directly. Deleting the first row and first column of $\tilde{H}$ gives determinant 1: its Schur complement is the unit triangular minor just used, and $\det K = 1$. In the digit-encoding matrix C_1 , delete its last digit row and the original first column. The remaining upper-left $(b-1) \times (b-1)$ block is triangular with diagonal 1, and the lower-right block is the previous unit minor. Each two-row conversion preserves that minor by retaining the new I_2 block and omitting the same old row and column. Identity padding preserves it as well. This gives an actual minor equal to 1, rather than only a greatest common divisor of minors equal to 1.

III.78.4 An improved secondary term

Proof of Theorem III.78.1. For the target order N , write $L = \log N$ and set

$$q = \left\lceil \frac{N}{L^2} \right\rceil, \quad t = \lfloor L^2 - 3L \rfloor, \quad b = \lceil \log_2 A(q) \rceil. \quad (\text{III.78.9})$$

For all sufficiently large N , the integer q lies in the range of Lemma III.78.2, $t \geq 2$, $N/L^2 > e^2$, and $q \leq N$. Put $c = 3/(2 \log 2) < 2.2$. The upper bound in (III.78.3) gives $3b \leq cq \log q + 3$. Consequently the order s in (III.78.8) satisfies

$$\begin{aligned} s &\leq q[L^2 - 3L - 1 + c \log q] + 3 \\ &\leq q[L^2 - (3 - c)L - 1] + 3 \\ &\leq N - \frac{(3 - c)N}{L} - \frac{N}{L^2} + L^2 - (3 - c)L + 2 \\ &\leq N - \frac{(3 - c)N}{L} + L^2 + 2 \leq N. \end{aligned}$$

The coefficient of q is positive eventually, justifying the insertion $q \leq N/L^2 + 1$. The last inequality holds eventually because $3 - c > 0$ and N/L grows faster than L^2 . A matrix of order s can therefore be padded by an identity matrix to exact order N .

For the covered range, the function $x \mapsto \frac{x}{2} \log x - \frac{3}{2}x$ is increasing for $x > e^2$. Since $q \geq N/L^2$, the lower bound in (III.78.3) gives

$$\log A(q) \geq \frac{N}{L^2} \left(\frac{L}{2} - \log L - \frac{3}{2} \right).$$

Also $t \geq L^2 - 3L - 1$. Both lower bounds are positive eventually, and their product is

$$\begin{aligned} t \log A(q) &\geq N \left[\frac{L}{2} - \log L - 3 + \frac{3 \log L + 4}{L} + \frac{\log L + 3/2}{L^2} \right] \\ &> \frac{N}{2} \log N - N \log \log N - 3N. \end{aligned}$$

In particular, the exponential in (III.78.1) is strictly less than $A(q)^t$. Every integer in the stated interval is covered by Proposition III.78.5. Its Smith-form assertion, Remark III.78.6, and identity padding prove all the remaining claims. $\square$

Remark III.78.7 (Quantifiers and attribution). The theorem is eventual: no numerical starting value N_0 is asserted. The threshold includes that in the asymptotic Alon–Vũ input. The auxiliary-block and radix strategy is credited to Shitov [147]; the displayed secondary estimate and the integral normal-form conclusions follow from the explicit calculations above. The factor 4 is a convenient stated constant, not an optimality claim.

Proposition III.78.8 (Optimizing the linear loss). *Put*

$$c = \frac{3}{2 \log 2}, \quad C_* = 2 \log 2 + \frac{1}{2} \log c + \frac{1}{2} = 2.272283375 \dots$$

For every $\varepsilon > 0$, Theorem III.78.1, including its Smith-form and unit-minor conclusions, holds with $4N$ in (III.78.1) replaced by $(C_ + \varepsilon)N$, for all sufficiently large N depending on ε .*

Proof. Retaining the sharper asymptotic input (III.78.2) in Lemma III.78.2 gives

$$\log A(q) \geq \frac{q}{2} \log q - (2 \log 2 + o(1))q.$$

Write $L = \log N$ and choose

$$q = \left\lceil \frac{N}{cL^2} \right\rceil, \quad t = \left\lfloor \frac{N - 3}{q} - c \log q \right\rfloor + 1.$$

Eventually $t \geq 2$. The unchanged estimate $3\lceil \log_2 A(q) \rceil \leq cq \log q + 3$ shows directly that the order in (III.78.8) is at most N . Moreover,

$$\log q = L - 2 \log L - \log c + o(1), \quad q(\log q)^2 = \frac{N}{c} + o(N).$$

Using $t \geq (N-3)/q - c \log q$ and the lower bound for $\log A(q)$, whose factors are positive eventually, yields

$$\begin{aligned} t \log A(q) &\geq \frac{N}{2} \log q - (2 \log 2)N - \frac{c}{2} q(\log q)^2 + o(N) \\ &= \frac{N}{2} \log N - N \log \log N - C_* N + o(N). \end{aligned}$$

Here $q \log q = o(N)$ absorbs the mixed term and the fixed rounding allowances. The positive margin εN absorbs the final $o(N)$ term and makes the proposed range strictly smaller than $A(q)^t$. Apply Proposition III.78.5 and pad by an identity block as before. $\square$

The choice of c minimizes this particular asymptotic parameter bound: using $q \sim N/(kL^2)$ instead gives linear loss $2 \log 2 + \frac{1}{2} \log k + c/(2k)$, minimized at $k = c$. This is not an optimality assertion for the determinant range itself.

III.79 Asymptotically optimal support for cyclic torsion

Source 34, delivered Section 7.

Recall the cyclic support parameter of Definition III.74.3. The support-compression lemma (Lemma III.75.5) transfers Theorem III.78.1 to a Boolean configuration, including composite cyclic orders. No assertion that all nonzero residues are units is needed.

Theorem III.79.1 (Leading asymptotic and an explicit eventual upper bound). *As $m \rightarrow \infty$ through the integers,*

$$h_{\text{cyc}}(m) \sim \frac{2 \log m}{\log \log m}. \quad (\text{III.79.1})$$

More precisely, put

$$L = \log m, \quad \lambda = \log L, \quad \mu = \log \lambda.$$

For every sufficiently large m ,

$$h_{\text{cyc}}(m) \leq \frac{2L}{\lambda - 3\mu + \log 2 - 8} + 2. \quad (\text{III.79.2})$$

For primes $p \rightarrow \infty$, the corresponding first-support parameter obeys

$$h(p) \sim h_{\text{cyc}}(p) \sim \frac{2 \log p}{\log \log p}, \quad D_{\text{div}}(p) \sim \frac{2 \log p}{\log \log p}.$$

Proof. Set $D = \lambda - 3\mu + \log 2 - 8$ and $n_0 = 2L/D$. For sufficiently large m , one has $2 \leq D \leq \lambda$, so

$$\log n_0 = \lambda + \log 2 - \log D \geq \lambda - \mu + \log 2, \quad \log \log n_0 \leq \mu.$$

It follows that

$$\frac{n_0}{2} (\log n_0 - 2 \log \log n_0 - 8) \geq \frac{n_0 D}{2} = L.$$

The function $x \mapsto \frac{x}{2} \log x - x \log \log x - 4x$ is increasing for all sufficiently large x . Thus $N = \lceil n_0 \rceil$ lies in the range of Theorem III.78.1 eventually, and that theorem supplies a binary matrix of order N with cyclic Smith factor m . Lemma III.75.5 gives $h_{\text{cyc}}(m) \leq N + 1 \leq n_0 + 2$, proving (III.79.2).

For the matching lower bound, Lemma III.76.1 gives

$$m \leq \frac{s^{s/2}}{2^{s-1}} \quad (\text{III.79.3})$$

for every admissible cyclic support of size s .

Taking logarithms in (III.79.3) gives $\log m \leq \frac{s}{2} \log s - (s-1) \log 2$. Together with the proved upper bound, this implies (III.79.1). For a prime p , one has $h(p) \leq h_{\text{cyc}}(p)$, and the determinant characterization $h(p) = D_{\text{div}}(p) + 1$ gives the same Hadamard lower bound. The remaining asymptotic statements follow. $\square$

Remark III.79.2 (The second-order gap remains). The theorem determines the leading constant, not a full asymptotic expansion of either minimum. For $m > 2$, the Hadamard comparison can be inverted exactly as

$$h_{\text{cyc}}(m) \geq \frac{2(L - \log 2)}{W((L - \log 2)/2)},$$

where W is the nonnegative real solution of $W(z)e^{W(z)} = z$. The lower comparison quantity expands as

$$\frac{2L}{\lambda} \left(1 + \frac{\mu + \log 2}{\lambda} + O\left(\frac{\mu^2}{\lambda^2}\right) \right),$$

whereas the upper comparison in (III.79.2) expands as

$$\frac{2L}{\lambda} \left(1 + \frac{3\mu - \log 2 + 8}{\lambda} + O\left(\frac{\mu^2}{\lambda^2}\right) \right).$$

The coefficients of μ/λ in these two comparison quantities are 1 and 3. Closing that gap is a further problem; neither coefficient is asserted to be the second-order coefficient of the actual minimum.

III.80 Universal positivity and its exact asymptotic cost

Source 34, delivered Section 8.

For $m \geq 2$, define $h_{\text{pos}}(m)$ to be the smallest number of vertices of an affinely independent Boolean configuration S such that $A_S \cong \mathbb{Z}/m\mathbb{Z}$, a faithful generator-coordinate vector $c = (c_1, \dots, c_s)$ has full support, and

$$T_S(f) \geq 0 \quad \text{for every finite abelian group } G \text{ and every real centered function } f : G \rightarrow \mathbb{R}.$$

No pairing of the coordinates is assumed in this definition. The following characterization shows that universal positivity forces precisely the pairing used in the constructive detector.

Theorem III.80.1 (Universal positivity is equivalent to inverse pairing). *Let S be an affinely independent Boolean configuration with $A_S \cong \mathbb{Z}/m\mathbb{Z}$ and full-support faithful generator coordinates $c_1, \dots, c_s \in \mathbb{Z}/m\mathbb{Z}$. The following are equivalent:*

1. $T_S(f) \geq 0$ for every finite abelian group and every real centered f .

2. The same statement holds just for $G = \mathbb{Z}/m\mathbb{Z}$.

3. The multiset $\{c_1, \dots, c_s\}$ can be partitioned into inverse pairs $\{a, -a\}$.

In the third condition, a nonzero self-inverse element, when present, must have even multiplicity. In particular, $s = 2t$.

Proof. The first condition implies the second. If the coordinates can be reordered as $(a_1, \dots, a_t, -a_1, \dots, -a_t)$, the Fourier formula of Proposition III.74.2 gives

$$T_S(f) = \sum_{\substack{\chi \in \widehat{G} \\ \chi^m = 1}} \prod_{j=1}^t |\widehat{f}(\chi^{a_j})|^2 \geq 0, \quad (\text{III.80.1})$$

proving the first condition.

For necessity, identify the dual of $\mathbb{Z}/m\mathbb{Z}$ with $\mathbb{Z}/m\mathbb{Z}$. Choose independent unit complex phases z_r for the non-self-inverse pairs, with $z_{-r} = \overline{z_r}$. If m is even, choose the additional phase $z_{m/2}$ independently from $\{1, -1\}$. The phase space is a compact torus, times a two-element group when necessary, with its probability Haar measure. Let $o(r)$ be the additive order of r . For a parameter $R > 0$, prescribe Fourier coefficients

$$\widehat{f}_R(0) = 0, \quad \widehat{f}_R(r) = R^{o(r)} z_r \quad (r \neq 0).$$

Fourier inversion gives a real centered function. Its moment is

$$T_S(f_R) = \sum_{u \in \mathbb{Z}/m\mathbb{Z}} \prod_{j=1}^s \widehat{f}_R(uc_j). \quad (\text{III.80.2})$$

Put $D = \sum_j o(c_j)$. If u is a unit modulo m , its summand has degree D in R . If u is not a unit, the summand is either zero or has strictly smaller degree. Indeed, multiplication cannot increase the order of any element. Choose a prime dividing $\gcd(u, m)$. Faithfulness means $\gcd(m, c_1, \dots, c_s) = 1$, so some c_j has full order at this prime; multiplication by u strictly decreases that order. Consequently,

$$\lim_{R \rightarrow \infty} R^{-D} T_S(f_R) = H(z) := \sum_{u \in (\mathbb{Z}/m\mathbb{Z})^\times} \prod_{j=1}^s z_{uc_j}. \quad (\text{III.80.3})$$

Suppose the coordinate multiset cannot be partitioned into inverse pairs. Then $\prod_j z_{c_j}$ is a nontrivial character of the phase group: either an inverse pair has unequal multiplicities, or the self-inverse element has odd multiplicity. Multiplication by a unit permutes inverse pairs and preserves this failure. Every summand of H is therefore a nontrivial character, and $\int H = 0$. On the other hand, $H(1) = \varphi(m) > 0$. The function H is real, by pairing u with $-u$; it is also continuous. These facts force $H(z) < 0$ for some phase choice. For that choice, (III.80.3) gives $T_S(f_R) < 0$ for all sufficiently large R , contradicting the second condition. This proves necessity for every m , including composite and even orders. $\square$

Lemma III.80.2 (Pairing any cyclic presentation). *If a full-support cyclic configuration has s vertices in dimension d , there is a universally positive configuration with the same cyclic quotient, $2s$ vertices, and dimension $d + s$. Consequently,*

$$h_{\text{cyc}}(m) \leq h_{\text{pos}}(m) \leq 2h_{\text{cyc}}(m). \quad (\text{III.80.4})$$

Proof. Let M be the original augmented Boolean matrix. Use generators $x_1, \dots, x_s, y_1, \dots, y_s$, retain the original rows on the x coordinates only, and add the binary relations $x_j + y_j = 0$. Eliminating $y_j = -x_j$ by integer unit pivots preserves the cyclic quotient and gives full-support coordinates $(c, -c)$. Replace the first pair row by the sum of all pair rows. This unimodular row operation produces an all-ones row, so the remaining $d + s$ binary rows define a Boolean configuration. Its finite quotient ensures rational column rank $2s$, hence distinctness and affine independence of the vertices. Formula (III.80.1) proves positivity. $\square$

Theorem III.80.3 (The sharp leading constant for positive detectors). *Every universally positive cyclic configuration of order m has an even number $s = 2t$ of vertices and satisfies*

$$m \leq t^{t/2}. \quad (\text{III.80.5})$$

As $m \rightarrow \infty$ through all positive integers,

$$h_{\text{pos}}(m) \sim \frac{4 \log m}{\log \log m}, \quad \frac{h_{\text{pos}}(m)}{h_{\text{cyc}}(m)} \rightarrow 2. \quad (\text{III.80.6})$$

Thus universal positivity has an asymptotic factor-two cost in the number of vertices. The explicit lower comparison is

$$h_{\text{pos}}(m) \geq \frac{4 \log m}{W(2 \log m)},$$

with W as in Remark III.79.2.

Proof. By Theorem III.80.1, order the generator coordinates as $(a, -a)$, with $a \in (\mathbb{Z}/m\mathbb{Z})^t$. Let $L = \text{row}_{\mathbb{Z}}(M) \subseteq \mathbb{Z}^{2t}$. Exactness of the quotient and faithfulness give

$$L = \ker((x, y) \mapsto a \cdot (x - y) \pmod{m}).$$

In particular, L contains the pair rows $e_j + e_{t+j}$. Project by $\pi(x, y) = x - y$. The quotient $\mathbb{Z}^t / \pi(L)$ is still $\mathbb{Z}/m\mathbb{Z}$, and the projections of the original binary rows are ternary rows, with entries in $\{-1, 0, 1\}$. They span a rank- t lattice. Choose t independent projected rows and place them in a square matrix B . Its nonzero determinant is a multiple of m , because its row lattice is a sublattice of $\pi(L)$, whose index is m . Every row has Euclidean norm at most $\sqrt{t}$. Hadamard's inequality proves $m \leq |\det B| \leq t^{t/2}$.

Inverting this inequality gives $t \geq (2 - o(1)) \log m / \log \log m$, hence the required lower bound with constant four. The cyclic construction of Theorem III.79.1, together with Lemma III.75.5, supplies $h_{\text{cyc}}(m) \sim 2 \log m / \log \log m$. Lemma III.80.2 gives the matching upper bound and then the ratio limit in (III.80.6). $\square$

Corollary III.80.4 (The first positive support sizes). *One has*

m	2	3	4	5	6	7	8
$h_{\text{pos}}(m)$	4	6	6	8	8	8	8.

Proof. The largest absolute determinants of ternary matrices of orders 1, 2, 3 are respectively 1, 2, 4. For order three, the maximum of the absolute determinant over the cube $[-1, 1]^9$ is attained at a sign matrix, by optimizing its entries one at a time. Such a determinant is divisible by four, while Hadamard bounds its absolute value by $3\sqrt{3} < 8$; hence the maximum is four. The smaller orders are immediate. Applying the ternary reduction in the proof of Theorem III.80.3 gives the displayed lower bounds. The elementary construction in Theorem III.77.1 has $2\lceil \log_2 m \rceil + 2$ vertices, which attains each bound. $\square$

III.81 The exact quartic term and its interface with Gowers's lemma

Source 34, delivered Section 9.

To connect the algebraic configurations and the norm comparison to the original paper, we recall the exact quartic expansion and give a short proof. This formula was already proved in the repository [155]; its role here is to make the subsequent improvement of the coefficient self-contained.

For a real function $F : G \rightarrow \mathbb{R}$, write

$$Q_d(F) = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{v \in \{0,1\}^d} F(x + v \cdot h).$$

This is $\|F\|_{U^d}^{2d}$. For an indicator function on a group of order N , the unnormalized number of parameterized cubes is $N^{d+1}Q_d(F)$. Degenerate choices of steps are included, as in Gowers's cube count.

Lemma III.81.1 (Small Boolean supports on odd-order groups). *Let G have odd order and let $f : G \rightarrow \mathbb{R}$ be centered. For a Boolean support S , the moment $T_S(f)$ is zero when $1 \leq |S| \leq 3$. At $|S| = 4$, it is zero unless S is a parallelogram of four distinct vertices over the integers. In the parallelogram case it equals $S_4(f) := \sum_{\chi} |\hat{f}(\chi)|^4$.*

Proof. Every two distinct Boolean vertices have a coordinate separating them, so their augmented matrix has a unit minor. Three distinct Boolean vertices are affinely independent: a straight line can meet the vertices of a cube in at most two points. A full minor including the all-ones row reduces to a nonsingular binary 2×2 determinant, necessarily of absolute value one. Thus the row quotient is trivial for supports of size at most three. Proposition III.74.2 and centering give vanishing.

For four affinely independent vertices, a nonsingular full minor reduces to a binary 3×3 determinant of absolute value at most two, by Lemma III.76.1. The row quotient has order one or two. It admits only the trivial homomorphism into the character group of an odd-order group, so the moment again vanishes.

If four distinct Boolean vertices are affinely dependent, their augmented rank is three. Any three of them give a unit minor, so the row quotient is torsion-free of rank one. Their primitive affine relation has two positive and two negative coefficients: one coefficient on either side would express a cube vertex as a strict convex combination of other cube vertices, which is impossible. Write the positive coefficients as a, b and the negative ones as $-c, -e$, so $a + b = c + e$.

In a coordinate where the four bits are not all equal, neither side can use both positive coefficients against only one negative coefficient: the remaining coefficient would then be zero. Hence the nonconstant coordinate pairs one coefficient on each side, with equal values. If the two positive coefficients were unequal, all such coordinate matchings would be forced, making a vertex on one side identical to a vertex on the other side. Therefore all four coefficients are equal, and primitivity gives the relation $(1, 1, -1, -1)$ after ordering. This is exactly an integer parallelogram. The quotient is $\mathbb{Z}$ with these generator coordinates. Its Fourier moment is $\sum_{\chi} \hat{f}(\chi)^2 \hat{f}(\chi^{-1})^2 = S_4(f)$. $\square$

Proposition III.81.2 (Exact quartic expansion, recalled with proof). *Let $d \geq 2$, let G have odd order, and let $F = \delta + f$ be real with $\delta \geq 0$ and $\mathbb{E}f = 0$. Put $u = \|f\|_{U^d}$ and*

$$P_d = \frac{6^d - 2 \cdot 4^d + 2^d}{8}.$$

Then

$$Q_d(\delta + f) = \delta^{2^d} + P_d \delta^{2^d-4} \|f\|_{U^2}^4 + R_d, \quad (\text{III.81.1})$$

where

$$|R_d| \leq \sum_{j=5}^{2^d} \binom{2^d}{j} \delta^{2^d-j} u^j. \quad (\text{III.81.2})$$

An empty sum is zero, and a zeroth power of δ is one.

Proof. Expand the product by its selected support. Lemma III.81.1 handles all supports of size at most four. To count the four-vertex parallelograms, first count ordered solutions of $v_1 + v_2 = v_3 + v_4$ in the Boolean cube over the integers. Each coordinate has six admissible bit patterns, giving 6^d solutions. A repeated vertex forces one of the two pairwise identifications $(v_1, v_2) = (v_3, v_4)$ or $(v_1, v_2) = (v_4, v_3)$. Each contributes 4^d , and their intersection contributes 2^d . The number with four distinct vertices is consequently $6^d - 2 \cdot 4^d + 2^d$. Each unordered parallelogram occurs in eight orderings, proving the formula for P_d .

For a support S of size $j \geq 5$, place f at its vertices and the constant one at all other vertices. Multilinear Gowers–Cauchy–Schwarz gives $|T_S(f)| \leq u^j$. Sum over these supports with their factors δ^{2^d-j} . $\square$

At $d = 4$, $P_4 = 100$. The sharp norm question is therefore exactly the question of the best universal leading constant in this perturbative cube bound when the error is measured by U^4 . The next section improves that constant. The earlier structural theorems answer a different question: at what support sizes and cube dimensions new prime Smith torsion can enter higher terms. For example, order seven can first occur at support degree seven in dimension six, while orders eleven and thirteen require support degree eight and dimension seven.

Remark III.81.3 (Compatibility with the original normalization). If $A \subseteq \mathbb{Z}/N\mathbb{Z}$ has density δ and $\|\mathbf{1}_A - \delta\|_{U^d}^{2^d} \leq \alpha$, insert $u \leq \alpha^{1/2^d}$ in (III.81.1)–(III.81.2) and multiply by N^{d+1} . This uses the same uniformity normalization as Gowers’s Lemma 3.10 after converting its sums to averages. The odd-order hypothesis is essential for the quartic formula used here; the earlier repository expansion has additional order-two terms on even-order groups.

III.82 Source 38’s Part I: exact quotient reduction in exponent five [write]

Added in the seventh write, 6 October 2026.

The next four sections are source 38’s Sections 2–5, its delivered Part I. *Logically they continue source 21’s chapter* (Section III.49) and source 23’s exponent-five theorem; they are printed here because no number printed earlier may move. Source 38’s introduction, with its main theorems, is Section F.43.

What is proved. On every nontrivial group of exponent five the maximum of the three-cube count of $\delta + f$ at fixed centered $\|f\|_{U^3} = u$ equals its value on $\mathbb{Z}/5\mathbb{Z}$ whenever $u \leq 10^{-5}\delta$, and every maximizer factors through $\mathbb{Z}/5\mathbb{Z}$ (Theorem III.84.1, with quantitative off-quotient control, Corollary III.84.2); so source 21’s u^8 coefficient 20/9 is universal, and the profile continues with u^{10} and u^{12} coefficients $869/(216 \cdot 2^{3/4})$ and $65759/(5832 \cdot 2^{3/2})$ (Theorem III.85.1); for every fixed odd exponent m the reduction is to a cyclic quotient when $u/\delta \leq 10^{-8}m^{-8}$ (Theorem III.86.1). This

answers three of source 21's questions (item III.27); source 38 credits sources 21 and 23 for $2^{3/4}/3$ and $20/9$.

Relation to the formal statements (checked at HEAD 89c1cbc38). `lemma_3_10` is exact (companion `lemma_3_10_holds`, `Proofs03CubeUpper.lean`, line 82); its scope is all moduli, and a theorem on $\mathbb{F}_5^n$ does not replace it, as source 38 says. Nothing in this chapter is formalized.

III.83 Fourier identities and the retained energy defect

Source 38, delivered Section 2.

*Delivered part heading of source 38: **Exact characteristic-five cube extremizers***

This section records the background identities in the form needed by the new projection argument. The fourth-order expansion and its leading norm gap were established in preceding project reports [169, 170]; they are reproved here so the main result has no dependence on an unquoted computation.

For $f : G \rightarrow \mathbb{C}$, use

$$a_r = \widehat{f}(r) = \mathbb{E}_x f(x) \overline{r(x)}, \quad f(x) = \sum_{r \in \widehat{G}} a_r r(x).$$

For real centered f , one has $a_{-r} = \overline{a_r}$ and $a_0 = 0$. Set

$$\lambda_r = |a_r|^2, \quad S = \sum_r |a_r|^4, \quad M = \sum_r |a_r|^8, \quad \mathcal{E}(\lambda) = \sum_{r+s=t+w} \lambda_r \lambda_s \lambda_t \lambda_w.$$

The Gowers–Cauchy–Schwarz inequality bounds a cube with eight possibly different functions by the product of their U^3 norms. It follows by applying Cauchy–Schwarz successively in the three directions and expanding each resulting square [1, Lemma 3.8]. Its homogeneous form requires no L^∞ hypothesis. Expanding a sum in the cube form then gives the triangle inequality. In particular, translation averages are contractive for U^3 .

Lemma III.83.1 (Fourier squares and their axes). *Put*

$$T_f(s, t) = \sum_r a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}.$$

Then

$$\|f\|_{U^3}^8 = \sum_{s,t} |T_f(s, t)|^2.$$

For real f , T_f is real, symmetric in its two arguments, and unchanged by reversing either argument. Its two coordinate axes, with their common origin counted once, contribute exactly

$$2\mathcal{E}(\lambda) - S^2.$$

Proof. Expand $|T_f(s, t)|^2$ and sum over s, t . Fourier expansion of the physical cube imposes the base and three direction equations on its eight frequencies. Their solutions are parametrized by a parity-adjusted affine frequency cube; grouping its two opposite faces gives precisely the displayed sum of squares. This can also be checked directly by using the two base frequencies and the two increments in the expanded square as its four free variables. No division by a group element is used.

For real f , substitution $r \mapsto -r - s - t$ pairs every summand in T_f with its conjugate. Interchange of s, t and translation of r give the other symmetries. Finally

$$T_f(0, t) = \sum_r \lambda_r \lambda_{r+t}, \quad T_f(0, 0) = S.$$

The squared sum on either axis is $\mathcal{E}(\lambda)$; subtract one copy of S^2 at their intersection. $\square$

Lemma III.83.2 (Odd-order quartic gap). *For real centered f on a finite abelian group of odd order,*

$$\|f\|_{U^3}^8 \geq 5S^2 - 6M \geq 2S^2.$$

If $\{\xi, -\xi\}$ is a largest conjugate Fourier pair and $D_{\text{pair}} = \sum_{r \notin \{\xi, -\xi\}} |a_r|^4$, then

$$\|f\|_{U^3}^8 \geq 2S^2 + 3SD_{\text{pair}}.$$

A pure conjugate pair whose character has order five attains $\|f\|_{U^3}^8 = 2S^2$.

Proof. Write the energy as a sum over zero-sum quadruples and retain the three families obtained by pairing the four positions into opposite pairs. Each family has weight S^2 , and every pairwise intersection has weight M . The triple intersection requires $2r = 0$; it has zero weight because the order is odd and $a_0 = 0$. Thus $\mathcal{E}(\lambda) \geq 3S^2 - 3M$. Retaining the axes in Lemma III.83.1 proves the first inequality.

If x_j are the total fourth-power masses of the conjugate pairs, then $S = \sum_j x_j$ and $M = \frac{1}{2} \sum_j x_j^2 \leq S^2/2$. For a largest pair with coefficient modulus ρ , $M \leq \rho^4 S = (S - D_{\text{pair}})S/2$, proving the stronger bound. For a pure pair of order five, the only nonzero Fourier-square slots are $(0, 0)$ and the four axis slots with increment $\pm 2\xi$. They contribute $4\rho^8 + 4\rho^8 = 8\rho^8 = 2S^2$. $\square$

Lemma III.83.3 (Complete centered expansion through degree seven). *Assume G has odd order and f is real and centered. Then*

$$\mathcal{C}_3(\delta + f) = \delta^8 + 12\delta^4 S + 8\delta^3 B_5(f) + \delta^2 C_6(f) + \delta C_7(f) + \|f\|_{U^3}^8,$$

where

$$B_5(f) = \sum_r a_{2r} a_{-r}^3 a_r, \quad C_6(f) = 12H_f + 12J_f + 4K_f,$$

with

$$\begin{aligned} H_f &= \sum_{r+s+t=0} \lambda_r \lambda_s \lambda_t, \\ J_f &= \sum_{r,s} \lambda_r a_s^2 a_{r-s} \overline{a_{r+s}}, \\ K_f &= \sum_{r+s+t=0} a_r^2 a_s^2 a_t^2. \end{aligned}$$

These statistics are real. If

$$L_f(s, t) = 2 \operatorname{Re}(a_s a_t \overline{a_{s+t}}) + 2 \operatorname{Re}(a_s \overline{a_t} \overline{a_{s-t}}),$$

then $C_7(f) = 2 \operatorname{Re}\langle T_f, L_f \rangle$, with counting measure in this inner product. In particular

$$|B_5(f)| \leq \|f\|_{U^3}^5, \quad |C_6(f)| \leq 28\|f\|_{U^3}^6, \quad |C_7(f)| \leq 8\|f\|_{U^3}^7.$$

Proof. Expand the eight-vertex product by the support of its centered factors. A support of size one, two, or three consists of independent cube forms whose coefficient equations have unit pivots, so centering kills it. For four vertices, the twelve parallelogram supports contribute S each; all other supports are independent. For five vertices, forty-eight supports force a zero Fourier coefficient. The other eight are cube symmetries of $\{000, 100, 010, 001, 111\}$, whose relation has coefficients $(2, -1, -1, -1, 1)$; their contribution is B_5 .

For clarity, these assertions follow by solving the four equations

$$\sum_{\omega} r_{\omega} = 0, \quad \sum_{\omega} \omega_j r_{\omega} = 0 \quad (1 \leq j \leq 3),$$

with frequencies outside the chosen support set equal to zero. All the relation systems here can be solved using only unit pivots and division by two. The latter is available in every group of odd order; in particular, these identities do not require exponent five. For six vertices classify the two omitted vertices by their Hamming distance:

omitted representative	number	contribution
000, 001	12	H_f
000, 011	12	J_f
000, 111	4	K_f .

Solving the same equations gives the displayed formulas. Their reality also follows from the real spatial cube products.

Replace a_0 by a real variable and differentiate the Fourier-square identity at zero. Differentiating its four factors gives exactly the four cubic summands in L_f ; differentiating the squared norm gives $2 \operatorname{Re}\langle T_f, L_f \rangle$. Repeated indices cause no extra terms because the remaining zero coefficient then vanishes. Finally each support is bounded by cube Cauchy–Schwarz, with constants at its complementary vertices. There are 28 six-vertex and 8 seven-vertex supports. $\square$

The new argument will use these exact formulas to compare a function with its projection. Bounding C_7 only by the product of norms would lose a square root of the projection deficit. The exact derivative formula avoids that loss.

III.84 Exact reduction to a five-point quotient

Source 38, delivered Section 3.

Write $N(f) = \|f\|_{U^3}^8 = C_3(f)$ for real functions. All Fourier transforms are normalized, while frequency sums are unnormalized. The following proves more than the formerly open universal eighth-order coefficient: at sufficiently small centered norm, the entire extremal problem reduces exactly to $\mathbb{Z}/5\mathbb{Z}$.

Theorem III.84.1 (Exact dimension reduction; explicit sufficient range). *Let $G \neq 0$ be a finite abelian group with $5G = 0$. For $\delta > 0$ and $0 < u \leq 10^{-5}\delta$, the maximum of $C_3(\delta + f)$ over real centered functions $f : G \rightarrow \mathbb{R}$ with $\|f\|_{U^3} = u$ is identical to the corresponding maximum on $\mathbb{Z}/5\mathbb{Z}$. Every maximizing f factors through a nonzero homomorphism $G \rightarrow \mathbb{Z}/5\mathbb{Z}$. The same conclusion for the maximum holds with norm at most u ; the unrestricted profile is strictly increasing throughout this range. For $0 < \delta < 1$, weights satisfying $0 \leq \delta + f \leq 1$ have the same maximum if, additionally, $4u \leq \min\{\delta, 1 - \delta\}$.*

[write] **6 October 2026; sources 34–39.** *Answers two of source 21's questions* (item III.27): the universal coefficient of u^8 exists in the stated range (for $u/\delta \leq 10^{-5}$ and interior weights) and is $20/9$, the value source 21 proves on $\mathbb{Z}/5\mathbb{Z}$ (its Corollary III.55.2), and it is the same on every fixed $\mathbb{F}_5^n$, with every maximizer factoring through $\mathbb{Z}/5\mathbb{Z}$. The cutoff 10^{-5} is a sufficient certificate; the reduction itself is not numerically testable at the scales the intake could afford (a 24-parameter probe on $(\mathbb{Z}/5\mathbb{Z})^2$ was stopped unfinished; no result is claimed from it).

The threshold 10^{-5} is only a convenient certificate and is not asserted sharp. We prove the norm-equality, unrestricted-real assertion first; norm-ball monotonicity and bounded Fourier support then give the last two statements.

Proof. Normalize $f = uF$, $\|F\|_{U^3} = 1$, and $t = u/\delta$. Thus the objective, after dividing by δ^8 , is $C_3(1 + tF)$. Let

$$a_r = \widehat{F}(r), \quad \lambda_r = |a_r|^2, \quad S = \sum_r |a_r|^4, \quad S_0 = 2^{-1/2}.$$

The exact centered expansion is

$$C_3(1 + tF) = 1 + 12St^4 + 8B_5(F)t^5 + C_6(F)t^6 + C_7(F)t^7 + t^8, \quad B_5(F) = \sum_r a_{2r}a_{-r}^3a_r.$$

The standard cube Cauchy–Schwarz inequalities give $|B_5(F)| \leq 1$, $|C_6(F)| \leq 28$, and $|C_7(F)| \leq 8$. The real centered norm gap gives

$$1 \geq 5S^2 - 6 \sum_r |a_r|^8 \geq 2S^2.$$

III.84.1 Localization requiring only the leading extremal term

A normalized pure Fourier pair gives exactly $1 + 6\sqrt{2}t^4 + t^8$. We may therefore assume the candidate F has at least this value. Set $\eta = S_0 - S$. For $t \leq 1$, the displayed expansion implies

$$0 \leq \eta \leq \frac{2}{3}t + \frac{7}{3}t^2 + \frac{2}{3}t^3 \leq 4t.$$

Choose a largest conjugate pair $\{\xi, -\xi\}$, put $a = |a_\xi|$, and let $D_{\text{pair}} = \sum_{r \notin \{\xi, -\xi\}} |a_r|^4$. Since $\sum_r |a_r|^8 \leq a^4 S = (S - D_{\text{pair}})S/2$,

$$1 \geq 2S^2 + 3SD_{\text{pair}}.$$

When $S \geq S_0/2$, this yields $D_{\text{pair}} \leq 2\eta \leq 8t$. Let $L = \langle \xi \rangle$ and let g be the Fourier projection of F to L , equivalently the subgroup average over $\ker \xi$. Write $h = F - g$, $b = |a_{2\xi}|$, and

$$S_g = \sum_{r \in L} |a_r|^4, \quad D = \sum_{r \notin L} |a_r|^4, \quad v = \|g\|_{U^3}, \quad \Delta = 1 - v^8.$$

Then

$$S_g \geq S_0 - 12t, \quad b \leq (4t)^{1/4}, \quad a \leq 2^{-3/8}.$$

Subgroup averaging is contractive for the Gowers norm, so $\Delta \geq 0$.

III.84.2 Coercivity of the norm loss outside the principal line

Set

$$T_F(s, t) = \sum_r a_r \overline{a_{r+s} a_{r+t}} a_{r+s+t}, \quad N(F) = \sum_{s, t} |T_F(s, t)|^2.$$

For $s, t \in L$, the base frequency r remains in a single coset of L throughout the parallelogram, and hence

$$T_F(s, t) = T_g(s, t) + T_h(s, t), \quad |T_h(s, t)| \leq D.$$

Let

$$R = \sum_{\substack{s, t \in L \\ s \neq 0, t \neq 0}} |T_g(s, t)|.$$

The elementary five-point slot enumeration gives

$$R \leq 8a^3b + 8a^2b^2 + 8ab^3.$$

Indeed the nonaxis slots, up to independent sign changes and interchange, are (ξ, ξ) with multiplicity four and modulus at most $2ab^3$, $(2\xi, 2\xi)$ with multiplicity four and modulus at most $2a^3b$, and $(\xi, 2\xi)$ with multiplicity eight and modulus a^2b^2 .

Let $\mathcal{E}(\lambda) = \sum_{r+s=t+w} \lambda_r \lambda_s \lambda_t \lambda_w$. The axes in the T sum contribute $2\mathcal{E}(\lambda) - S^2$. Write $\lambda_g = \lambda \mathbf{1}_L$ and $\lambda_h = \lambda \mathbf{1}_{L^c}$. In addition to all entirely inside and entirely outside energy tuples, retain the mixed tuples in the three families

$$r = t, s = w; \quad r = w, s = t; \quad s = -r, w = -t.$$

Each family has mixed weight $2S_g D$. Their pairwise intersections contain no mixed tuple, because L and its complement are stable under negation. All terms are nonnegative. Consequently

$$\mathcal{E}(\lambda) \geq \mathcal{E}(\lambda_g) + \mathcal{E}(\lambda_h) + 6S_g D.$$

The usual three-family argument on the even sequence λ_h gives $\mathcal{E}(\lambda_h) \geq 3D^2 - 3 \sum \lambda_h^4 \geq \frac{3}{2}D^2$; the last inequality uses conjugate pairing and odd group order. Subtracting $S^2 = (S_g + D)^2$ gives the axes estimate

$$2\mathcal{E}(\lambda) - S^2 \geq 2\mathcal{E}(\lambda_g) - S_g^2 + 10S_g D + 2D^2.$$

The nonaxis slots in L^2 lose at most $2RD$ relative to those of g , by $|T_g + T_h|^2 \geq |T_g|^2 - 2|T_g|D$; all other slots are nonnegative. We have therefore proved the exact finite inequality

$$\boxed{\Delta \geq (10S_g - 2R)D + 2D^2.} \quad (\text{III.84.1})$$

For $t \leq 10^{-5}$, we have $S_g \geq 2/3$ and the rational bounds $a < 193/250$ and $b < 2/25$. Indeed $8(193/250)^8 > 1$ and $(2/25)^4 > 4 \cdot 10^{-5}$. Direct rational substitution gives

$$8(193/250)^3(2/25) + 8(193/250)^2(2/25)^2 + 8(193/250)(2/25)^3 < 1/3.$$

Thus $R < 1/3$, $10S_g - 2R \geq 6$, and

$$D \leq \Delta/6, \quad v^8 \geq 2S_g^2 \geq 8/9, \quad 0 \leq \Delta \leq 1/9.$$

III.84.3 Quantitative subgroup projection

We use the general estimate

$$\|h\|_{U^3}^8 \leq 2^8 \Delta. \quad (\text{III.84.2})$$

For completeness, Gowers–Cauchy–Schwarz and the expansion of $\|f + g\|_{U^3}^8 + \|f - g\|_{U^3}^8$ give Clarkson’s inequality

$$\left\| \frac{f+g}{2} \right\|_{U^3}^8 + \left\| \frac{f-g}{2} \right\|_{U^3}^8 \leq \frac{\|f\|_{U^3}^8 + \|g\|_{U^3}^8}{2}.$$

To see the constant directly, the odd mixed terms cancel, each even mixed term is bounded by the product of the corresponding norms, and weighted arithmetic–geometric mean bounds the resulting scalar sum by $2^7(\|f\|_{U^3}^8 + \|g\|_{U^3}^8)$. Dividing by 2^8 gives the displayed inequality, in agreement with the general norm-geometric perspective of [31]. Apply it to F and each translate $T_y F$, $y \in \ker \xi$. Projection of their midpoint is g , so contractivity bounds the first term below by v^8 . This gives $\|F - T_y F\|_{U^3} \leq 2\Delta^{1/8}$; average over y and use the triangle inequality to obtain (III.84.2).

III.84.4 Sixth-degree differences are linear in the norm loss

Put

$$H_F = \sum_{r+s+t=0} \lambda_r \lambda_s \lambda_t.$$

The exact sixth-degree decomposition is

$$C_6(F) = 12H_F + 12J_F + 4K_F, \quad J_F = \sum_{r,s} \lambda_r a_s^2 a_{r-s} \overline{a_{r+s}}, \quad K_F = \sum_{r+s+t=0} a_r^2 a_s^2 a_t^2.$$

In the J sum, the entirely inside part is exactly the restriction $(r, s) \in L^2$. Cauchy–Schwarz on the complementary domain gives

$$|J_F - J_g| \leq H_F - H_g.$$

Indeed its two squared bounds are the sums of $\lambda_r \lambda_s \lambda_{r-s}$ and $\lambda_r \lambda_s \lambda_{r+s}$ over $(r, s) \notin L^2$; both equal $H_F - H_g$, using evenness and $s \mapsto -s$. Also $|K_F - K_g| \leq H_F - H_g$. Hence

$$|C_6(F) - C_6(g)| \leq 28(H_F - H_g).$$

A zero-sum triple cannot have exactly one frequency outside L . Writing $A_g = \sum_{r \in L} |a_r|^2$, note that g has at most four nonzero Fourier coefficients, so $A_g^2 \leq 4S_g \leq 4$ and $A_g \leq 2$. We obtain

$$H_F - H_g \leq 3A_g D + H_h.$$

The first term comes from the three choices of an inside frequency; for each such frequency, the remaining convolution is at most D by Cauchy–Schwarz. For the entirely outside term,

$$H_h \leq \sqrt{D\mathcal{E}(\lambda_h)} \leq \sqrt{D(128\Delta + D^2/2)},$$

because the axes inequality gives $\mathcal{E}(\lambda_h) \leq (\|h\|_{U^3}^8 + D^2)/2$ and (III.84.2) applies. Using $D \leq \Delta/6$ and $\Delta \leq 1$ therefore yields

$$H_F - H_g \leq 6\Delta, \quad |C_6(F) - C_6(g)| \leq 168\Delta. \quad (\text{III.84.3})$$

III.84.5 Seventh-degree differences are also linear in the norm loss

Define

$$L_F(s, t) = 2 \operatorname{Re}(a_s a_t \overline{a_{s+t}}) + 2 \operatorname{Re}(a_s \overline{a_t} \overline{a_{s-t}}).$$

Differentiating the sum-of-squares identity with respect to the zero Fourier coefficient gives $C_7(F) = 2 \operatorname{Re}\langle T_F, L_F \rangle$. For $s, t \in L$ one has $L_F(s, t) = L_g(s, t)$ exactly, because all its indices then belong to L . Thus the contribution to the difference from L^2 has modulus at most

$$2D \sum_{L^2} |L_g| \leq 200D \leq \frac{100}{3} \Delta.$$

Here $|a_r| \leq 1$, so each of the 25 values of L_g has modulus at most four.

For the complement of L^2 , the same expansion of the norm gives

$$\sum_{(s,t) \notin L^2} |T_F(s, t)|^2 \leq \Delta + 2RD \leq \frac{4}{3} \Delta.$$

The axes cross terms within L^2 are nonnegative, and the remaining cross terms lose at most $2RD$, which proves this inequality. Each of the four cubic summands of L_F has squared norm on the complement of L^2 equal to $H_F - H_g$. Consequently

$$\sum_{(s,t) \notin L^2} |L_F(s, t)|^2 \leq 16(H_F - H_g) \leq 96\Delta.$$

Cauchy–Schwarz bounds their contribution by $16\sqrt{2} \Delta$. Adding the two regions proves

$$|C_7(F) - C_7(g)| \leq 60\Delta. \quad (\text{III.84.4})$$

The linear estimate (III.84.4) is essential for exact localization; a generic mixed cube bound would give only $O(\sqrt{\Delta})$ and would settle the eighth-order coefficient without proving exact reduction.

III.84.6 Rescaling the projection strictly improves every off-line candidate

Doubling preserves L and its complement, so $B_5(F) - B_5(g) = B_5(h)$ exactly. Therefore

$$|B_5(F) - B_5(g)| \leq D^{5/4} \leq D \leq \Delta/6.$$

Let $g_* = g/v$; then $\|g_*\|_{U^3} = 1$. Since $0 \leq \Delta \leq 1/9 < 1/2$, for $k = 5, 6, 7$ the mean value theorem gives

$$|v^{-k} - 1| = |(1 - \Delta)^{-k/8} - 1| \leq 4\Delta.$$

Combining this with (III.84.3), (III.84.4), homogeneity, and cube Cauchy–Schwarz on g , one obtains

$$|B_5(F) - B_5(g_*)| \leq 5\Delta, \quad |C_6(F) - C_6(g_*)| \leq 280\Delta, \quad |C_7(F) - C_7(g_*)| \leq 92\Delta.$$

At fourth degree,

$$\begin{aligned} 12t^4(S - S_{g_*}) &= 12t^4[D - S_g((1 - \Delta)^{-1/2} - 1)] \\ &\leq 12t^4(D - S_g\Delta/2) \leq -2t^4\Delta. \end{aligned}$$

The eighth-degree terms cancel exactly because F and g_* have the same norm. Hence

$$\mathcal{C}_3(1 + tF) - \mathcal{C}_3(1 + tg_*) \leq t^4\Delta(-2 + 40t + 280t^2 + 92t^3) \leq -t^4\Delta \quad (0 < t \leq 10^{-5}). \quad (\text{III.84.5})$$

If F has any nonzero off-line coefficient, then $D > 0$, and (III.84.1) implies $\Delta > 0$. Thus its projected and rescaled competitor is strictly better. If the candidate was initially below the pure-pair value, the pure-pair competitor already improves it. Every maximum therefore occurs on a five-point quotient. Conversely, every function on the five-point group pulls back along any nontrivial character and preserves its mean, all Gowers norms, and its cube count. This proves the equality of maxima and the assertion about every maximizer.

For completeness, the norm-ball conclusion does not require an unspecified smaller analytic neighborhood. Let F be a normalized maximizer at norm $0 < r \leq 10^{-5}$. Localization gives $S \geq 2/3$. For $r \leq s \leq 10^{-5}$, direct differentiation of the centered polynomial gives

$$\frac{d}{ds}\mathcal{C}_3(1 + sF) \geq s^3(48S - 40s - 168s^2 - 56s^3) > 0.$$

Thus scaling a lower-norm maximizer strictly increases its objective throughout the range. The norm-zero value is strictly smaller by the pure-pair benchmark. The norm-equality maximum is strictly increasing, and the norm-ball maximum occurs on its boundary.

For interval-valued weights, every Fourier coefficient of a maximizer has modulus at most its U^3 norm u . Its support has at most four frequencies, so $\|f\|_\infty \leq 4u$. Thus the unrestricted maximizing function is feasible for the interval constraint in the stated range; the reverse inequality between maxima is immediate from inclusion. $\square$

III.84.7 Quantitative stability of quotient dependence

Corollary III.84.2 (Off-quotient control by the extremal deficit). *Assume the hypotheses of Theorem III.84.1 and that f has at least the pure-pair benchmark,*

$$\mathcal{C}_3(\delta + f) \geq \delta^8 + 6\sqrt{2}\delta^4u^4 + u^8.$$

Let $\mathcal{D} = \mathcal{M}_{\delta,G}(u) - \mathcal{C}_3(\delta + f)$. There is a nonzero character ξ , with P the average over its kernel, such that

$$\|f - Pf\|_{U^2}^4 \leq \frac{\mathcal{D}}{6\delta^4}, \quad (\text{III.84.6})$$

$$\|f - Pf\|_{U^3}^8 \leq \frac{256u^4\mathcal{D}}{\delta^4}. \quad (\text{III.84.7})$$

The constants do not depend on G .

Proof. Apply the construction in the proof with $F = f/u$. The rescaled projection is an admissible competitor, so (III.84.5) gives $\mathcal{D} \geq \delta^8 t^4 \Delta = \delta^4 u^4 \Delta$. Now use $D \leq \Delta/6$, the Fourier identity $\|f - Pf\|_{U^2}^4 = u^4 D$, and (III.84.2). $\square$

For fixed $\delta > 0$, attaining the extremal expansion with error $o(u^8)$ therefore forces an off-quotient U^2 error $o(u^2/\delta)$ and an off-quotient U^3 error $o(u^{3/2}/\delta^{1/2})$. The benchmark assumption is automatic for such a family at sufficiently small u , because the sharp u^6 coefficient is positive. The conclusion concerns uniformity norms. It does not assert that indicator approximations have vanishing L^2 distance from a nonconstant fractional weight.

III.85 The five-point profile and its analytic expansion

Source 38, delivered Section 4.

Theorem III.84.1 reduces the dimension-uniform extremal problem to a fixed, four-dimensional real space of centered functions. We now solve its local optimization, including the phase variables. The coefficient 20/9 was calculated for this fixed group in the preceding characteristic-five report [170]; it is reproduced below as part of the calculation of two additional terms.

Write $\mathcal{M}_{\delta,5}(u) = \mathcal{M}_{\delta, \mathbb{Z}/5\mathbb{Z}}(u)$. The interval restriction $0 \leq \delta + f \leq 1$ is temporarily absent. This permits the exact scaling relation

$$\mathcal{M}_{\delta,5}(u) = \delta^8 \mathcal{M}_{1,5}(u/\delta). \quad (\text{III.85.1})$$

Theorem III.85.1 (The extremal profile through twelfth order). *There are absolute constants $\eta, C > 0$ such that, for every nontrivial finite abelian group G with $5G = 0$, every $\delta > 0$, and $0 < u/\delta < \eta$,*

$$\begin{aligned} \mathcal{M}_{\delta,G}(u) = & \delta^8 + 6\sqrt{2}\delta^4 u^4 + \frac{2^{3/4}}{3}\delta^2 u^6 + \frac{20}{9}u^8 \\ & + \frac{869}{216} \frac{u^{10}}{2^{3/4}\delta^2} + \frac{65759}{5832} \frac{u^{12}}{2^{3/2}\delta^4} + E_\delta(u), \end{aligned} \quad (\text{III.85.2})$$

where $|E_\delta(u)| \leq Cu^{14}/\delta^6$. More generally, $\delta^{-8}\mathcal{M}_{\delta,G}(\delta t)$ is represented near zero by a convergent power series in t^2 . The constants and the neighborhood are independent of the ambient dimension. All sufficiently small maximizers on the five-point group are obtained from one real analytic family by translations, reflection, and the choice of a generating character.

[write] **6 October 2026; sources 34–39.** *Answers source 21's question on further terms on the five-point group* (item III.27): $c_{10} = 869/(216 \cdot 2^{3/4}) = 2.39218$, $c_{12} = 65759/(5832 \cdot 2^{3/2}) = 3.98651$ (decimals recomputed at the write). The intake confirmed them on $\mathbb{Z}/5\mathbb{Z}$ by direct optimization of the cube average over two Fourier coefficients: $(M - 1 - 6\sqrt{2}u^4 - (2^{3/4}/3)u^6 - (20/9)u^8)/u^{10} = 2.4079, 2.4121, 2.4248, 2.4412, 2.4610$ at $u = 0.05, \dots, 0.13$ against $c_{10} + c_{12}u^2 = 2.4021, \dots, 2.4596$ (evidence, not proof).

The analytic neighborhood in this theorem may be smaller than the explicit range $u/\delta \leq 10^{-5}$ of exact quotient reduction. The asymptotic calculation does not require a numerical lower bound for its radius of convergence.

III.85.1 A complete Fourier certificate

Identify the dual of $\mathbb{Z}/5\mathbb{Z}$ with $\mathbb{Z}/5\mathbb{Z}$. After choosing a generator so that a largest Fourier pair is $\{1, -1\}$, write

$$a_0 = \delta, \quad a_1 = \rho e^{i\alpha}, \quad a_2 = b e^{i\beta}, \quad a_{-r} = \overline{a_r}, \quad \rho \geq b \geq 0.$$

For $b > 0$ define

$$\theta = 2\alpha - \beta, \quad \phi = 3\alpha + \beta, \quad \psi = \phi - \theta = \alpha + 2\beta.$$

If $b = 0$, any choice of the unused phase gives the same formulas. For these five Fourier coefficients set

$$T_\delta(s, t) = \sum_{r \in \mathbb{Z}/5\mathbb{Z}} a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}.$$

The sum-of-squares identity in Lemma III.83.1 gives $\mathcal{C}_3(\delta + f) = \sum_{s,t} |T_\delta(s, t)|^2$. Realness of the underlying function makes T_δ real and invariant under independent sign changes of its two arguments and their interchange. The following six rows therefore account for all 25 slots.

Representative	Multiplicity	Value of $T_\delta(s, t)$
(0, 0)	1	$\delta^4 + 2\rho^4 + 2b^4$
(0, 1)	4	$2\delta^2\rho^2 + 2\rho^2b^2 + b^4$
(0, 2)	4	$2\delta^2b^2 + 2\rho^2b^2 + \rho^4$
(1, 1)	4	$\delta^2\rho^2 + 2\delta\rho^2b \cos \theta + 2\rho b^3 \cos(2\theta - \phi)$
(2, 2)	4	$\delta^2b^2 + 2\delta\rho b^2 \cos \psi + 2\rho^3b \cos \phi$
(1, 2)	8	$\rho^2b^2 + 2\delta\rho^2b \cos \theta + 2\delta\rho b^2 \cos \psi$

Each row follows by substituting $r = 0, 1, 2, -2, -1$ in the defining sum; thus the table is a finite algebraic certificate, including arbitrary Fourier phases. In particular the centered norm is exactly

$$N(\rho, b, \theta, \phi) := \|f\|_{U^3}^8 = 8\rho^8 + 16(1 + \cos^2 \phi)\rho^6b^2 + 48\rho^4b^4 + 16(1 + \cos^2(2\theta - \phi))\rho^2b^6 + 8b^8. \quad (\text{III.85.3})$$

Squaring all six rows gives the full objective

$$\begin{aligned} \mathcal{C}_3(\delta + f) = & \delta^8 + 24\delta^4(\rho^4 + b^4) \\ & + 16\delta^3(\rho^4b \cos \theta + \rho b^4 \cos \psi) \\ & + 24\delta^2\left((3 + \cos 2\theta)\rho^4b^2 + (3 + \cos 2\psi)\rho^2b^4 \right. \\ & \quad \left. + 2\rho^3b^3(\cos \phi + \cos(2\theta - \phi))\right) \\ & + 16\delta\left(\rho^4b^3(3 \cos \theta + \cos(2\phi - \theta)) \right. \\ & \quad \left. + \rho^3b^4(3 \cos \psi + \cos(3\theta - \phi))\right) + N(\rho, b, \theta, \phi). \end{aligned} \quad (\text{III.85.4})$$

All optimization below uses these exact expressions. In particular, the phases are not fixed in advance.

III.85.2 Localization of every maximum at the secondary scale

By (III.85.1), take $\delta = 1$ and put $t = u$. The norm sphere of centered real functions on the five-point group is compact, so the maximum exists. Since $\rho \geq b$, the nonnegative terms in (III.85.3) imply

$$8\rho^8 \leq t^8 \leq 128\rho^8. \quad (\text{III.85.5})$$

Thus $\rho \asymp t$ uniformly in the phases, and both amplitudes are $O(t)$.

Lemma III.85.2 (Uniform secondary localization). *Every five-point maximizer has $b = O(t^2)$ as $t \downarrow 0$, with an absolute implied constant.*

Proof. Put $S = 2(\rho^4 + b^4)$. Equation (III.85.3) gives $t^8 - 2S^2 \geq 16\rho^6 b^2$. Therefore

$$6\sqrt{2}t^4 - 12S = \frac{6(t^8 - 2S^2)}{t^4/\sqrt{2} + S} \geq ct^2 b^2$$

for an absolute $c > 0$, using (III.85.5) and $S \leq t^4/\sqrt{2}$. The fifth-, sixth-, and seventh-degree parts of (III.85.4) have moduli at most, respectively, $Ct^4 b$, $Ct^4 b^2$, and $Ct^4 b^3$. For example $\rho b^4 \leq \rho^4 b$, $\rho^2 b^4 \leq \rho^4 b^2$, and $\rho^3 b^3 \leq \rho^4 b^2$, because $b \leq \rho$. The constants are absolute because the displayed polynomial has finitely many terms with bounded trigonometric factors.

The pure-pair function $b = 0$ has value $1 + 6\sqrt{2}t^4 + t^8$. For a maximizer, comparison with this function and absorption of $Ct^4 b^2 + Ct^4 b^3$ into $ct^2 b^2/2$, for small t , give

$$0 \leq C_3(1 + f) - 1 - 6\sqrt{2}t^4 - t^8 \leq -\frac{c}{2}t^2 b^2 + Ct^4 b.$$

If $b > 0$, division by $t^2 b$ yields $b \leq (2C/c)t^2$; the claim is immediate if $b = 0$. $\square$

This lemma supplies the compactness needed for a perturbative maximum. It rules out functions whose second harmonic leaves every bounded region at the scale relevant to the next coefficient.

III.85.3 Analytic optimization with both phases retained

Set

$$q_0 = 2^{-3/4}, \quad b = kt^2, \quad \rho^2 = t^2 R.$$

After dividing the norm equation by t^8 , one obtains

$$\begin{aligned} 1 &= 8R^4 + 16(1 + \cos^2 \phi)R^3 k^2 t^2 + 48R^2 k^4 t^4 \\ &\quad + 16(1 + \cos^2(2\theta - \phi))Rk^6 t^6 + 8k^8 t^8. \end{aligned} \quad (\text{III.85.6})$$

At $t = 0$, the positive solution is $R = q_0$, and the derivative of the right side with respect to R is $32q_0^3 > 0$. The implicit function theorem gives a positive real analytic solution $R(t, k, \theta, \phi)$ near zero. It is analytic in t^2 , uniformly for bounded k and all phases: this follows either from a finite cover of the phase torus or directly from the uniform nonzero derivative at $R = q_0$.

Define

$$H(t, k, \theta, \phi) = \frac{C_3(1 + f) - 1 - 6\sqrt{2}t^4}{t^6}, \quad (\text{III.85.7})$$

with $\rho = t\sqrt{R}$ for positive t . The apparent singularity at $t = 0$ is removable, as substitution in (III.85.4) shows. The resulting expression has a real analytic continuation to signed t using this same formula for ρ . Its expansion begins

$$H = H_0 + t^2 H_2 + t^3 H_3 + O(t^4), \quad (\text{III.85.8})$$

where, writing $A = 1 + \cos^2 \phi$,

$$H_0 = -24q_0 A k^2 + 16q_0^2 k \cos \theta, \quad (\text{III.85.9})$$

$$H_2 = 1 + 24(A^2 - 2)k^4 - 16q_0 A k^3 \cos \theta + 24(3 + \cos 2\theta)q_0^2 k^2, \quad (\text{III.85.10})$$

$$H_3 = 16\sqrt{q_0} k^4 \cos(\phi - \theta) + 48q_0^{3/2} k^3 (\cos(2\theta - \phi) + \cos \phi). \quad (\text{III.85.11})$$

For example the first two corrections in the norm solution are

$$R = q_0 - \frac{A}{2}k^2t^2 + \frac{3(A^2 - 4)}{8q_0}k^4t^4 + O(t^6),$$

which already verify (III.85.9) and (III.85.10).

Proposition III.85.3 (All local maximizing branches). *For sufficiently small positive t , every global maximum is on an analytic critical branch converging, in the coordinates (k, θ, ϕ) , to one of*

$$y_+ = (q_0/3, 0, \pi/2), \quad y_- = (q_0/3, 0, 3\pi/2), \quad (\text{III.85.12})$$

with phases understood modulo 2π . There is exactly one critical branch near each class. They have equal objective values.

Proof. For $k \geq 0$,

$$H_0 \leq -24q_0k^2 + 16q_0^3k \leq \frac{8q_0^3}{3} = \frac{2^{3/4}}{3}.$$

Equality in the second inequality requires $k = q_0/3 > 0$. Equality in the first then forces $\cos \theta = 1$ and $\cos \phi = 0$, yielding exactly (III.85.12). Lemma III.85.2 confines all maximizers to a fixed compact set of k and the phase torus. On that set $H \rightarrow H_0$ uniformly. Each of the points in (III.85.12), together with its analytic norm solution, is an admissible competitor for small positive t . Compactness therefore forces every sequence of maximizers with $t \downarrow 0$ to approach one of these two classes.

At either class the Hessian of H_0 , in coordinates (k, θ, ϕ) , is

$$\text{diag} \left(-48q_0, -\frac{16q_0^3}{3}, -\frac{16q_0^3}{3} \right). \quad (\text{III.85.13})$$

It is negative definite. Apply the implicit function theorem to $\nabla_{k,\theta,\phi}H = 0$ at each point. This gives one analytic critical branch in a neighborhood of each class, and its Hessian remains negative definite. The preceding compactness argument, applied to these smaller neighborhoods, shows that these branches exhaust the global maxima. Their amplitude constraints are inactive: k remains positive and bounded, while $b/\rho = O(t)$. Conjugating the Fourier coefficients sends (θ, ϕ) to $(-\theta, -\phi)$ and interchanges the branches without changing the objective, so their values agree. $\square$

The map $(\alpha, \beta) \mapsto (\theta, \phi)$ has determinant 5. Its five lifts on the two-dimensional phase torus correspond exactly to translations of the five-point function. Choosing the other largest-pair generator is a group automorphism, and conjugation of the Fourier coefficients is reflection. This proves the symmetry assertion in Theorem III.85.1.

III.85.4 Evenness and a recursion for all further coefficients

Use the branch near y_+ and view $\phi - \pi/2$ as a local real coordinate. The exact normalized equations have the symmetry

$$(t, k, \theta, \phi) \mapsto (-t, k, -\theta, \pi - \phi). \quad (\text{III.85.14})$$

To check it, note that $\cos \theta$, $\cos 2\theta$, $\cos 2\psi$, and $\cos(2\phi - \theta)$ are unchanged, whereas $\cos \psi$, $\cos \phi$, $\cos(2\theta - \phi)$, and $\cos(3\theta - \phi)$ change sign. The latter factors occur precisely with the odd powers of signed t in the normalized objective. Both squared cosine factors in (III.85.6) are unchanged.

The involution fixes y_+ . Uniqueness of the analytic critical branch thus implies that $k(t)$ is even, $\theta(t)$ is odd, $\phi(t) - \pi/2$ is odd, and its objective value is even. Consequently the extremal profile is analytic in t^2 , rather than merely possessing a finite asymptotic expansion.

This gives an effective recursion. First solve (III.85.6) coefficient by coefficient for R ; the coefficient to be solved is multiplied by $32q_0^3$. Then expand $\nabla H = 0$. At each successive order, the new coefficient vector of (k, θ, ϕ) is multiplied by the fixed invertible matrix (III.85.13); all other terms are already known from lower orders. Every coefficient is therefore determined by finite algebraic operations. The analytic implicit function theorem proves convergence of the recursively obtained series.

III.85.5 Fourth, sixth, eighth, and tenth orders

At the limiting phases $\theta = 0$, $\phi = \pi/2$, put $z = k^2 t^2 / q_0$ and write $R = q_0 X(z)$. The exact norm becomes

$$X^4 + 2zX^3 + 6z^2X^2 + 2z^3X + z^4 = 1, \quad X(0) = 1. \quad (\text{III.85.15})$$

Coefficient comparison gives

$$X = 1 - \frac{1}{2}z - \frac{9}{8}z^2 + \frac{3}{4}z^3 + \frac{39}{128}z^4 + O(z^5). \quad (\text{III.85.16})$$

At these phases the objective simplifies to

$$\mathcal{C}_3(1 + f) = 1 + 24(\rho^4 + b^4) + 16\rho^4 b + 96\rho^4 b^2 + 48\rho^2 b^4 + 32\rho^4 b^3 + t^8. \quad (\text{III.85.17})$$

Its first coefficient beyond the leading quartic term is the maximum $8q_0^3/3 = 2^{3/4}/3$ of H_0 . At these fixed phases the next coefficients of H are

$$H_2(k) = 1 - 24k^4 - 16q_0k^3 + 96q_0^2k^2, \quad (\text{III.85.18})$$

$$H_4(k) = \frac{63k^6}{q_0} - 32k^5 - 48q_0k^4 + 32q_0^2k^3, \quad (\text{III.85.19})$$

$$H_6(k) = \frac{27k^8}{q_0^2} + \frac{42k^7}{q_0} - 216k^6 - 32q_0k^5. \quad (\text{III.85.20})$$

Here $H_j(k)$ denotes the coefficient of t^j after the phases are set to their limiting values; the arbitrary-phase functions H_2, H_3 remain those in (III.85.10)–(III.85.11).

Let $k_0 = q_0/3$. Since $q_0^4 = 1/8$,

$$H_2(k_0) = 1 - \frac{1}{27} - \frac{2}{27} + \frac{4}{3} = \frac{20}{9}. \quad (\text{III.85.21})$$

The analytic maximizing coordinates have no term of order t , because (III.85.8) has none and the Hessian is invertible. Equation (III.85.10) shows that its phase gradient vanishes at y_+ . Thus the displacement at order t^2 occurs only in the amplitude coordinate:

$$k(t) = k_0 + k_2 t^2 + O(t^4), \quad k_2 = -\frac{H'_2(k_0)}{H''_0(k_0)} = \frac{31q_0^2}{27}, \quad (\text{III.85.22})$$

where

$$H'_2(k_0) = \frac{496q_0^3}{9}, \quad H''_0(k_0) = -48q_0.$$

The optimized coefficient at order t^4 in H , hence at order t^{10} in the original objective, is

$$\begin{aligned} K_{10} &= H_4(k_0) + \frac{(H'_2(k_0))^2}{96q_0} \\ &= \frac{133q_0^5}{243} + \frac{7688q_0^5}{243} = \frac{869q_0}{216} = \frac{869}{216 \cdot 2^{3/4}}. \end{aligned} \quad (\text{III.85.23})$$

The phase displacement begins at order t^3 , so it cannot affect this coefficient. The next subsection computes its first effect.

III.85.6 The first phase adjustment and the twelfth-order coefficient

At y_+ , differentiation of (III.85.11) gives

$$\nabla_{\theta,\phi} H_3(y_+) = \frac{304q_0^{9/2}}{81}(1, -1), \quad \partial_k H_3(y_+) = 0. \quad (\text{III.85.24})$$

The phase part of the Hessian is $-(16q_0^3/3)I$. The order- t^3 critical-point equations therefore yield

$$\begin{aligned} \theta(t) &= d_3 t^3 + O(t^5), \\ \phi(t) &= \frac{\pi}{2} - d_3 t^3 + O(t^5), \quad d_3 = \frac{19q_0^{3/2}}{27}. \end{aligned} \quad (\text{III.85.25})$$

The absence of fourth-order phase terms follows from (III.85.14). In the original phases, one lift has

$$\alpha(t) = \frac{\pi}{10} + O(t^5), \quad \beta(t) = \frac{\pi}{5} - \frac{19q_0^{3/2}}{27} t^3 + O(t^5).$$

Thus keeping both phases permanently at their limiting values is already insufficient for the twelfth-order extremal coefficient.

We give the coefficient calculation with its optimization terms retained. Write $y(t) = y_+ + t^2 y_2 + t^3 y_3 + t^4 y_4 + \dots$, where $y_2 = (k_2, 0, 0)$ and $y_3 = (0, d_3, -d_3)$. The coefficient of t^6 in $H(t, y(t))$ is

$$\begin{aligned} K_{12} &= H_6(k_0) + k_2 H'_4(k_0) + \frac{1}{2} k_2^2 H''_2(k_0) \\ &\quad - \frac{1}{2} (\nabla_{\theta,\phi} H_3(y_+))^T (\nabla_{\theta,\phi}^2 H_0(y_+))^{-1} \nabla_{\theta,\phi} H_3(y_+). \end{aligned} \quad (\text{III.85.26})$$

To justify this formula, the terms containing the unknown y_4 cancel because $\nabla^2 H_0 y_2 + \nabla H_2 = 0$. The cubic derivative of H_0 in the direction y_2 is zero, since its restriction to the amplitude coordinate is quadratic. The terms involving y_3 complete the displayed quadratic form, using $\nabla^2 H_0 y_3 + \nabla H_3 = 0$. No term involving H_5 contributes at this order: the coordinate displacement starts at t^2 , and H_5 has prefactor t^5 . These observations account for every possible term through t^6 .

The needed fixed-phase values are

$$H_6(k_0) = -\frac{295q_0^6}{729}, \quad H'_4(k_0) = \frac{254q_0^4}{81}, \quad H''_2(k_0) = 128q_0^2.$$

The amplitude contribution in (III.85.26) and the phase contribution are, respectively,

$$k_2 H'_4(k_0) + \frac{1}{2} k_2^2 H''_2(k_0) = \frac{192386q_0^6}{2187}, \quad \frac{5776q_0^6}{2187}.$$

Consequently

$$K_{12} = \frac{65759q_0^6}{729} = \frac{65759}{5832 \cdot 2^{3/2}}. \quad (\text{III.85.27})$$

The phase contribution is strictly positive. It quantifies the first improvement obtained by optimizing the phases beyond their limiting values.

Completion of Theorem III.85.1. Proposition III.85.3 identifies all maxima near zero with the analytic branches just computed. Symmetry (III.85.14) makes their common value even. Equations (III.85.21), (III.85.23), and (III.85.27) therefore give an error $O(t^{14})$ after restoring the constant and quartic terms in (III.85.7). Its constant is absolute, because this is an analytic function on a fixed finite-dimensional neighborhood. Scale by (III.85.1) and apply Theorem III.84.1. This proves the claimed remainder and its independence of the ambient dimension. $\square$

III.85.7 Sharp realization by bounded weights and exact verification

Corollary III.85.4 (Weighted extremizers). *Let $0 < \delta < 1$ and let G be nontrivial with $5G = 0$. If $0 < u \leq 10^{-5}\delta$ and $4u \leq \min\{\delta, 1 - \delta\}$, then $\mathcal{M}_{\delta,G}(u)$ is attained by a weight $W : G \rightarrow [0, 1]$ of mean δ . The same maximum is obtained when the centered norm constraint is $\|W - \delta\|_{U^3} \leq u$. In particular, all coefficients in Theorem III.85.1 are sharp for bounded weights as well as for unrestricted real functions.*

Proof. Every five-point centered function has at most four nonzero Fourier coefficients. Each coefficient has modulus at most its U^2 norm, and hence at most its U^3 norm. Thus $\|f\|_\infty \leq 4u$ for a centered five-point function of norm u . The hypotheses place $\delta + f$ in $[0, 1]$. Pullback along a nontrivial character of G preserves the mean, the norm, and the cube count. The unrestricted upper bound then proves equality for weights. The norm-ball assertion follows from the strict monotonicity in Theorem III.84.1. $\square$

Corollary III.85.5 (An indicator version of the cube-count bound). *Let G be nontrivial with $5G = 0$, let $A \subseteq G$ have density $\delta > 0$, and suppose*

$$\|\mathbf{1}_A - \delta\|_{U^3}^8 \leq \alpha, \quad \alpha^{1/8} \leq 10^{-5}\delta.$$

The number of ordered cube parameters $(x, h_1, h_2, h_3) \in G^4$ whose eight vertices all belong to A is at most

$$|G|^4 \mathcal{M}_{\delta,5}(\alpha^{1/8}). \quad (\text{III.85.28})$$

Here $\mathcal{M}_{\delta,5}(0) = \delta^8$ by continuous extension. Repeated vertices and zero increments are included. As $\alpha^{1/8}/\delta \rightarrow 0$, its normalized upper bound is

$$\begin{aligned} C_3(\mathbf{1}_A) \leq & \delta^8 + 6\sqrt{2}\delta^4\alpha^{1/2} + \frac{2^{3/4}}{3}\delta^2\alpha^{3/4} + \frac{20}{9}\alpha \\ & + \frac{869}{216 \cdot 2^{3/4}}\delta^{-2}\alpha^{5/4} + \frac{65759}{5832 \cdot 2^{3/2}}\delta^{-4}\alpha^{3/2} + C\delta^{-6}\alpha^{7/4}, \end{aligned} \quad (\text{III.85.29})$$

for an absolute C , on a sufficiently small absolute range of $\alpha^{1/8}/\delta$.

Proof. Apply the norm-ball form of Theorem III.84.1 to $\mathbf{1}_A - \delta$, and multiply its normalized cube count by $|G|^4$. If $\alpha = 0$, the centered function vanishes and the assertion is immediate. Otherwise Theorem III.85.1, with $u = \alpha^{1/8}$, gives the displayed powers and the positive remainder bound. $\square$

Gowers' Lemma 3.10 gives the normalized bound $(\delta + \alpha^{1/8})^8$ in this notation [1, Lemma 3.10]. Its first error is of order $\alpha^{1/8}$ at fixed positive density, whereas (III.85.29) begins at $\alpha^{1/2}$. The sharp leading coefficient $6\sqrt{2}$ was already obtained in the preceding project reports [169, 170]; the additions here are exact quotient reduction and the dimension-uniform higher coefficients. The corollary is an upper bound for indicators; the exact extremizers and sharp realizations proved above are weights.

The program `code/verify_twelfth_order.py` checks (III.85.16), all the displayed H_j coefficients, the Hessian and phase displacements, and both optimized higher coefficients by exact symbolic arithmetic. It records the checks in `data/twelfth_order_checks.json`. A separate high-precision stationary-branch calculation in the same program compares the twelfth-order residual at decreasing positive values of t . That numerical calculation checks the analytic branch; it is not used to establish global optimality or the size of its neighborhood.

III.86 Cyclic reduction for every fixed odd exponent

Source 38, delivered Section 5.

The mechanism behind exact reduction is not exclusive to characteristic five. The finite size of the cyclic frequency group generated by a dominant character is what bounds the potentially negative cross terms. The following version keeps the dependence on that size explicit.

Theorem III.86.1 (Exact cyclic reduction at bounded odd exponent). *Let $m \geq 3$ be odd, let G be a finite abelian group of exponent exactly m , and put $c_m = 10^{-8}m^{-8}$. For every $\delta > 0$,*

$$\mathcal{M}_{\delta,G}(u) = \mathcal{M}_{\delta,\mathbb{Z}/m\mathbb{Z}}(u) \quad (0 < u \leq c_m\delta). \quad (\text{III.86.1})$$

Every maximizing function on G factors through a cyclic quotient of odd order dividing m . The same identity of maxima holds with the norm constraint replaced by $\|f\|_{U^3} \leq u$. For $0 < \delta < 1$, these unrestricted maxima are attainable by weights in $[0, 1]$ if also $mu \leq \min\{\delta, 1 - \delta\}$.

The threshold is a sufficient bound; neither its constant nor its power of m is claimed optimal. In particular, this theorem does not supply a threshold independent of all odd exponents.

Proof. Normalize $f = uF$, $\|F\|_{U^3} = 1$, and $t = u/\delta$. We first verify the pure-pair benchmark used in localization. For a real function with Fourier support $\{\xi, -\xi\}$ and coefficients $\rho e^{i\alpha}$ and its conjugate, the centered norm is $8\rho^8$ for every nonzero odd-order character. Indeed a two-point subset of an odd group has no parallelogram with both increments nonzero, so only the axes of the Fourier-square formula contribute. If the character has order greater than three, the fifth-, sixth-, and seventh-degree terms vanish. For the sixth and seventh degrees this follows from the statistic H : no three frequencies from this pair sum to zero.

If the character has order three, the terms are instead

$$B_5 = 2\rho^5 \cos 3\alpha, \quad C_6 = (24 + 8 \cos 6\alpha)\rho^6, \quad C_7 = 0.$$

These identities follow directly from the H, J, K and T, L formulas: here $H = 2\rho^6$, $J = 0$, $K = 2\rho^6 \cos 6\alpha$, and the nonzero slots of L are disjoint from those of T . Choosing $\alpha = 0$ makes both additional terms positive. Thus every nontrivial odd-order group has a normalized pure-pair competitor of value at least $1 + 6\sqrt{2}t^4 + t^8$.

For any maximizing candidate put $S = \sum_r |\widehat{F}(r)|^4$ and $S_0 = 2^{-1/2}$. Lemma III.83.3, cube Cauchy–Schwarz, and the benchmark imply $0 \leq S_0 - S \leq 4t$. Choose a largest Fourier pair, generated by ξ , and put $D_{\text{pair}} = \sum_{r \notin \{\xi, -\xi\}} |\widehat{F}(r)|^4$. Lemma III.83.2 gives

$$1 \geq 2S^2 + 3SD_{\text{pair}}, \quad D_{\text{pair}} \leq 8t$$

in the present range. Let $L = \langle \xi \rangle$, of size at most m , let g be the Fourier projection to L , and write $h = F - g$. As in the exact reduction proof, put

$$S_g = \sum_{r \in L} |\widehat{F}(r)|^4, \quad D = \sum_{r \notin L} |\widehat{F}(r)|^4, \quad v = \|g\|_{U^3}, \quad \Delta = 1 - v^8.$$

Then $S_g \geq S_0 - 12t$.

Let p denote the Fourier projection of g onto the principal pair. For $s, t \in L$ with $s, t \neq 0$, the preceding two-point observation gives $T_p(s, t) = 0$. Telescope the four factors of $T_g - T_p$ and apply ℓ^4 Hölder to each of the four terms. Each unchanged factor has norm at most one, whereas the changed factor has norm at most $D_{\text{pair}}^{1/4}$. Therefore

$$|T_g(s, t)| \leq 4D_{\text{pair}}^{1/4}, \quad R := \sum_{\substack{s, t \in L \\ s, t \neq 0}} |T_g(s, t)| \leq 4m^2(8t)^{1/4}.$$

For $t \leq c_m$, this is at most $4 \cdot 8^{1/4}/100 < 1/3$. Also $S_g \geq 2/3$. The energy argument proving (III.84.1) uses only odd order and a subgroup L , before its final five-point bound on R is inserted. It therefore gives here

$$\Delta \geq (10S_g - 2R)D + 2D^2 \geq 6D, \quad 0 \leq \Delta \leq 1/9. \quad (\text{III.86.2})$$

The last bound follows from $v^8 \geq 2S_g^2 \geq 8/9$. The subgroup-projection estimate (III.84.2) still gives $\|h\|_{U^3}^8 \leq 256\Delta$.

We spell out the dependence of the higher-degree estimates on m . Write H_F, H_g for the nonnegative triple statistics of the two functions. Cauchy–Schwarz gives

$$A_g := \sum_{r \in L} |\widehat{F}(r)|^2 \leq \sqrt{|L|S_g} \leq \sqrt{m}.$$

Exactly as in the proof of (III.84.3),

$$\begin{aligned} H_F - H_g &\leq 3A_g D + \sqrt{D(128\Delta + D^2/2)} \\ &\leq C_H \Delta, \quad C_H = 5 + \frac{\sqrt{m}}{2} \leq 3m. \end{aligned}$$

Thus $|C_6(F) - C_6(g)| \leq 28C_H \Delta$. For the seventh-degree difference the part on L^2 is at most $8|L|^2 D \leq (4/3)m^2 \Delta$, because each value of $L_g(s, t)$ has modulus at most four. On the complement, the two squared norms in the Cauchy–Schwarz estimate are at most $(4/3)\Delta$ and $16C_H \Delta$. Therefore

$$|C_7(F) - C_7(g)| \leq \left(\frac{4}{3}m^2 + \frac{16}{\sqrt{3}}\sqrt{C_H} \right) \Delta.$$

This is the same linear estimate as (III.84.4), now with its dependence on m retained.

Multiplication by two preserves both L and its complement, because the group has odd order. Consequently $B_5(F) - B_5(g) = B_5(h)$ and its modulus is at most $D^{5/4} \leq \Delta/6$. Set $g_* = g/v$. For

$k = 5, 6, 7$, the rescaling estimate $|v^{-k} - 1| \leq 4\Delta$ remains valid. Combining it with the preceding bounds and cube Cauchy–Schwarz yields

$$\begin{aligned} |B_5(F) - B_5(g_*)| &\leq 5\Delta, \\ |C_6(F) - C_6(g_*)| &\leq (28C_H + 112)\Delta \leq 122m\Delta, \\ |C_7(F) - C_7(g_*)| &\leq 10m^2\Delta. \end{aligned}$$

For the last simplification, $C_H \leq 3m$ and $m \geq 3$ give $16\sqrt{C_H/3} \leq 16\sqrt{m} \leq 10m$; the remaining terms are $(4/3)m^2 + 32$, whose sum with $10m$ is less than $10m^2$.

The fourth-degree improvement is at least $2t^4\Delta$, by (III.86.2), and the eighth-degree terms cancel because both functions have norm one. Hence

$$C_3(1 + tF) - C_3(1 + tg_*) \leq t^4\Delta(-2 + 40t + 122mt^2 + 10m^2t^3) \leq -t^4\Delta.$$

The coefficient in parentheses is strictly less than -1 throughout $t \leq 10^{-8}m^{-8}$; substitution bounds the three positive terms by $40 \cdot 10^{-8}m^{-8}$, $122 \cdot 10^{-16}m^{-15}$, and $10 \cdot 10^{-24}m^{-22}$, respectively, with sum less than one. If $D > 0$, the improvement is strict. Every maximizer consequently has Fourier support in a cyclic group L of order $d \mid m$.

The dual of G has an element of order m , so G has a cyclic quotient of that order. Conversely every function on a cyclic group of order $d \mid m$ pulls back to $\mathbb{Z}/m\mathbb{Z}$ with its mean, norm, and objective preserved. These two pullback statements prove (III.86.1).

For the norm-ball assertion, let F be normalized and maximizing at centered norm $0 < r \leq c_m$. The localization above gives $S \geq 2/3$. For $r \leq s \leq c_m$, the centered polynomial satisfies

$$\frac{d}{ds}C_3(1 + sF) \geq s^3(48S - 40s - 168s^2 - 56s^3) > 0.$$

Scaling a positive lower-norm maximizer therefore proves strict monotonicity throughout the range. The norm-zero value is strictly smaller by the pure-pair benchmark. The ball maximum is attained at its boundary. Finally, a centered function on $\mathbb{Z}/m\mathbb{Z}$ has at most $m - 1$ nonzero Fourier coefficients, each of modulus at most u . The additional bound $mu \leq \min\{\delta, 1 - \delta\}$ puts its maximizing weight in $[0, 1]$, and pullback concludes the proof. $\square$

Remark III.86.2 (Extremal values and the order of individual quotients). The equality of extremal values with $\mathbb{Z}/m\mathbb{Z}$ does not say that every maximizing function itself factors through an order- m quotient. A lower-order character need not lie in a cyclic subgroup of order m : in the dual of $\mathbb{Z}/9\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$, for example, the character represented by $(0, 1)$ is not contained in any cyclic subgroup of order nine. The theorem gives cyclic dependence of each extremizer, while the extremal value is compared by pullbacks between the resulting cyclic groups.

III.87 Source 38's Part III: six-term norm-extension defects [write]

Added in the seventh write, 6 October 2026.

The next section is source 38's Section 7, its delivered Part III. *Logically it follows source 22's chapter on polynomial colourings* (Section III.60), whose cubic-core defect and zero-defect classification it extends, and the norm-colouring material of sources 10 and 14; it is printed here because no number printed earlier may move. For a layered linear–cubic–quintic norm colouring plus an

arbitrary function of independent coordinates it counts the symmetric six-term progressions exactly; the excess over the surjectivity count is governed by centered third and fifth differences and a quadratic-character statistic (Theorem III.88.2). The layered construction is Shi and Dong’s; no better colouring exponent is claimed, and the quintic four-term dimension question stays open (item III.19). Nothing in this section is formalized.

III.88 An exact six-term extension defect and its quadratic-character term

Source 38, delivered Section 7.

*Delivered part heading of source 38: **Exact six-term norm-extension defects***

Gowers’ Conjecture 4.2 proposed a random-density lower bound for even-length progressions under a weaker uniformity hypothesis [1]. Symmetric-progression colorings are relevant to the limits of such a principle. In particular, Shi and Dong use layered odd-degree field norms to construct colorings avoiding symmetric progressions, with applications to counterexamples to the conjecture [33]. The question studied here is an exact counting problem inside that construction method: what happens after a function of new, independent coordinates is added to a complete norm core?

The preceding degree-stratification report [173] proves that such an addition cannot preserve avoidance, and gives an exact third-difference formula for the linear–cubic core. It asks for exact formulas beyond that case. We answer the next case. The six-term core contains both a cubic and a quintic norm; after one averages over its centers, their interaction is governed by the value distribution of a nondegenerate quadratic form on a five-dimensional extension field. The resulting formula applies to an arbitrary added function, without a polynomial-degree assumption.

III.88.1 Fields, extension degrees, and norm fibers

Fix a prime power $q = p^r$ of characteristic $p > 5$. Let N_j denote the norm from $\mathbb{F}_{q^j}$ to $\mathbb{F}_q$. The subscripts 3 and 5 below are *extension degrees over $\mathbb{F}_q$* ; neither is the characteristic. The base field need not be prime. The assumption concerns p , not merely q : it guarantees six distinct progression points in every nonzero direction, the invertibility of 120, and the nonvanishing trace $\mathrm{Tr}_{\mathbb{F}_{q^5}/\mathbb{F}_q}(1) = 5$.

Lemma III.88.1 (Norm presentation and fibers). *After any linear identification $\mathbb{F}_{q^j} \cong \mathbb{F}_q^j$, the norm N_j is represented by a homogeneous polynomial of total degree j . Its zero fiber is $\{0\}$, and each nonzero scalar has exactly*

$$L_j = \frac{q^j - 1}{q - 1}$$

preimages.

Proof. In a basis $b_1, \dots, b_j$, write $x = \sum_i X_i b_i$. Then

$$N_j(x) = \prod_{s=0}^{j-1} \left(\sum_i X_i b_i^{q^s} \right).$$

This is a product of j linear forms. Frobenius permutes the factors, so its coefficients belong to $\mathbb{F}_q$. The product vanishes precisely when $x = 0$. On $\mathbb{F}_{q^j}^*$ it is the homomorphism $x \mapsto x^{L_j}$. The

multiplicative group is cyclic of order $q^j - 1$, and the norm of a generator has order $q - 1$. Thus the map is onto $\mathbb{F}_q^*$ and has kernel of size L_j , which gives every nonzero fiber size. $\square$

In particular, put

$$L_3 = q^2 + q + 1, \quad L_5 = q^4 + q^3 + q^2 + q + 1, \quad \chi : \mathbb{F}_q \longrightarrow \{-1, 0, 1\},$$

where χ is the quadratic character extended by $\chi(0) = 0$. For an integer $e \geq 0$ and an arbitrary function $R : \mathbb{F}_q^e \rightarrow \mathbb{F}_q$, consider

$$P(a, u, v, w) = a + N_3(u) + N_5(v) + R(w).$$

Here $(a, u, v, w) \in \mathbb{F}_q \times \mathbb{F}_{q^3} \times \mathbb{F}_{q^5} \times \mathbb{F}_q^e$, so its domain has dimension $9 + e$ over $\mathbb{F}_q$. Write $A_6^{\text{sym}}(P)$ for the number of ordered center–direction pairs (z, h) with $h \neq 0$ such that

$$P(z + h/2) = P(z - h/2), \quad P(z + 3h/2) = P(z - 3h/2), \quad P(z + 5h/2) = P(z - 5h/2).$$

This counts ordered nontrivial six-term arithmetic progressions with the three stated symmetric color equalities. The direction is the common difference, and no quotient by sign or by rescaling is taken.

For $b, g \in \mathbb{F}_q^e$, define the centered odd differences

$$\begin{aligned} D_3(b, g) &= \Delta_g^3 R(b - 3g/2), \\ D_5(b, g) &= \Delta_g^5 R(b - 5g/2), \end{aligned}$$

where $\Delta_g R(x) = R(x + g) - R(x)$. Define three finite statistics

$$\begin{aligned} T_0 &= \#\{(b, g) : D_5(b, g) = 0, D_3(b, g) \neq 0\}, \\ T_1 &= \#\{(b, g) : D_5(b, g) \neq 0\}, \\ S &= \sum_{\substack{b, g \\ D_5(b, g) \neq 0}} \chi\left(\frac{40D_3(b, g)}{D_5(b, g)} - 5\right). \end{aligned}$$

All quotients are taken in $\mathbb{F}_q$. The integers appearing in the character argument are reduced in the same field.

Theorem III.88.2 (Exact six-term defect). *With the notation above,*

$$\begin{aligned} A_6^{\text{sym}}(P) &= q^{9+e}(q^e - 1) + q^9(q^2 + q)T_0 \\ &\quad + q^9(q^2 L_5 - 1)T_1 - q^7(q + 1)L_5 S. \end{aligned} \tag{III.88.1}$$

In particular the general surjectivity lower bound $q^{9+e}(q^e - 1)$ is attained exactly when all pure third additive differences of R vanish. Equivalently, after regarding its domain as a vector space over $\mathbb{F}_p$, the function R has the form

$$R(x) = c + L(x) + B(x, x),$$

where L is $\mathbb{F}_p$ -linear and B is symmetric $\mathbb{F}_p$ -bilinear, with values in $\mathbb{F}_q$.

[write] **6 October 2026; sources 34–39.** *In this report.* This extends source 22’s exact cubic-core defect and zero-defect classification (Corollary III.64.4) to the linear–cubic–quintic core with an independent addition; source 22’s question on defect formulas for more odd norm layers (item III.28) is advanced for three layers. The layered construction is Shi and Dong’s, as the source says; no better colouring exponent is claimed. The exact finite checks over the fields of orders 7 and 13 were rerun on a copy at the write.

The formula gives a sharper hierarchy than the statement that every added direction has at least one matching core direction. A nonzero third difference with zero fifth difference contributes $q^2 + q$ extra core directions on average. A nonzero fifth difference contributes approximately q^6 extra core directions on average; its exact deviation has a quadratic-character sign. The conclusion concerns this specified independent extension of a norm coloring. It does not improve the unrestricted symmetric-progression coloring exponent or the global Szemerédi bound.

III.88.2 The quadratic coefficient of the quintic norm

For $x \in E = \mathbb{F}_{q^5}$, write

$$N_5(x + T) = T^5 + e_1(x)T^4 + e_2(x)T^3 + e_3(x)T^2 + e_4(x)T + e_5(x).$$

Expanding the square of the sum of the five Frobenius conjugates gives

$$e_2(x) = \frac{(\mathrm{Tr} x)^2 - \mathrm{Tr}(x^2)}{2}.$$

Lemma III.88.3 (Exact value distribution). *For every $c \in \mathbb{F}_q$,*

$$\#\{x \in E : e_2(x) = c\} = q^4 + q^2\chi(2c).$$

Proof. Choose an $\mathbb{F}_q$ -basis $b_1, \dots, b_5$ of E , and let $T = (\mathrm{Tr}(b_i b_j))_{i,j}$ be the trace-pairing matrix. The pairing is nondegenerate: for $x \neq 0$, pairing with x^{-1} gives $\mathrm{Tr}(1) = 5 \neq 0$. Its determinant is a nonzero square in $\mathbb{F}_q$. Indeed, if $M = (b_j^{q^i})_{0 \leq i \leq 4, 1 \leq j \leq 5}$, then $T = M^T M$; moreover Frobenius acts on M by a five-cycle of its rows, so $(\det M)^q = \det M$. Thus $\det M \in \mathbb{F}_q^*$ and $\det T = (\det M)^2$.

The quadratic form e_2 is represented relative to the trace pairing by the self-adjoint operator

$$\frac{1}{2}(1 \otimes \mathrm{Tr} - I).$$

The operator in parentheses has eigenvalue 4 on the span of 1 and eigenvalue -1 on the trace-zero subspace. These subspaces are complementary because $\mathrm{Tr}(1) = 5 \neq 0$. Hence its determinant is 4, and the determinant of a matrix for e_2 is

$$2^{-5} \cdot 4 \det T = \frac{\det T}{8}.$$

In particular, e_2 is nondegenerate of rank five and its determinant has quadratic character $\chi(2)$.

For completeness, the standard odd-rank quadratic-form count follows by diagonalization and additive-character orthogonality. For a nontrivial additive character ψ , put $G = \sum_{x \in \mathbb{F}_q} \psi(x^2) = \sum_t \chi(t)\psi(t)$. The identity $G^2 = \chi(-1)q$ follows by writing the two nonzero variables in G^2 as u, ut : the sum over $u \neq 0$ of $\psi(u(1+t))$ is $q-1$ at $t = -1$ and -1 otherwise. If Q is a nondegenerate quadratic form of rank five with matrix A , then

$$\sum_x \psi(sQ(x)) = \chi(s)\chi(\det A)G^5 \quad (s \neq 0).$$

Orthogonality gives q^4 solutions when $c = 0$. When $c \neq 0$, use $\sum_{s \neq 0} \chi(s)\psi(-sc) = \chi(-c)G$ to obtain

$$\#\{x : Q(x) = c\} = q^4 + q^{-1}\chi(\det A)\chi(-c)G^6 = q^4 + q^2\chi(c \det A).$$

Applying this with $\chi(\det A) = \chi(2)$ proves the result. $\square$

III.88.3 The exact averaged reflection fibers

For fixed (b, g) , let $\beta_1, \beta_3, \beta_5$ be the unique coefficients such that

$$R(b + \alpha g) - R(b - \alpha g) = 2(\beta_1 \alpha + \beta_3 \alpha^3 + \beta_5 \alpha^5) \quad \left(\alpha = \frac{1}{2}, \frac{3}{2}, \frac{5}{2} \right).$$

The matrix is invertible because the three nonzero squared parameters are distinct when $p > 5$. This is interpolation on six points, so it does not assert that R is a polynomial. Direct finite-difference calculation yields

$$\beta_5 = D_5/120, \quad \beta_3 = D_3/6 - D_5/48. \quad (\text{III.88.2})$$

In fact $D_3 = 6\beta_3 + 15\beta_5$ and $D_5 = 120\beta_5$.

Let $b_3 = -\beta_3$, $b_5 = -\beta_5$ be the target cubic and quintic coefficients that the core must supply. Its linear coefficient can always be set by a unique direction in the a coordinate. If the quintic direction is h , it must satisfy $N_5(h) = b_5$. When $h \neq 0$, its contribution to the cubic coefficient at quintic center v is

$$N_5(h)e_2(v/h) = b_5 e_2(v/h).$$

The remaining cubic direction must therefore lie in the norm fiber

$$N_3(h_3) = b_3 - b_5 e_2(v/h).$$

The cubic norm has one preimage of zero and L_3 preimages of every nonzero scalar; write this fiber size as

$$\nu_3(t) = 1 + (q^2 + q)1_{\{t \neq 0\}}.$$

If $b_5 = 0$, the quintic direction is zero, and the reflection fiber has size $\nu_3(b_3)$ at every core center. If $b_5 \neq 0$, there are L_5 possible quintic directions. For each such direction, $v \mapsto v/h$ is a bijection of E . Consequently the sum of the fiber size over all q^5 quintic centers is exactly

$$\begin{aligned} H(b_3, b_5) &= L_5 \sum_{x \in E} \nu_3(b_3 - b_5 e_2(x)) \\ &= L_5 \left[q^5 + (q^2 + q) \left(q^5 - q^4 - q^2 \chi(2b_3/b_5) \right) \right] \\ &= L_5 \left[q^7 - (q^4 + q^3) \chi(2b_3/b_5) \right]. \end{aligned}$$

Thus the mean reflection fiber over all core centers is

$$\mu(b_3, b_5) = \begin{cases} 1 + (q^2 + q)1_{\{b_3 \neq 0\}}, & b_5 = 0, \\ L_5 [q^2 - (q^{-1} + q^{-2})\chi(2b_3/b_5)], & b_5 \neq 0. \end{cases} \quad (\text{III.88.3})$$

This is an average; it need not be an integer. The integer quantity H above is the sum over quintic centers. It is not claimed that the fiber has size μ at each individual center.

Proof of Theorem III.88.2. The coefficients in the cubic and linear core centers affect only the unique final linear adjustment and do not change the preceding count. There are q^4 choices of these centers. Therefore the total number of symmetric center–direction pairs, including zero directions, is

$$q^9 \sum_{b,g} \mu(-\beta_3(b, g), -\beta_5(b, g)).$$

By (III.88.2), when $D_5 \neq 0$ the character in (III.88.3) is

$$\chi(2\beta_3/\beta_5) = \chi(40D_3/D_5 - 5).$$

Split the sum into $D_3 = D_5 = 0$, the T_0 cases, and the T_1 cases. Subtract the exactly q^{9+e} zero-direction pairs, one at each center. This gives (III.88.1).

For $q \geq 7$, every value of the second line of (III.88.3) is greater than one. The first line equals one precisely when $b_3 = 0$. Hence equality with the baseline holds precisely when $D_3 = D_5 = 0$ for every (b, g) , which is equivalent to vanishing of all pure third differences: a fifth difference is a second difference of a third difference.

For completeness, we prove the prime-field classification. Fix an $\mathbb{F}_p$ -basis of the additive domain $\mathbb{F}_q^e$, so it becomes $\mathbb{F}_p^{re}$. The function R has a unique reduced polynomial presentation with coefficients in $\mathbb{F}_q$,

$$R(X) = \sum_a c_a X^a, \quad 0 \leq a_i < p.$$

The restriction of R to each prime-field line has reduced degree at most two. To see this, a reduced one-variable polynomial of degree $d \in \{3, \dots, p-1\}$ has a nonzero third forward difference: its leading coefficient is multiplied by $d(d-1)(d-2) \neq 0$. Thus the assumed vanishing of every pure third difference excludes such a degree.

It follows that the coefficient of T^3 in $R(X + TH)$, after reducing T modulo $T^p - T$, vanishes as a function of (X, H) on $\mathbb{F}_p^{re} \times \mathbb{F}_p^{re}$. Suppose $c_a \neq 0$ and $|a| \geq 3$. Choose a multi-index $b \leq a$ with $|b| = 3$. This coefficient contains

$$c_a \binom{a}{b} X^{a-b} H^b.$$

Every X - and H -coordinate exponent is already below p ; moreover $\binom{a}{b} \neq 0$ in characteristic p . Different pairs (a, b) give distinct monomials $X^{a-b} H^b$. Contributions with larger $|b| \equiv 3 \pmod{p-1}$, which arise on reducing the parameter T , also have different H -monomials. The displayed term therefore cannot cancel. Uniqueness of the reduced polynomial as a function of (X, H) gives a contradiction. Hence R has total degree at most two in the prime-field coordinates.

Conversely, every such quadratic has zero pure third differences. Because p is odd, its quadratic part is $B(x, x)$ for a symmetric $\mathbb{F}_p$ -bilinear map B , and its degree-one part is an $\mathbb{F}_p$ -linear map L . This proves the classification, including proper extension fields and the zero-dimensional domain. $\square$

III.88.4 Explicit added monomials and exact finite checks

For one added coordinate $w \in \mathbb{F}_q$, all three elementary monomial extensions have closed formulas.

Corollary III.88.4 (Three exact monomial counts). *Write $P_j(a, u, v, w) = a + N_3(u) + N_5(v) + w^j$. Then*

$$\begin{aligned} A_6^{\text{sym}}(P_3) &= q^{10}(q-1)L_3, \\ A_6^{\text{sym}}(P_4) &= q^{12}(q-1), \\ A_6^{\text{sym}}(P_5) &= q^7(q-1)L_5[q^5 - (q^2-1)\chi(5)]. \end{aligned}$$

Proof. The statistics in Theorem III.88.2 are

$R(w)$	T_0	T_1	S
w^3	$q(q-1)$	0	0
w^4	$(q-1)^2$	0	0
w^5	0	$q(q-1)$	$(q-1)^2\chi(5)$.

For $R = w^3$, we have $D_3 = 6g^3$ and $D_5 = 0$; for $R = w^4$, we have $D_3 = 24bg^3$ and $D_5 = 0$. These give the first two rows. For $R = w^5$, the interpolated coefficients are $\beta_5 = g^5$ and $\beta_3 = 10b^2g^3$. Thus $D_5 \neq 0$ exactly when $g \neq 0$, and the character $\chi(2\beta_3/\beta_5) = \chi(20(b/g)^2)$ is zero for $b = 0$ and is $\chi(5)$ whenever $b, g \neq 0$. This proves the last row. Substitution into (III.88.1) and simplification gives the displayed counts. $\square$

The standard-library program `code/verify_six_ap_defect.py` constructs irreducible finite-field presentations and forms e_2 independently as the sum of pairwise Frobenius conjugates. It exhausts all $7^5 + 13^5 = 388100$ quintic-field elements, checks the entire e_2 distribution, and directly verifies cubic norm fibers on all $7^3 + 13^3 = 2540$ cubic-field elements. It then verifies all $7 \cdot 6 + 13 \cdot 12 = 198$ pairs of cubic targets and nonzero quintic targets by an independent weighted-fiber sum, including all three quadratic-character values. For example, for $q = 7$ the three integer sums H are

$$H_{+1} = 2299057999, \quad H_0 = 2306743943, \quad H_{-1} = 2314429887.$$

For $q = 13$ they are

$$H_{+1} = 1940550181219, \quad H_0 = 1941501864497, \quad H_{-1} = 1942453547775.$$

Finally it evaluates the added monomials at the actual six progression nodes and verifies the aggregate formula. The resulting ordered nontrivial progression counts are

$R(w)$	$q = 7$	$q = 13$
w^3	96606535158	302737248100404
w^4	83047723206	279577021469772
w^5	233281014955590	8654306689055041404.

These are exact factorized counts. The script does not enumerate all center–direction pairs in the ten-dimensional domain, and no such enumeration is needed for the proof.

What remains. For an eight-term core, the next norm layer has degree seven. The same descending procedure forces joint value distributions of several polarized coefficients, rather than one quadratic form. Determining whether those distributions admit comparably explicit character formulas is a concrete next problem. The global quintic avoidance dimension for symmetric four-term progressions, between four and eight in the preceding reports [173], remains unresolved here.

III.89 Source 45’s chapter: the real fourth-uniformity gap [write]

Added in the eighth write, 7 October 2026.

The next two sections are source 45’s Sections 4–5. *Logically they continue the chapter on the odd-order constants* (Section III.66), after source 34’s Section 10 and source 35’s Section 6; they are printed here because that chapter is no longer the last of Part III and no number printed earlier may move.

What is proved. For real centered f on a finite abelian group of odd order, $\|f\|_{U^4}^{16} \geq (4795/832) \|f\|_{U^2}^{16}$ (Theorem III.90.1), so $c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$, the best upper bound among sources 01–46 (source 49, placed by `f8bc5e2ec` and not yet written in, records $29/4$, that is $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$ (for its write)). The proof applies a mean-sensitive U^3 bound $Q_3(g) \geq v^2 + 10vw + 2w^2$ (Lemma III.90.4; the three-pairing count of sources 21, 35 and 38 with the zero frequency kept) to the derivatives $f \cdot f(\cdot + h)$, the even-moment bounds of the autocorrelation (sources 29’s and 34’s C_m), $W \geq V - 1$, and the scalar certificate $P(t) = -t^2/4 + (33/26)t - 99/676$ with $10t^2 - 4P = 11(t - 3/13)^2$. The five-point function $(2, 1, -2, -2, 1)$ on $\mathbb{Z}/5\mathbb{Z}$ gives $c_4^{\text{odd}} \geq (39037448/404304625)^{1/4} = 0.5574336$ (Proposition III.90.9), weaker than sources 28 and 34 (0.5587294) and the batch-121 certificate (0.5587725); a dual-cube identity rules out every real single-character function of order at least five, order three treated separately (sources 28’s and 34’s results, uncited). Section III.91 multiplies source 04’s quartic coefficient P_d by $(832/4795)^{1/4}$ for $d \geq 4$ (Corollary III.91.2) and computes the defect of rectified holes. The bracket is now $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ (item III.1).

Relation to the formal statements (checked at HEAD 6d4942222). `lemma_3_10` (Sections01_03.lean, line 340) has the exact companion `lemma_3_10_holds` (Proofs03CubeUpper.lean, line 82); no declaration concerns c_d^{odd} . Nothing in this chapter is formalized.

III.90 A quantitative real fourth-uniformity gap

Source 45, delivered Section 4.

The real, centered setting retains information that is lost in the ordinary monotonicity of Gowers norms. The pinned report [202] establishes the sharp comparison

$$\|f\|_{U^3}^8 \geq 2 \|f\|_{U^2}^8$$

for real functions of mean zero on finite abelian groups of odd order. It also asks for the corresponding optimal comparison with U^d when $d \geq 4$. We give a strictly stronger fourth-order comparison, an exact finite lower bound for its optimal constant, and a structural obstruction to carrying the third-order extremizers into dimension four.

Our argument uses the Fourier and cube identities underlying Gowers’s proof [1], together with an elementary moment count and a rational inequality certificate. The broader theory of functions whose Gowers norms are near an extremal value under L^p or L^∞ constraints is developed, for example, by Eisner and Tao [7]. The quotient considered here imposes realness and centering and compares two different uniformity norms. We state the exact remaining uncertainty: the numerical constant proved below is a certified lower bound for the fourth-order norm gap, and its optimal value is not determined in this article.

III.90.1 Normalization and the results

Let G be a finite abelian group, written additively. Averages over G and its powers are normalized. Characters take values on the unit circle, and the dual group $\widehat{G}$ is also written additively. For a function $f : G \rightarrow \mathbb{C}$, write

$$a_\xi = \widehat{f}(\xi) = \mathbb{E}_{x \in G} f(x) \overline{\xi(x)}, \quad f(x) = \sum_{\xi \in \widehat{G}} a_\xi \xi(x). \quad (\text{III.90.1})$$

The Fourier sums in this section are *unnormalized*; in particular, the normalization is already incorporated in a_ξ .

Let $\mathcal{C}$ denote complex conjugation. For $d \geq 1$ set

$$Q_d(f) = \|f\|_{U^d}^{2d} = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{\omega \in \{0,1\}^d} \mathcal{C}^{|\omega|} f(x + \omega \cdot h). \quad (\text{III.90.2})$$

Here $\|f\|_{U^1} = |\mathbb{E}f|$; for $d \geq 2$ this is a norm. For real functions, every conjugation in (III.90.2) can be omitted. The recursion, with $\Delta_h f(x) = f(x) \overline{f(x+h)}$, is

$$Q_{d+1}(f) = \mathbb{E}_h Q_d(\Delta_h f). \quad (\text{III.90.3})$$

Orthogonality gives

$$S(f) := Q_2(f) = \sum_{\xi} |a_\xi|^4. \quad (\text{III.90.4})$$

If f is real, $a_{-\xi} = \overline{a_\xi}$; if it is centered, $a_0 = 0$. Odd group order ensures that every nonzero character belongs to a distinct pair $\{\xi, -\xi\}$.

Theorem III.90.1 (Explicit real fourth-order gap). *Let G be a finite abelian group of odd order and let $f : G \rightarrow \mathbb{R}$ satisfy $\mathbb{E}f = 0$. Then*

$$\boxed{Q_4(f) \geq \frac{4795}{832} S(f)^4.} \quad (\text{III.90.5})$$

Consequently, for every $d \geq 4$,

$$\|f\|_{U^2}^4 \leq \left(\frac{832}{4795} \right)^{1/4} \|f\|_{U^d}^4. \quad (\text{III.90.6})$$

No bound on $\|f\|_\infty$ is required.

[write] **7 October 2026; sources 40–46.** *Where this stands* (checked at the write). In source 29's normalization $\|f\|_{U^4}^{16} \geq C \|f\|_{U^2}^{16}$ the coefficients are $(323/160)^2$ (28), $35/8$ (29), 5 (35), $81/16$ (34) and $4795/832 = 5.7632212$ (here), that is $c_4^{\text{odd}} \leq 0.7038153$, 0.6914416 , 0.6687403 , $2/3$ and $(832/4795)^{1/4} = 0.6454070$; $4795/832 - 81/16 = 583/832$. So this is the best upper bound among sources 01–46 (source 49, placed by **f8bc5e2ec** and not yet written in, records $29/4$, that is $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$ (for its write)), and $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$, the lower end being the batch-121 intake's certificate on $\mathbb{Z}/7\mathbb{Z}$ (note after source 28's Corollary III.70.8). The intake re-derived the proof and checked every identity of the certificate in exact rationals $(10t^2 - 4P = 11(t - 3/13)^2$, the final quadratic in V) and every intermediate inequality on 47 functions over nine odd groups. Local numerical minimization puts the truth near $C \approx 10.2571$ (dossier 122; evidence only).

The theorem is homogeneous. Thus it also applies to the 1-bounded functions used in density arguments, and imposing $\|f\|_\infty \leq 1$ does not alter the optimal quotient below: every nonzero function on a finite group can be rescaled to satisfy that condition.

Define

$$c_d^{\text{odd}} = \sup \left\{ \frac{\|f\|_{U^2}^4}{\|f\|_{U^d}^4} : \begin{array}{l} G \text{ finite abelian of odd order,} \\ f : G \rightarrow \mathbb{R}, \quad \mathbb{E}f = 0, \quad f \neq 0 \end{array} \right\}. \quad (\text{III.90.7})$$

Corollary III.90.2 (A rigorous interval for the optimal constant). *One has*

$$\left(\frac{39037448}{404304625} \right)^{1/4} \leq c_4^{\text{odd}} \leq \left(\frac{832}{4795} \right)^{1/4}. \quad (\text{III.90.8})$$

Numerically, the two endpoints are

$$0.5574336443118301 \quad \text{and} \quad 0.6454070108505990.$$

Moreover, no function of the form $2\text{Re}(c\xi)$, with $c \neq 0$ and ξ a nontrivial character, attains the supremum defining c_4^{odd} .

The upper endpoint is proved in Section III.90.4. The exact five-point example providing the lower endpoint appears in Section III.90.6. The exclusion of the single-character class is proved in Section III.90.5.

Each of the three restrictions in Theorem III.90.1 matters. A nontrivial complex character is centered and has U^j norm equal to 1 for every $j \geq 2$, so realness cannot be dropped. A nonzero constant function shows that centering cannot be dropped. On $\mathbb{Z}/2\mathbb{Z}$, the nontrivial real character is centered and again has U^j norm equal to 1 for every $j \geq 2$, so an unrestricted even-order version is false.

For completeness, ordinary monotonicity follows directly from the cube identities. With $j-1$ derivatives grouped into F_h , one has

$$Q_j(f) = \mathbb{E}_h |\mathbb{E}_x F_h(x)|^2, \quad Q_{j+1}(f) = \mathbb{E}_h \|F_h\|_{U^2}^4.$$

By (III.90.4), $\|F_h\|_{U^2}^4 \geq |\mathbb{E} F_h|^4$, and Cauchy–Schwarz therefore gives $Q_{j+1}(f) \geq Q_j(f)^2$. This proves $\|f\|_{U^{j+1}} \geq \|f\|_{U^j}$ and the passage from dimension four to (III.90.6). Combining only monotonicity with the third-order result in [202] would give the weaker constant $1/\sqrt{2}$.

III.90.2 A third-order inequality retaining the mean

The essential first step is to retain the zero Fourier coefficient when performing the third-order argument. Derivatives of a centered function need not be centered; their means are its autocorrelations. Discarding those means before the next averaging would lose the improvement.

Lemma III.90.3 (Fourier face identity). *For every complex function g on a finite abelian group, with normalized Fourier coefficients a_r , one has*

$$Q_3(g) = \sum_{s,t \in \widehat{G}} |T(s,t)|^2, \quad (\text{III.90.9})$$

$$T(s,t) = \sum_{r \in \widehat{G}} a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}. \quad (\text{III.90.10})$$

The identity requires no assumption on the order of the group.

Proof. Expand (III.90.2) for $d = 3$ using Fourier inversion. For the term with frequency labels r_ω , orthogonality in x, h_1, h_2, h_3 imposes exactly

$$\sum_{\omega} (-1)^{|\omega|} r_\omega = 0, \quad \sum_{\omega} (-1)^{|\omega|} \omega_i r_\omega = 0 \quad (1 \leq i \leq 3). \quad (\text{III.90.11})$$

These equations are equations in $\widehat{G}$, so they must be solved without dividing by an integer. Subtract the h_3 equation from the x equation. The result is

$$r_{000} - r_{100} - r_{010} + r_{110} = 0.$$

Subtracting the h_2 and h_1 equations in the same way determines r_{101} and r_{011} . Substitution in any one of the h_i equations then determines r_{111} . Thus, writing

$$r = r_{000}, \quad s = r_{100} - r, \quad t = r_{010} - r, \quad u = r_{001} - r,$$

all solutions are exactly

$$r_\omega = r + \omega_1 s + \omega_2 t + \omega_3 u.$$

Conversely these labels satisfy (III.90.11), as direct substitution shows. There are no multiplicities or divisibility factors.

For fixed s, t , put

$$P_{s,t}(r) = a_r \overline{a_{r+s}} \overline{a_{r+t}} a_{r+s+t}.$$

The two parallel frequency faces contribute $P_{s,t}(r) \overline{P_{s,t}(r+u)}$. Summing over r, u is therefore $|\sum_r P_{s,t}(r)|^2$. The remaining sum over s, t proves the identity. All averages used in orthogonality equal either zero or one; this accounts for the unnormalized sums in (III.90.9). $\square$

Lemma III.90.4 (Mean-sensitive real third-order bound). *Let G have odd order and let $g : G \rightarrow \mathbb{R}$ be arbitrary. Set*

$$v = |\mathbb{E}g|^4, \quad w = Q_2(g) - v \geq 0. \quad (\text{III.90.12})$$

Then

$$\boxed{Q_3(g) \geq v^2 + 10vw + 2w^2.} \quad (\text{III.90.13})$$

Proof. Put

$$\lambda_r = |a_r|^2, \quad H = \sum_r \lambda_r^2 = v + w, \quad M = \sum_r \lambda_r^4.$$

Because g is real, $\lambda_{-r} = \lambda_r$ and $\lambda_0^2 = v$. Introduce the unnormalized additive energy of the nonnegative weights λ :

$$\mathcal{E}(\lambda) = \sum_{r+s=t+u} \lambda_r \lambda_s \lambda_t \lambda_u.$$

On either coordinate axis in (III.90.9),

$$T(0, t) = \sum_r \lambda_r \lambda_{r+t}.$$

The squared sums on one axis add up to $\mathcal{E}(\lambda)$. Retaining the union of the two axes, and subtracting their common origin once, gives

$$Q_3(g) \geq 2\mathcal{E}(\lambda) - H^2. \quad (\text{III.90.14})$$

Every summand of $\mathcal{E}(\lambda)$ is nonnegative. Retain the union of these three families of solutions of $r + s = t + u$:

$$\begin{aligned}\mathcal{A}: & \quad r = t, \quad s = u, \\ \mathcal{B}: & \quad r = u, \quad s = t, \\ \mathcal{D}: & \quad s = -r, \quad u = -t.\end{aligned}$$

Each family has total weight H^2 . Each pairwise intersection has total weight M . In the triple intersection all four indices coincide and $2r = 0$. Odd group order makes $r = 0$ its only possibility, so the triple intersection has weight $\lambda_0^4 = v^2$. Inclusion–exclusion yields

$$\mathcal{E}(\lambda) \geq 3H^2 - 3M + v^2. \quad (\text{III.90.15})$$

For representatives of the nonzero opposite pairs write $b_j = \lambda_{r_j}^2$. Then

$$w = 2 \sum_j b_j, \quad M = v^2 + 2 \sum_j b_j^2 \leq v^2 + \frac{1}{2}w^2.$$

Substitution into (III.90.14) and (III.90.15) gives

$$\begin{aligned}Q_3(g) &\geq 5(v+w)^2 - 6\left(v^2 + \frac{1}{2}w^2\right) + 2v^2 \\ &= v^2 + 10vw + 2w^2,\end{aligned}$$

as required. □

When g is centered this reduces to the third-order factor 2. The extra mixed term in (III.90.13) is what permits the fourth-order improvement. Notice also why the zero frequency could not be omitted in the proof: it contributes the triple intersection v^2 in (III.90.15).

III.90.3 Positive Fourier coefficients and even autocorrelation moments

For a real centered function f , define its autocorrelation by

$$R(h) = \mathbb{E}_x f(x)f(x+h). \quad (\text{III.90.16})$$

Fourier inversion and realness give

$$R(h) = \sum_{\xi} \lambda_{\xi} \xi(h), \quad \lambda_{\xi} = \left| \widehat{f}(\xi) \right|^2, \quad \lambda_{-\xi} = \lambda_{\xi}, \quad \lambda_0 = 0. \quad (\text{III.90.17})$$

Thus R is real, even, and has nonnegative Fourier coefficients. Also

$$\mathbb{E}_h R(h)^2 = \sum_{\xi} \lambda_{\xi}^2 = S(f). \quad (\text{III.90.18})$$

Lemma III.90.5 (All even moments of the autocorrelation). *If G has odd order, $f : G \rightarrow \mathbb{R}$ is centered, and $k \geq 1$ is an integer, then*

$$\boxed{\mathbb{E}_h R(h)^{2k} \geq \frac{\binom{2k}{k}}{2^k} S(f)^k.} \quad (\text{III.90.19})$$

For $k = 1$ equality always holds.

Proof. Choose one character from each nonzero opposite pair. With $b_j \geq 0$ we may write

$$R(h) = \sum_j b_j (\chi_j(h) + \chi_j(h)^{-1}), \quad S(f) = 2 \sum_j b_j^2.$$

In the expansion of $\mathbb{E}R^{2k}$, each character word averages to zero or one. Its scalar coefficient is nonnegative. Retain those words that contain the same number k_j of occurrences of χ_j and χ_j^{-1} , for every j . These words certainly average to one, irrespective of any other relations among the characters. Their total contribution is

$$(2k)! \sum_{\sum_j k_j = k} \prod_j \frac{b_j^{2k_j}}{(k_j!)^2}. \quad (\text{III.90.20})$$

For every multi-index in this sum, the multinomial coefficient $k!/\prod_j k_j!$ is a positive integer. Consequently

$$\prod_j \frac{1}{(k_j!)^2} \geq \frac{1}{k!} \prod_j \frac{1}{k_j!}.$$

Using the multinomial theorem in (III.90.20), we obtain

$$\begin{aligned} \mathbb{E}R^{2k} &\geq \frac{(2k)!}{k!} \sum_{\sum_j k_j = k} \prod_j \frac{b_j^{2k_j}}{k_j!} \\ &= \binom{2k}{k} \left(\sum_j b_j^2 \right)^k = \frac{\binom{2k}{k}}{2^k} S(f)^k. \end{aligned}$$

For $k = 1$, this is precisely (III.90.18). □

The lemma does not require the character representatives to be independent or dissociated. Additional additive relations contribute further nonnegative terms; none invalidates the selected family of balanced words. This observation is particularly useful for handling small odd torsion uniformly.

We shall use the four instances

$$\begin{aligned} \mathbb{E}R^2 &= S, & \mathbb{E}R^4 &\geq \frac{3}{2}S^2, \\ \mathbb{E}R^6 &\geq \frac{5}{2}S^3, & \mathbb{E}R^8 &\geq \frac{35}{8}S^4, \end{aligned} \quad (\text{III.90.21})$$

where $S = S(f)$. These particular numerical coefficients are not arbitrary estimates: they are $\binom{2k}{k}/2^k$ at $k = 1, 2, 3, 4$.

III.90.4 A rational certificate for the fourth-order gap

Proof of Theorem III.90.1. If $f = 0$, the result is immediate. Otherwise $S(f) > 0$ by Fourier inversion. Replace f by $S(f)^{-1/4}f$; it is enough to prove the statement under the normalization $S(f) = 1$.

For each $h \in G$ let

$$g_h(x) = f(x)f(x+h), \quad t(h) = R(h)^2, \quad w(h) = Q_2(g_h) - t(h)^2. \quad (\text{III.90.22})$$

The zero Fourier coefficient of g_h is $R(h)$, so $w(h) \geq 0$. Introduce the scalar moments

$$V = \mathbb{E}t^2, \quad B = \mathbb{E}t^3, \quad A = \mathbb{E}t^4, \quad W = \mathbb{E}w. \quad (\text{III.90.23})$$

By (III.90.21),

$$\mathbb{E}t = 1, \quad V \geq \frac{3}{2}, \quad B \geq \frac{5}{2}, \quad A \geq \frac{35}{8}. \quad (\text{III.90.24})$$

There is one more constraint linking W and V . The cube recursion gives

$$V + W = \mathbb{E}_h Q_2(g_h) = Q_3(f).$$

Apply the axis estimate (III.90.14) directly to f . Here its H equals $S(f) = 1$, and Fourier orthogonality with the even weights λ_ξ gives

$$\mathcal{E}(\lambda) = \mathbb{E}_h R(h)^4 = V.$$

Therefore

$$V + W \geq 2V - 1, \quad W \geq V - 1. \quad (\text{III.90.25})$$

Now apply Lemma III.90.4 to each g_h . Its variable v is $R(h)^4 = t(h)^2$, and its variable w is exactly that in (III.90.22). Averaging the result yields

$$Q_4(f) \geq \mathbb{E}[t^4 + 10t^2w + 2w^2]. \quad (\text{III.90.26})$$

We finish with a scalar inequality, retaining the mean and the next three moments of t . Set

$$a = \frac{99}{676}, \quad b = \frac{33}{26}, \quad P(t) = -\frac{1}{4}t^2 + bt - a. \quad (\text{III.90.27})$$

The exact identity

$$10t^2 - 4P(t) = 11 \left(t - \frac{3}{13} \right)^2 \quad (\text{III.90.28})$$

and $w \geq 0$ imply

$$t^4 + 10t^2w + 2w^2 \geq t^4 + 2(w + P(t))^2 - 2P(t)^2. \quad (\text{III.90.29})$$

The pointwise difference is $11w(t - 3/13)^2$, so the direction of this inequality does not depend on the sign of $P(t)$.

Expand the nonsquare terms:

$$t^4 - 2P(t)^2 = \frac{7}{8}t^4 + \frac{33}{26}t^3 - \frac{2277}{676}t^2 + 4abt - 2a^2. \quad (\text{III.90.30})$$

Taking expectations and applying Jensen only to the displayed square in (III.90.29), we obtain

$$\begin{aligned} Q_4(f) &\geq \frac{7}{8}A + \frac{33}{26}B - \frac{2277}{676}V + 4ab - 2a^2 \\ &\quad + 2 \left(W - \frac{1}{4}V + b - a \right)^2. \end{aligned} \quad (\text{III.90.31})$$

The coefficients of A and B are positive, permitting substitution of their lower bounds in (III.90.24). The expression in the last square is also positive, because

$$W - \frac{1}{4}V + b - a \geq \frac{3}{4}V + \frac{83}{676} > 0. \quad (\text{III.90.32})$$

It is therefore legitimate to replace W by its lower bound $V - 1$ in that square. After these substitutions, the right side of (III.90.31) is exactly

$$\frac{4795}{832} + \frac{3}{8} \left(V - \frac{3}{2} \right) + \frac{9}{8} \left(V - \frac{3}{2} \right)^2. \quad (\text{III.90.33})$$

This last equality is a rational polynomial identity, obtained by substituting the two fractions in (III.90.27); the supplementary verifier checks it using exact fraction arithmetic.

Since $V \geq 3/2$, both additional terms in (III.90.33) are nonnegative. We have proved $Q_4(f) \geq 4795/832$ under $S(f) = 1$. Restoring the scale proves (III.90.5), and monotonicity proves (III.90.6). $\square$

Several losses in this proof are visible and independently nonnegative: the discarded terms in the Fourier face sum, the unselected terms in the autocorrelation moments, $11w(t - 3/13)^2$, and the variance discarded by Jensen. Their equality conditions have not been jointly optimized. Accordingly, $4795/832$ is presented as an explicit improved certificate, not as the optimal fourth-order factor.

III.90.5 Why one Fourier pair ceases to be extremal

The exact third-order comparison in [202] is attained by real parts of characters. The fourth-order cube has more surviving frequency patterns, and these produce a first-order direction of improvement away from that family.

Let ξ have odd order $q \geq 3$ and fix $\theta \in \mathbb{R}$. For each integer j define the real function

$$\phi_j(x) = e^{ij\theta} \xi(x)^j + e^{-ij\theta} \xi(x)^{-j}. \quad (\text{III.90.34})$$

The index j is an integer exponent, not a claim that all these Fourier pairs are distinct. In particular, the possible aliases at orders five and seven will be treated explicitly by orthogonality.

For a real function u , define its fourth cube dual function by

$$\mathcal{D}_4 u(x) = \mathbb{E}_{h_1, h_2, h_3, h_4} \prod_{\substack{\omega \in \{0,1\}^4 \\ \omega \neq 0}} u(x + \omega \cdot h). \quad (\text{III.90.35})$$

Then $Q_4(u) = \mathbb{E}_x u(x) \mathcal{D}_4 u(x)$.

Lemma III.90.6 (Dual polynomial for a real character pair). *If $q \geq 5$ is odd, then*

$$\mathcal{D}_4 \phi_1 = 111\phi_1 + 27\phi_3 + \phi_5. \quad (\text{III.90.36})$$

In particular,

$$Q_2(\phi_1) = 2, \quad Q_4(\phi_1) = 222, \quad \mathbb{E} \phi_3 \mathcal{D}_4 \phi_1 = 54. \quad (\text{III.90.37})$$

Proof. Expand the fifteen factors in (III.90.35). A term is indexed by signs $\sigma_\omega \in \{-1, 1\}$, one for each nonzero vertex. If $j = \sum_{\omega \neq 0} \sigma_\omega$, that term contributes $e^{ij\theta} \xi(x)^j$ precisely when

$$\sum_{\omega \neq 0} \omega_i \sigma_\omega \equiv 0 \pmod{q} \quad (1 \leq i \leq 4). \quad (\text{III.90.38})$$

Each sum in (III.90.38) consists of eight signs and is an even integer between -8 and 8 . For odd $q \geq 5$, a nonzero multiple of q in this range cannot be even: the first possible nonzero even multiple has absolute value $2q \geq 10$. Thus the congruences are integer equalities, uniformly in all such q .

The number of integer-balanced sign assignments is recorded in Table III.90.1. An exact polynomial certificate for the count is

$$\begin{aligned} [z_1^4 z_2^4 z_3^4 z_4^4] \prod_{\omega \in \{0,1\}^4 \setminus \{0\}} \left(1 + y \prod_{i=1}^4 z_i^{\omega_i} \right) \\ = y^5 + 27y^6 + 111y^7 + 111y^8 + 27y^9 + y^{10}. \end{aligned} \quad (\text{III.90.39})$$

Indeed, a chosen subset of positive-sign vertices must contain four vertices with coordinate i equal to one, for each i . If the chosen subset has size k , its total sign sum is $j = 2k - 15$.

For clarity, the coefficient evaluation in (III.90.39) can be performed by the following finite integer recurrence. Begin with the coefficient 1 at $(k, u_1, u_2, u_3, u_4) = (0, 0, 0, 0, 0)$. For each successive nonzero vertex ω , copy each current coefficient to the unchanged index and add it at $(k + 1, u_1 + \omega_1, \dots, u_4 + \omega_4)$. Terms having some $u_i > 4$ may be discarded. After fifteen steps, the coefficients at $(k, 4, 4, 4, 4)$ are respectively 1, 27, 111, 111, 27, 1 for $k = 5, 6, 7, 8, 9, 10$, and zero otherwise. This specifies an exact integer evaluation of the displayed finite product; the supplied program also checks it independently by enumerating all 2^{15} sign assignments.

Total sign sum j	-5	-3	-1	1	3	5
Number of assignments	1	27	111	111	27	1

Table III.90.1: The fifteen-vertex integer-balanced sign count.

Grouping the opposite values of j proves (III.90.36), even when some resulting characters alias in the cyclic subgroup generated by ξ .

We now justify each orthogonality assertion required for (III.90.37). The two characters ξ and ξ^{-1} are distinct, so $Q_2(\phi_1) = 2$ and $\mathbb{E}\phi_1^2 = 2$. The exponents in $\phi_1\phi_3$ are $\pm 2, \pm 4$, and those in $\phi_1\phi_5$ are $\pm 4, \pm 6$. No odd $q \geq 5$ divides any of these nonzero exponents. Hence

$$\mathbb{E}\phi_1\phi_3 = \mathbb{E}\phi_1\phi_5 = 0, \quad Q_4(\phi_1) = 111 \cdot 2 = 222.$$

Similarly q does not divide 6, so $\mathbb{E}\phi_3^2 = 2$. The exponents in $\phi_3\phi_5$ are $\pm 2, \pm 8$; again no odd $q \geq 5$ divides them. It follows that $\mathbb{E}\phi_3\phi_5 = 0$ and

$$\mathbb{E}\phi_3\mathcal{D}_4\phi_1 = 27 \cdot 2 = 54.$$

In particular, at $q = 5$ the function ϕ_5 is constant, but its pairing with either centered ϕ_1 or ϕ_3 still vanishes. At $q = 7$ some exponent pairs are represented by negative residues; the divisibility checks just made show that this causes no additional nonzero pairing. No independence assumption about ϕ_1, ϕ_3, ϕ_5 has been used. $\square$

Proposition III.90.7 (A strict direction of improvement). *For every odd $q \geq 5$, the real centered functions $f_\varepsilon = \phi_1 - \varepsilon\phi_3$ satisfy*

$$Q_2(f_\varepsilon) = 2(1 + \varepsilon^4), \quad (\text{III.90.40})$$

$$Q_4(f_\varepsilon) = 222 - 864\varepsilon + O(\varepsilon^2) \quad (\varepsilon \rightarrow 0). \quad (\text{III.90.41})$$

Consequently $Q_2(f_\varepsilon)/Q_4(f_\varepsilon)^{1/4}$ is strictly larger than $2/222^{1/4}$ for all sufficiently small positive ε .

Proof. The character pairs $\{\xi, \xi^{-1}\}$ and $\{\xi^3, \xi^{-3}\}$ are disjoint: an intersection would imply $q \mid 2$ or $q \mid 4$. The second pair consists of two nontrivial, distinct characters because $q \nmid 3, 6$. Fourier inversion therefore gives (III.90.40) exactly, including when $q = 5$.

For any real functions u, v , differentiating the finite polynomial $Q_4(u + \varepsilon v)$ gives sixteen terms, according to the vertex at which v replaces u . Each equals $\mathbb{E}v\mathcal{D}_4u$. To see this directly, if that vertex is η , change variables by

$$x' = x + \eta \cdot h, \quad h'_i = (-1)^{\eta_i} h_i.$$

This is a bijection of G^5 and relabels the vertices by coordinatewise flipping at η . Since the functions are real, no conjugation changes the product. Thus

$$\left. \frac{d}{d\varepsilon} Q_4(u + \varepsilon v) \right|_{\varepsilon=0} = 16\mathbb{E}v\mathcal{D}_4u. \quad (\text{III.90.42})$$

Taking $u = \phi_1$, $v = -\phi_3$ and using Lemma III.90.6 gives the derivative $-16 \cdot 54 = -864$. This proves (III.90.41). The numerator in the quotient has derivative zero at the origin, while its positive denominator has a strictly negative derivative. The asserted improvement follows. $\square$

The notation $O(\varepsilon^2)$ here hides no limiting group argument: for each fixed function pair, $Q_4(f_\varepsilon)$ is an ordinary real polynomial of degree at most sixteen. The nonzero first derivative alone establishes a strict improvement on that same finite group.

Lemma III.90.8 (Order-three characters). *If ξ has order three, then*

$$Q_4(\phi_1) = 286 + 32 \cos(6\theta) + 16 \cos(12\theta) = 262 + 32 \left(\cos(6\theta) + \frac{1}{2} \right)^2. \quad (\text{III.90.43})$$

In particular $Q_4(\phi_1) \geq 262$, whereas $Q_2(\phi_1) = 2$.

Proof. At order three the integer-equality reduction used in (III.90.38) is unavailable, so expand the full sixteen-vertex cube instead. A sign assignment contributes precisely when its total sign sum and each of its four coordinate sign sums vanish modulo three. Its phase is $e^{ij\theta}$, where j is the total sign sum. Since j is even and $|j| \leq 16$, the only possible values are $-12, -6, 0, 6, 12$. Their counts are

$$\begin{array}{c|ccccc} j & -12 & -6 & 0 & 6 & 12 \\ \hline \text{count} & 8 & 16 & 286 & 16 & 8. \end{array} \quad (\text{III.90.44})$$

Here is an exact recurrence evaluating these five integers. Enumerate the sixteen vertices as $\omega^{(1)}, \dots, \omega^{(16)}$. Let $N_j(s, r)$ count sign choices on the first j vertices with total integer sign sum s and four coordinate sums $r \in (\mathbb{Z}/3\mathbb{Z})^4$. Begin with $N_0(0, 0) = 1$ and all other entries zero. At a new vertex ω , add each entry $N_j(s, r)$ to both

$$N_{j+1}(s+1, r+\omega) \quad \text{and} \quad N_{j+1}(s-1, r-\omega).$$

After sixteen steps, retain $N_{16}(s, 0)$ for $3 \mid s$; this gives exactly (III.90.44). The recurrence is the signed counterpart of (III.90.39) and uses only integer additions. Exhaustive enumeration of the 2^{16} choices in the supplementary program independently reproduces the same table.

The opposite values of j now combine to give the first expression in (III.90.43). Substituting $\cos(12\theta) = 2\cos(6\theta)^2 - 1$ gives its completed-square form. The second-order statement follows from the two distinct Fourier coefficients of modulus one. $\square$

Every nonzero real single-character function is a positive scalar multiple of some ϕ_1 in (III.90.34). Combining the last two lemmas shows

$$\sup_{\substack{G \text{ odd, } \xi \neq 0 \\ c \neq 0}} \frac{\|2 \operatorname{Re}(c\xi)\|_{U^2}^4}{\|2 \operatorname{Re}(c\xi)\|_{U^4}^4} = \frac{2}{222^{1/4}} = 0.5181335948243558 \dots \quad (\text{III.90.45})$$

The upper value is attained whenever the character order is at least five, but Proposition III.90.7 gives an improving perturbation. The order-three class has an even smaller upper bound $2/262^{1/4}$. Thus the same character-pair extremizer description that works at order three fails at order four.

III.90.6 An exact five-point certificate

We now give a fixed rational-valued function realizing a quotient larger than the whole class in (III.90.45). Its verification uses integer cube products and requires neither numerical Fourier transforms nor an optimization routine.

Proposition III.90.9 (A rational lower bound). *On $G = \mathbb{Z}/5\mathbb{Z}$, set*

$$(f(0), f(1), f(2), f(3), f(4)) = (2, 1, -2, -2, 1). \quad (\text{III.90.46})$$

Then $\mathbb{E}f = 0$ and

$$Q_2(f) = \frac{94}{25}, \quad Q_3(f) = \frac{19208}{625}, \quad Q_4(f) = \frac{6468874}{3125}. \quad (\text{III.90.47})$$

Consequently

$$\left(\frac{\|f\|_{U^2}^4}{\|f\|_{U^4}^4} \right)^4 = \frac{39037448}{404304625} > \frac{8}{111}. \quad (\text{III.90.48})$$

Proof. The five values sum to zero. For dimension d , enumerate the 5^{d+1} tuples $(x, h_1, \dots, h_d)$ and form the integer

$$p(x, h) = \prod_{\omega \in \{0,1\}^d} f(x + \omega \cdot h \bmod 5).$$

Let $H_d(z)$ be the number of tuples with $p(x, h) = z$. This defines a finite exact certificate:

$$\sum_z H_d(z) = 5^{d+1}, \quad Q_d(f) = 5^{-d-1} \sum_z z H_d(z). \quad (\text{III.90.49})$$

For $d = 2$, the nonzero entries of this histogram are

z	−8	−4	−2	1	4	8	16
$H_2(z)$	8	24	8	6	36	24	19.

Their weighted sum is 470, hence $Q_2 = 470/125 = 94/25$. For $d = 3$ the nonzero entries are

z	−32	−16	1	4	16	32	64	128	256
$H_3(z)$	96	80	8	32	168	64	128	16	33.

They have total multiplicity 625 and weighted sum 19208. The fourth-dimensional histogram is given in Table III.90.2. Its multiplicities sum to 3125, and their product-weighted sum is 6468874. Equation (III.90.49) therefore gives all three identities in (III.90.47).

Cube product z	Multiplicity $H_4(z)$
−2048	160
−1024	320
−512	160
−64	32
1	10
16	80
256	760
512	320
1024	800
2048	32
4096	320
16384	80
65536	51
Total multiplicity	3125

Table III.90.2: Exact fourth-cube certificate for (III.90.46).

For an explicit algorithm generating these tables, start each histogram empty; run $x, h_1, \dots, h_d$ independently through $0, 1, 2, 3, 4$; initialize a product to one; for every binary vector ω multiply it by the corresponding entry of (III.90.46); and increase the resulting product's histogram count by one. This enumerates every normalized cube tuple exactly once and performs only exact integer operations. The complete implementation is included with the article.

Finally, using (III.90.47) and reducing the fraction gives

$$\frac{(94/25)^4}{6468874/3125} = \frac{39037448}{404304625}.$$

Cross-multiplication shows that this exceeds $8/111$, which is the fourth power of (III.90.45). This proves (III.90.48). $\square$

[write] **7 October 2026; sources 40–46.** Recomputed at the write in exact rationals: $Q_2 = 94/25$, $Q_4 = 6468874/3125$, $Q_2^4/Q_4 = 39037448/404304625$, fourth root 0.5574336 . Sources 28 and 34 give 0.5587294 and the batch-121 certificate 0.5587725 .

The function has only two nontrivial Fourier pairs. To see its connection with Proposition III.90.7, choose $\xi(x) = e^{2\pi ix/5}$ and $\theta = 0$. Its coefficients at the two opposite pairs have values

$$a_1 = \frac{5 + 3\sqrt{5}}{10}, \quad a_2 = \frac{5 - 3\sqrt{5}}{10}.$$

Here $a_2 < 0$, and on $\mathbb{Z}/5\mathbb{Z}$ the real functions ϕ_2 and ϕ_3 coincide at this phase. Thus

$$f = a_1(\phi_1 - \varepsilon\phi_3), \quad \varepsilon = -\frac{a_2}{a_1} = \frac{7 - 3\sqrt{5}}{2} > 0.$$

This identifies the exact rational example as a concrete member of the improving two-pair family. Its cube values, however, were established above without relying on radicals or trigonometric rounding. Dividing f by two gives a real centered 1-bounded example with the same quotient.

Proof of Corollary III.90.2. Theorem III.90.1 bounds every quotient in (III.90.7) by $(832/4795)^{1/4}$. Proposition III.90.9 supplies the lower endpoint. Its strict inequality (III.90.48), together with the full single-pair envelope (III.90.45), excludes every real single-character function as a global maximizer. This proves all parts of the corollary. $\square$

III.90.7 Reproducibility and the remaining problem

The mathematical upper bound is proved for every finite odd-order abelian group by the preceding inequalities. Its validity does not depend on a search over groups or functions. The finite computations serve two specific purposes: evaluating the explicit cosine sign-count identities and verifying the exact five-point example. The rational scalar certificate is also checked independently.

From the extracted package directory, run

```
python3 code/verify_u4.py --json certificates/u4_certificate.json
```

The program uses the Python standard library. Integer sums and `fractions.Fraction` carry all mathematical checks; floating-point approximations are unnecessary. It refuses to run under `python -O` or `python -OO`, so its assertions cannot be silently disabled. The deterministic JSON report records the rational certificate, the cosine coefficient tables, and the complete cube histograms and weighted sums. Direct sign enumeration and coefficient dynamic programming independently verify (III.90.39).

The following questions remain specific to this norm comparison. First, determine the exact value of c_4^{odd} and whether the supremum over all finite groups is attained. Second, classify the frequency support and phases of any extremizing functions: the single-pair classification valid at order three has now been excluded at order four. Third, retain more of the nonnegative remainders in (III.90.9), (III.90.20), and (III.90.29) to improve the explicit upper endpoint. Fourth, determine dimension-dependent bounds for c_d^{odd} , rather than using the same fourth-order bound for every $d \geq 4$.

The results here resolve the sharpness question for the single-character candidate and tighten a quantitative question posed in the pinned report. They do not determine the optimal fourth-order constant, assert a global publication-priority claim for the comparison, or provide a new global bound for progression-free sets. The exact scope of the progress is the proved interval (III.90.8), the universal inequality (III.90.5), and the strict improving direction in Proposition III.90.7.

III.91 Applications to cube counting and structured holes

Source 45, delivered Section 5.

We make the relationship with Gowers’s Lemma 3.10 explicit. The cancellation and exact quartic coefficient in the next proposition are credited inputs from the previous ProveIt reports, especially sources 03, 04, 08, and 09 [202]. A short proof is included to make the new numerical substitution self-contained.

Let G be a finite abelian group of odd order, let $d \geq 2$, and put $q = 2^d$. For a real function W , write

$$Q_d(W) = \mathbb{E}_{x, h_1, \dots, h_d} \prod_{v \in \{0,1\}^d} W(x + v \cdot h) = \|W\|_{U^d}^q.$$

Suppose $W = \rho + f$, where $\rho \geq 0$, $f : G \rightarrow \mathbb{R}$, and $\mathbb{E}f = 0$. Set $u = \|f\|_{U^d}$.

Proposition III.91.1 (Credited exact fourth-order expansion). *With the preceding notation,*

$$Q_d(\rho + f) = \rho^q + P_d \rho^{q-4} \|f\|_{U^2}^4 + R_d, \quad (\text{III.91.1})$$

$$P_d = \frac{6^d - 2 \cdot 4^d + 2^d}{8}, \quad (\text{III.91.2})$$

$$|R_d| \leq \sum_{r=5}^q \binom{q}{r} \rho^{q-r} u^r. \quad (\text{III.91.3})$$

The sum in (III.91.3) is zero if its index set is empty.

Proof. For a subset S of the Boolean vertices, expand the product by choosing f at the vertices in S and ρ elsewhere. Any three distinct Boolean vertices give jointly uniform affine forms on every finite abelian group. To verify this, reflect coordinates to move one vertex to zero. The two other row vectors are distinct nonzero Boolean vectors. Their supports supply a 2×2 minor of determinant 1 or -1 : if neither support contains the other use one coordinate from each difference; if they are nested use one coordinate in the smaller support and one in the difference. The one- and two-vertex cases are immediate. Thus every centered term of degree one, two, or three vanishes.

Four distinct Boolean vertices that are affinely dependent over $\mathbb{R}$ form an ordinary parallelogram. Indeed their affine span is a plane, because any three are independent, and projection onto two suitable coordinates is injective on that plane. The four projected points must be the four Boolean corners of a square. The affine inverse preserves their parallelogram relation. Any three of the corresponding forms are jointly uniform, so the fourth-order correlation is exactly $\|f\|_{U^2}^4$.

If the four vertices are affinely independent, reflect the first to zero and select a nonsingular 3×3 Boolean minor B from the other rows. Its determinant has absolute value at most two. For completeness, border B by a row and column of ones and replace its entries by $1 - 2B_{ij}$. Subtracting the first row shows that the new 4×4 determinant has absolute value $8|\det B|$, whereas Hadamard's inequality bounds it by 16. Hence $\det B = \pm 1$ or ± 2 . These integers act invertibly on an odd-order group; the adjugate identity makes the selected coordinate map invertible. Consequently the four forms are jointly uniform and their centered correlation is zero.

There are six solutions to $a + b = c + e$ in $\{0, 1\}$, hence 6^d ordered solutions on the Boolean cube. The solutions with identical unordered pairs on both sides number $2 \cdot 4^d - 2^d$. Every remaining solution uses four distinct vertices. Every parallelogram support has eight orderings and a unique pairing into opposite vertices, proving (III.91.2). Finally, cube Cauchy–Schwarz bounds a term supported on r vertices by u^r , since the other factors are one. Summing over supports of size at least five gives (III.91.3). $\square$

Corollary III.91.2 (Improved leading coefficient for $d \geq 4$). *Put $\kappa = (832/4795)^{1/4}$. If $d \geq 4$, then*

$$0 \leq Q_d(\rho + f) - \rho^q \leq \kappa P_d \rho^{q-4} u^4 + \sum_{r=5}^q \binom{q}{r} \rho^{q-r} u^r. \quad (\text{III.91.4})$$

Proof. The lower bound follows from $\|\rho + f\|_{U^d} \geq |\mathbb{E}(\rho + f)| = \rho$. The fourth-uniformity inequality of Section III.90 and monotonicity imply

$$\|f\|_{U^2}^4 \leq \kappa \|f\|_{U^4}^4 \leq \kappa \|f\|_{U^d}^4.$$

Substitute this into (III.91.1) and use the remainder bound. $\square$

The first values are $P_2 = 1$, $P_3 = 12$, $P_4 = 100$, and $P_5 = 720$. In dimension four, (III.91.4) has leading coefficient

$$100\kappa = 64.5407010850\dots,$$

where using only $c_3^{\text{odd}} = 1/\sqrt{2}$ would give $100/\sqrt{2} = 70.7106781187\dots$. This is an improvement of about 8.73% in that coefficient. The cancellation of the first three orders and the value $P_4 = 100$ were already present in the report; the smaller multiplier is the present contribution. The best possible quartic coefficient for this uniformity comparison is $P_d c_d^{\text{odd}}$, which is still unknown when $d \geq 4$.

III.91.1 The indicator and uniformity-parameter formulation

For $A \subset G$, let $N = |G|$, $\rho = |A|/N$, and $f = \mathbf{1}_A - \rho$. The number of ordered additive d -cubes in A , including degenerate cubes, is $N^{d+1}Q_d(\mathbf{1}_A)$. If $\|f\|_{U^d}^q \leq \alpha$, then for $d \geq 4$,

$$\#\{\text{ordered additive } d\text{-cubes in } A\} \leq N^{d+1} \left[\rho^q + \kappa P_d \rho^{q-4} \alpha^{4/q} + \sum_{r=5}^q \binom{q}{r} \rho^{q-r} \alpha^{r/q} \right]. \quad (\text{III.91.5})$$

The displayed uniformity condition is α -uniformity of degree $d - 1$ in the normalization of Gowers's lemma and the inspected repository definitions. This is a finite-parameter inequality, with an explicit remainder. It does not merely assert a formal asymptotic expansion. At fixed $\rho > 0$, the leading excess has exponent $4/q$ in α . Gowers's Minkowski estimate uses $N^{d+1}(\rho + \alpha^{1/q})^q$ [1, Lemma 3.10]; the improved exponent from centering is credited to the preceding reports, and (III.91.5) tightens its leading constant.

III.91.2 How far this reaches in the original proof

The torsion-free results refine the extremal discussion immediately before Gowers's Theorem 7.2. If $E(A) > M_m - 8(m - 3)$ and $m \geq 5$, they identify A exactly as a progression or a progression with an endpoint-adjacent hole. This is substantially more precise information in that narrow regime than a general large-subset structural conclusion. The hypothesis is correspondingly much closer to the maximum. It supplies no improved exponent in the general Balog–Szemerédi reduction.

The coset and collision results concern the regime where an additive triple almost always completes, and distinguish exact puncture extremizers from other high-energy sets. They provide useful rigidity statements for the energy-conversion step. They do not identify a large linear or multilinear piece under an arbitrary fixed positive energy density. In particular, the present collision equality theorem is a domain theorem; additional label-compatibility hypotheses must be retained when a graph or a derivative label is part of an application.

To obtain a new global bound for Szemerédi's theorem one would have to show that a sharper local estimate changes a parameter that survives all the later restriction, recurrence, and density-increment losses. That propagation is not supplied here. The proven improvements are the explicit local inequalities and classifications stated above.

III.91.3 A bridge between the two energy endpoints

The ordered energy theorem also describes the first defect levels when the hole of a dense set is rectified. A *Freiman 2-isomorphism* is a bijection that preserves, in both directions, every relation $a + b = c + d$ among four elements of its domain.

Corollary III.91.3 (Rectified holes). *Let C be a finite subgroup coset, $K \subset C$, $|K| = u \geq 5$, and $A = C \setminus K \neq \emptyset$, with $|A| = m$. Suppose that K admits a Freiman 2-isomorphism ι to a subset of a torsion-free abelian group. Put $\delta = u/m$ and*

$$\varepsilon_0(m, u) = \delta(1 - \delta) + \frac{u^3 - M_u}{m^3} = \delta(1 - \delta) + \frac{\delta^3}{3} - \frac{\delta}{3m^2}.$$

Then the actual defect $\varepsilon = 1 - E(A)/m^3$ obeys the following alternatives:

- (i) *If $\iota(K)$ is an arithmetic progression, then $\varepsilon = \varepsilon_0(m, u)$.*
- (ii) *If $\iota(K)$ is a second-level model from Section II.184, then $\varepsilon = \varepsilon_0(m, u) + 4(u - 2)/m^3$.*
- (iii) *In all other cases, $\varepsilon \geq \varepsilon_0(m, u) + 8(u - 3)/m^3$.*

All three lower values are attained, for example, when C is cyclic of order $m + u > 2u + 2$, by placing the three model holes in an interval without additive wraparound.

Proof. The complement identity proved in Section II.185 is exact:

$$\varepsilon = \delta(1 - \delta) + \frac{u^3 - E(K)}{m^3}.$$

Energy is preserved by ι . Substitute the three alternatives of the torsion-free theorem. For attainment, the integer holes $\{0, \dots, u - 1\}$, $H_u = \{0, \dots, u - 2, u\}$, and $J_u = \{0, \dots, u\} \setminus \{2\}$ lie in $[0, u]$. Their pair sums lie in $[0, 2u]$, so reduction modulo $m + u > 2u + 2$ preserves all additive quadruples. Their complements give the stated values. $\square$

For example, a rectified hole of relative size δ has a forced additional defect asymptotic to $\delta^3/3$ beyond the coset envelope, whereas a subgroup-coset hole has no such additional defect. This gives a precise way to distinguish two possible geometries of the deleted part. No rectification is inferred from the energy hypothesis alone.

Part IV

Floor patterns and the Proposition 17.7 phase extraction

Contents. The number of floor patterns of subset sums, which controls how a cube meets a partition into progressions (Corollaries 17.5–17.6 and Proposition 17.7). Sections IV.1–IV.5: source 01, delivered Sections 9–13 (exact range factorization, quadratic-exponent upper and lower bounds, $\log_2 C_k \sim k^2$ via the classical threshold-function count, affine patterns and translation classes, polynomial features, certified $C_1, \dots, C_4 = 1, 2, 10, 154$). Section IV.6: source 04, delivered Section 8 (the same counts as F_k , the stronger elementary lower bound $2^{k(k-1)/2}$, exact modular range dependence, few profiles at a fixed slope, and a local phase-extraction theorem with coefficient $2^{-k^2-k \log_2 k - O(k)}$ at the stage of Proposition 17.7).

Overlaps. Sources 01 and 04 are independent manuscripts; they share only this count ($C_k = F_k$), which they prove independently with different certificate formats. Dated notes credit the shared lemmas and record that source 01’s asymptotic answers source 04’s Question 8.

Reading conventions of this Part (the full dictionary is Section F.3).

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
C_k, F_k, A_k	01: C_k fractional carry patterns, A_k affine patterns; 04: F_k (= 01’s C_k) and A_k (= 01’s A_k).
H_k, J_k, Q_k	Both: $H_k = (k-2)2^{k-1} + 1$; 01: $J_k = k2^{k-1}$; 04: $Q_k = k2^{k-1}$ (= 01’s J_k).
region bound	01: $\mathcal{R}(h, d) = \sum_{j \leq d} \binom{h}{j}$; 04: $R_d(H) = \sum_{j \leq d} \binom{H}{j}$. <i>The arguments are in the other order: 01’s $\mathcal{R}(H, d)$ is 04’s $R_d(H)$.</i>
B_k	01: translation budget $(2(k+1))^k \mathcal{R}(k2^{k-1}, k+1)$; 04: $(2k)^k R_{k+1}(k2^{k-1})$. <i>Different numbers</i> (note after Corollary IV.6.4).
ranges, M	01: coefficients in $(-r_i, r_i)$, M a modulus, T_n threshold counts, M_n nonnegative ones; 04: (a_i, b_i) with $m_i = b_i - a_i$, M a modulus, $\Omega_k = \{0, 1\}^k$, L labels and K local multiplicity in Lemma IV.6.6.

Added in the second write (6 October 2026): sources 06–10. Contents. Section IV.7: source 06, delivered Section 2 (exact separation of range and carries for every finite $V \subset \mathbb{Z}_{\geq 0}^k$ containing 0 and the unit vectors, the modular count $\min(2r, M)^k C(V; M)$, affine carries and translation classes, and $\log_2 C_k \sim k^2$ uniformly modulo every $M \geq 2$). Section IV.8: delivered Section 4 (localized phase removal at Proposition 17.7 with coefficient $2^{-2k^2 - O(k \log k)}$). Section IV.9: delivered Section 7 (the certified carry counts $C_0, \dots, C_4 = 1, 1, 2, 10, 154$ and $D_0, \dots, D_3 = 1, 2, 6, 38$, the uniformity and density checks, and the size of the improvements).

Overlaps (dated notes). The counts C_k are certified independently by sources 01 and 06 up to $k = 4$ ($C_4 = 154$ twice, with different certificate formats); D_k agrees with 04’s A_k for $k \leq 3$. Exact range scaling (01, 04, 06), the modular count (04, 06), general coefficient families (01’s polynomial features, 06’s V), $\log_2 C_k \sim k^2$ through the threshold-function count (01, 06). At Proposition 17.7 three coefficients are proved: 04’s $2^{-k^2-k \log_2 k - O(k)}$, 06’s $2^{-2k^2 - O(k \log k)}$, and 01’s weaker selection interface (note after Corollary IV.6.8).

Reading conventions for the sections of sources 06–10 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
C_k, D_k, L_k	06: C_k ($= 01$'s $C_k = 04$'s F_k), D_k affine carry patterns ($D_1, D_2, D_3 = 2, 6, 38 = 04$'s A_1, A_2, A_3), $C_{k,M}, D_{k,M}$ their reductions modulo M , $L_k(r, M)$ translation classes, $C(V), D(V)$ for a general family V .
$h_k, \tilde{h}_k, \mathcal{R}_d(m)$	06: $h_k = (k-2)2^{k-1} + 1$ ($= H_k$ of 01, 04), $\tilde{h}_k = k2^{k-1}$ ($= 01$'s J_k , 04's Q_k), $\mathcal{R}_d(m) = \sum_{j \leq d} \binom{m}{j}$ ($= 01$'s $\mathcal{R}(m, d) = 04$'s $R_d(m)$). <i>In $\mathcal{R}_d(m)$ the subscript is the dimension.</i>
$K_k, c_k, \mathcal{E}_d$	06: $K_k = (2(k+1))^k \mathcal{R}_{k+1}(k2^{k-1})$ ($= 01$'s B_k) and $c_k = 1/(8K_k^2)$; $\mathcal{E}_d(g) = p^{d+1} \ g\ _{U^d}^{2^d}$ an unnormalized cube energy; q, M, w, ℓ the partition scales. <i>06's c_k is not 04's c_k of Corollary IV.6.8; this $\mathcal{E}_d$ is none of the $\mathcal{E}$'s of Parts II–III.</i>
$T(n), T_+(n)$	06: the number of Boolean threshold functions and of those with nonnegative weights (01: T_n, M_n).

Added in the fourth write (6 October 2026): sources 15–20. Contents. Sections IV.10–IV.14 are source 16's chapter: a guide written for this report and its delivered Sections 2–5 (cube forms and the partition quotient; explicit polarization, a factorial criterion and a functional test over $\mathbb{F}_p$; sliding-window localization without carry patterns, with its width optimization and a local-scale ceiling; a refinement that keeps the original small cells).

Overlaps (dated notes). Proposition 17.7 now has four coefficients in this Part: source 16's $(4/(3(k+2)))^{k+2}$ (the strongest at every k), source 04's, source 06's and source 01's selection interface; the comparison in one normalization is the note after Corollary IV.6.8. Source 16's Section IV.14 repeats source 04's Lemmas IV.6.5–IV.6.6 (credited at both ends); its polarization is source 04's and the formal development's. The carry-pattern counts of this Part stay needed for Corollaries 17.5–17.6.

Reading conventions for the sections of sources 15–20 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
windows	16: N prime, $m = 2h + 1$, $\mathcal{C}_j(u) = N^{j+1} \ u\ _{U^j}^{2^j}$, $\mathcal{B}_k(g; \mathcal{Q}, U)$ the partition quotient with normalization bound U (<i>not 01's or 04's B_k; U is the formal $l + 1$</i>), $c_k = (4/(3(k+2)))^{k+2}$ (<i>not 04's or 06's c_k</i>), $R = kh$, $w = N/M$, $U = \lceil w \rceil$, S_t windows, $\mathcal{P}_j$ partitions, $D(a) = \sum_i a_i $, $T = (k+2)h$, $A_d(L)$ interval cube counts, R_0 and L active and global pattern counts (04's 2^k and L), $\mathcal{C}$ conjugation.

Added in the seventh write (6 October 2026): sources 34–39. Contents. Sections IV.15–IV.24: a guide and source 36's delivered Sections 2–10 (normalization and the cube identity; the sharp bilinear estimate; the derivative rank profile; the symmetry threshold; equality and stability; lossless polarization and the Section 17 interface; robust and local variants; multiaffine selectors and extension fields; small characteristic).

Overlaps (dated notes). Source 36's bilinear estimate sharpens source 31's noncommuting-subgroup gap, and its threshold at $k = 1$ is a vector-space analogue of source 29's symmetry step; it cites neither. **Cross-source answers.** None; its questions are new (items IV.8 and IV.9).

Reading conventions for the sections of sources 34–39 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
Section 17	36: $V = \mathbb{F}_p^n$, p odd, $\sigma : V^k \rightarrow V^*$ a multilinear selector, T its scalar $(k+1)$ -linear form, $\mathcal{A}_f(\sigma)$ the tested energy, $\vartheta_{k,p} = 1 - (1 - 1/p)^k$, $\mathbf{h}, \mathbf{u}$ tuples, $\mathcal{Q}_B$ a bilinear functional (<i>not $\mathbb{Q}$</i>), rad the radical (<i>not $\mathbb{R}$</i>), r half-ranks, P the canonical polynomial, $e_p(t) = e^{2\pi it/p}$.

Added in the eighth write (7 October 2026): sources 40–46. Contents. Sections IV.25–IV.41: a guide, source 46’s Sections 2–9 (conventions and the first integration obstruction; the exact binary mixed cubic norm; restriction, agreement and stability; constructive integration and phase order; all-characteristic scalar polarization; trace-multiplication tensors; restriction dimensions and repair costs; Gowers’s derivative-spectrum step) and source 43’s Sections 2–9 (cube identities and phase invariance; division-free finite-abelian orthogonality; symmetry thresholds on finite abelian groups; Boolean nonclassical integration; the shear identity and Boolean certification; exact cubic obstruction ranks; mixed correlations; the quartic frontier).

Overlaps (dated notes). Sources 43 and 46 prove the same cubic theorem and the same improvement of Tidor’s codimension independently; source 43’s orthogonality and symmetry threshold extend source 36’s to every finite abelian group. **Cross-source answers.** Source 36’s characteristic-two question is answered for symmetric trilinear forms by sources 46 and 43, and its nonclassical and composite questions are advanced by source 43 (item IV.9).

IV.1 Fractional carry patterns and exact range dependence

Source 01, delivered Section 9.

We turn to the floor-pattern interface. For $k \geq 1$ and $x = (x_1, \dots, x_k) \in [0, 1)^k$, define

$$c_x(S) = \left\lfloor \sum_{i \in S} x_i \right\rfloor, \quad S \subseteq [k], \quad C_k = \#\{c_x : x \in [0, 1)^k\}. \quad (\text{IV.1.1})$$

The values at the empty set and at singletons are always zero. We call c_x a *fractional carry pattern*. The terminology refers only to this finite function; no probabilistic assumption on x is made. For completeness set $C_0 = 1$.

IV.1.1 Why boundary points do not introduce extra patterns

A hyperplane-region count normally concerns strict inequalities. Floor functions also take values on the hyperplanes, so that issue must be settled before counting chambers.

Lemma IV.1.1 (Positive perturbation). *Every fractional carry pattern has a representative $y \in (0, 1)^k$ such that $\sum_{i \in S} y_i$ is nonintegral for every nonempty $S \subseteq [k]$.*

Proof. Given $x \in [0, 1)^k$, put $y_i = x_i + \varepsilon$. There are finitely many coordinates and subset sums. Choose $\varepsilon > 0$ so small that $x_i + \varepsilon < 1$ for every i and

$$|S|\varepsilon < \left\lfloor \sum_{i \in S} x_i \right\rfloor + 1 - \sum_{i \in S} x_i \quad (\emptyset \neq S \subseteq [k]).$$

Every right-hand side is strictly positive, including when the subset sum is an integer. The perturbation moves the sum positively but not to the next integer. Its floor is unchanged, and it is no longer an integer. All coordinates become strictly positive. $\square$

Theorem IV.1.2 (Exact separation of the coefficient range). *Let $r_1, \dots, r_k$ be positive integers and let $\mathcal{F}(\mathbf{r})$ be the family of functions*

$$S \mapsto \left\lfloor \sum_{i \in S} \alpha_i \right\rfloor, \quad -r_i < \alpha_i < r_i.$$

Then

$$|\mathcal{F}(\mathbf{r})| = \left(\prod_{i=1}^k 2r_i \right) C_k. \quad (\text{IV.1.2})$$

Proof. Write $\alpha_i = m_i + x_i$, where $m_i = \lfloor \alpha_i \rfloor$ and $x_i \in [0, 1)$. Necessarily

$$m_i \in \{-r_i, -r_i + 1, \dots, r_i - 1\}.$$

For every subset,

$$F_\alpha(S) = \sum_{i \in S} m_i + c_x(S). \quad (\text{IV.1.3})$$

The singleton values of F_α recover all m_i ; after subtracting their subset sums, they also recover c_x . Thus this decomposition is injective as a coding of the resulting functions.

Conversely, take any permitted integer vector m and any carry pattern. By Lemma IV.1.1, choose a representative $x \in (0, 1)^k$. Then $-r_i < m_i + x_i < r_i$ for every i , even when $m_i = -r_i$. Equation (IV.1.3) realizes the chosen pair. Hence there is a bijection between the pattern family and the Cartesian product of the integer vectors with the C_k carry patterns. $\square$

The endpoint convention is essential for the exact statement. The proof handles the open interval $(-r_i, r_i)$ precisely because each fractional pattern admits an interior representative. For nonintegral range bounds $R_i > 0$, replacing r_i by $\lceil R_i \rceil$ gives an immediate upper bound, but generally not the same exact factorization.

IV.1.2 A hyperplane-arrangement upper bound

Inside the open unit cube, a nonempty subset S produces integer threshold hyperplanes

$$\sum_{i \in S} x_i = j, \quad 1 \leq j \leq |S| - 1.$$

There are exactly

$$H_k = \sum_{\emptyset \neq S \subseteq [k]} (|S| - 1) = k2^{k-1} - (2^k - 1) = (k - 2)2^{k-1} + 1 \quad (\text{IV.1.4})$$

such hyperplanes. Different subsets have different normal vectors, and none of these hyperplanes is a duplicate of another.

Lemma IV.1.3 (Region bound). *The number of regions cut out by h affine hyperplanes in $\mathbb{R}^d$ is at most*

$$\mathcal{R}(h, d) = \sum_{j=0}^d \binom{h}{j}.$$

The same bound holds for their regions restricted to an open convex set.

Proof. Let $R(h, d)$ be the maximal possible number of regions. When one adds a hyperplane, each newly created region comes from splitting an old region that meets it. The old hyperplanes induce on the new hyperplane an arrangement of at most $h - 1$ hyperplanes in dimension $d - 1$; coincident or empty intersections create no additional regions. Therefore

$$R(h, d) \leq R(h - 1, d) + R(h - 1, d - 1).$$

The initial values $R(0, d) = 1$ and $R(h, 0) = 1$, together with Pascal's identity, prove the bound by induction. A region is an intersection of open half-spaces and is convex. Intersecting it with an open convex set cannot split it into several nonempty connected pieces, so restriction cannot increase the number. $\square$

Theorem IV.1.4 (Quadratic-exponent carry bound). *For every $k \geq 1$,*

$$C_k \leq \mathcal{R}(H_k, k). \quad (\text{IV.1.5})$$

For $k \geq 3$ this implies

$$\log_2 C_k \leq k^2 + (\log_2 e - 1)k. \quad (\text{IV.1.6})$$

Proof. Lemma IV.1.1 realizes every carry pattern off the threshold hyperplanes. Off those hyperplanes, the floor values determine, and are determined by, the sides of all the listed integer thresholds. A given sign pattern is an intersection of open half-spaces with the cube and is convex. Thus distinct carry patterns correspond exactly to nonempty regions of this arrangement inside the open cube. Apply Lemma IV.1.3.

For $h \geq k \geq 1$, set $t = k/h \leq 1$. Then

$$t^k \sum_{j=0}^k \binom{h}{j} \leq \sum_{j=0}^k \binom{h}{j} t^j \leq (1 + t)^h \leq e^k.$$

Hence $\mathcal{R}(h, k) \leq (eh/k)^k$. For $k \geq 3$, $H_k \geq k$ and $H_k \leq k2^{k-1}$. Substitute these inequalities and take binary logarithms. $\square$

Corollary IV.1.5 (A strengthened floor-pattern bound). *For positive integers r_i ,*

$$|\mathcal{F}(\mathbf{r})| \leq \left(\prod_i 2r_i \right) \mathcal{R}(H_k, k).$$

In particular, for $r_i = r$ and $k \geq 3$,

$$\log_2 |\mathcal{F}(r, \dots, r)| \leq k \log_2(2r) + k^2 + (\log_2 e - 1)k. \quad (\text{IV.1.7})$$

Proof. Combine Theorems IV.1.2 and IV.1.4. $\square$

k	H_k	old log bound, $r = 1$	new log bound, $r = 1$
2	1	16	3.000
3	5	54	7.700
4	17	128	15.650
8	769	1024	69.358
12	20481	3456	155.025
16	458753	8192	272.667

Table 5: Binary logarithms of the bounds 2^{2k^3} and $2^k \mathcal{R}(H_k, k)$ for the coefficient range $(-1, 1)^k$. These upper bounds are not asserted to be exact counts.

IV.2 Lower bounds and the optimal entropy scale

Source 01, delivered Section 10.

IV.2.1 An elementary independent-choice construction

Theorem IV.2.1 (Elementary quadratic-exponent lower bound). *For $k \geq 1$,*

$$C_k \geq 2^{\lfloor k^2/4 \rfloor}. \quad (\text{IV.2.1})$$

Proof. The assertion for $k = 1$ is immediate. Write $k = m + n$ with $m, n \geq 1$. Use m anchor coordinates

$$x_j = \frac{2^{j-1}}{2^m} \quad (1 \leq j \leq m).$$

Their subset sums are precisely $t/2^m$, for $0 \leq t \leq 2^m - 1$. For each of the remaining n coordinates independently choose

$$y_i = \frac{h_i + 1/2}{2^m}, \quad 0 \leq h_i \leq 2^m - 1.$$

For an anchor subset with sum $t/2^m$,

$$\left\lfloor y_i + \frac{t}{2^m} \right\rfloor = \begin{cases} 0, & h_i + t < 2^m, \\ 1, & h_i + t \geq 2^m. \end{cases}$$

This threshold, as t ranges over all anchor subset sums, recovers h_i : for $h_i = 0$ there is no value 1, and otherwise the first value 1 occurs at $t = 2^m - h_i$. Therefore different choices of the vector $(h_1, \dots, h_n)$ give different carry patterns. There are 2^{mn} choices. Taking $m = \lfloor k/2 \rfloor$ and $n = \lceil k/2 \rceil$ proves the theorem. $\square$

This construction is independent of any threshold-function enumeration. Together with (IV.1.6), it already determines the order $\log C_k = \Theta(k^2)$ by elementary arguments.

IV.2.2 Embedding Boolean threshold functions

Let T_n denote the number of Boolean linear threshold functions on $\{0, 1\}^n$ admitting a strict representation

$$g(\varepsilon) = \mathbf{1}_{\sum_i w_i \varepsilon_i > t}, \quad \sum_i w_i \varepsilon_i \neq t \text{ for all } \varepsilon.$$

Let M_n count the nonconstant such functions with a representation using nonnegative weights. We need only a simple relation between these two counts and carry patterns.

Lemma IV.2.2 (Thresholds inject into one higher carry dimension). *For every $n \geq 1$,*

$$C_{n+1} \geq M_n \geq 2^{-n}T_n - 2. \quad (\text{IV.2.2})$$

Proof. If a coefficient w_i is negative, replace the Boolean variable ε_i by $1 - \varepsilon_i$ and adjust the constant threshold. This makes that coefficient nonnegative. Thus every threshold function is a coordinate-flipped version of a nonnegative-weight threshold function, with at most 2^n choices of coordinate flips. Including the two constant functions gives $T_n \leq 2^n(M_n + 2)$.

For the first inequality, fix a nonconstant nonnegative-weight threshold function. Strictness and nonconstancy imply $0 < t < \sum_i w_i$. Choose $c > 0$ such that $c \sum_i w_i < 1$, and set

$$x_0 = 1 - ct, \quad x_i = cw_i \quad (1 \leq i \leq n).$$

All coordinates lie in $[0, 1)$, and $x_0 \in (0, 1)$. For $S \subseteq [n]$, the sum $x_0 + \sum_{i \in S} x_i$ lies strictly between 0 and 2, is not 1, and satisfies

$$\left\lfloor x_0 + \sum_{i \in S} x_i \right\rfloor = \mathbf{1}_{\sum_{i \in S} w_i > t}.$$

Therefore the carry pattern restricted to subsets containing coordinate 0 recovers the original Boolean function. Distinct functions have distinct resulting carry patterns, regardless of the chosen strict representations and sufficiently small scaling constants. $\square$

The classical external input is

$$\log_2 T_n = n^2 - n \log_2 n + O(n). \quad (\text{IV.2.3})$$

The leading n^2 asymptotic is due to Zuev; the refinement in (IV.2.3) is attributed to Kahn–Komlós–Szemerédi. Baldi and Vershynin explicitly record both results and also recover the leading asymptotic as the degree-one case of their theorem [8, Section 1.4 and Theorem 1.1]. We use this input, rather than claiming to reprove it; the original references are [9, 10].

Theorem IV.2.3 (Optimal leading carry entropy). *Using the classical input (IV.2.3),*

$$k^2 - k \log_2 k - O(k) \leq \log_2 C_k \leq k^2 + (\log_2 e - 1)k. \quad (\text{IV.2.4})$$

In particular $\log_2 C_k \sim k^2$. Consequently, for arbitrary positive integer ranges $r_1, \dots, r_k$,

$$\log_2 |\mathcal{F}(\mathbf{r})| = \sum_{i=1}^k \log_2(2r_i) + k^2 + o(k^2), \quad (\text{IV.2.5})$$

where the error depends only on k , not on the ranges.

Proof. For $n = k - 1$, Lemma IV.2.2 and (IV.2.3) give

$$\log_2 C_k \geq (k - 1)^2 - (k - 1) \log_2(k - 1) - O(k).$$

The subtraction of two constant functions is negligible at this scale, and the factor 2^{-n} costs only $O(k)$ in the logarithm. The right side is $k^2 - k \log_2 k - O(k)$. Combine this with Theorem IV.1.4. Finally take logarithms in the exact identity (IV.1.2); its range term has no approximation error. $\square$

The leading coefficient 1 in (IV.2.4) is therefore settled by the stated classical input. The present estimates leave a possible $k \log k$ correction unresolved. For a completely elementary version of the article, omit (IV.2.3) and replace the asymptotic claim by the bounds in (F.6.5); every local density theorem is unaffected.

[write] 6 October 2026. This theorem answers source 04's Question 8 (dated note there, Section V.17): source 04's F_k is C_k and its A_k is the A_k of Section IV.3. Source 04's elementary lower bound $F_k \geq 2^{k(k-1)/2}$ (Theorem IV.6.2) is stronger than Theorem IV.2.1 for every $k \geq 3$ (note there).

[write] 6 October 2026; sources 06–10. Source 06's Theorem IV.7.6 proves the same leading entropy through the same external threshold-function count (Zuev), and extends it: $\log_2 C_{k,M}$ and $\log_2 D_{k,M}$ are $(1 + o(1))k^2$ uniformly in the modulus $M \geq 2$, and so is the number $L_k(r, M)$ of translation classes. It does not state the secondary term $-k \log_2 k - O(k)$ given here. Credited to both.

IV.3 Affine patterns, translation classes, and general features

Source 01, delivered Section 11.

IV.3.1 Fractional affine offsets

For $t = (t_0, t_1, \dots, t_k) \in [0, 1)^{k+1}$ define

$$a_t(S) = \left\lfloor t_0 + \sum_{i \in S} t_i \right\rfloor, \quad A_k = \#\{a_t : t \in [0, 1)^{k+1}\}.$$

Here $a_t(\emptyset) = 0$. Let

$$J_k = \sum_{S \subseteq [k]} |S| = k2^{k-1} \quad (k \geq 1). \quad (\text{IV.3.1})$$

Theorem IV.3.1 (Affine fractional-pattern bound). *For $k \geq 1$,*

$$C_k \leq A_k \leq \mathcal{R}(J_k, k+1). \quad (\text{IV.3.2})$$

In particular, with the classical input of Theorem IV.2.3, $\log_2 A_k \sim k^2$.

Proof. Taking $t_0 = 0$ shows $A_k \geq C_k$. For the upper bound, perturb all $k+1$ coordinates by a common sufficiently small positive number. Each nonempty affine sum increases by $(|S|+1)\varepsilon$ but does not reach the next integer, and t_0 remains less than one. Thus every pattern has an interior representative off all integer threshold hyperplanes. For each subset S the internal thresholds are

$$t_0 + \sum_{i \in S} t_i = j, \quad 1 \leq j \leq |S|.$$

Their number is J_k . Apply Lemma IV.1.3 in dimension $k+1$. For $k \geq 2$, $J_k \geq k+1$, and the binomial-sum estimate gives

$$\log_2 A_k \leq (k+1) \log_2 \frac{ek2^{k-1}}{k+1} = k^2 + O(k).$$

Use the lower bound from C_k for the leading asymptotic. □

IV.3.2 Reduction modulo a modulus and quotienting by translations

For a positive integer M , let $\mathcal{A}_M(\mathbf{r})$ consist of

$$S \mapsto \left[\alpha_0 + \sum_{i \in S} \alpha_i \right] \pmod{M}, \quad \alpha_0 \in \mathbb{R}, \quad -r_i < \alpha_i < r_i.$$

The group $\mathbb{Z}/M\mathbb{Z}$ acts on these functions by adding a constant to all values. This action preserves the family, since α_0 is unrestricted.

Theorem IV.3.2 (Modulus-free translation-class budget). *For positive integers r_i and M ,*

$$|\mathcal{A}_M(\mathbf{r})| \leq M \left(\prod_i 2r_i \right) \mathcal{R}(J_k, k+1), \quad (\text{IV.3.3})$$

$$|\mathcal{A}_M(\mathbf{r})/(\mathbb{Z}/M\mathbb{Z})| \leq \left(\prod_i 2r_i \right) \mathcal{R}(J_k, k+1). \quad (\text{IV.3.4})$$

Proof. Write $\alpha_0 = m_0 + t_0$ and $\alpha_i = m_i + t_i$ with fractional parts in $[0, 1)$. Every pattern equals

$$m_0 + \sum_{i \in S} m_i + a_t(S) \pmod{M}.$$

There are M choices of m_0 modulo M , at most $\prod_i 2r_i$ integer coefficient vectors, and A_k fractional affine patterns. This proves (IV.3.3).

Every translation orbit has a unique representative with value zero at the empty set: subtract the original value there. This cancels m_0 while retaining the information in t_0 . The remaining possibilities are counted by at most $(\prod_i 2r_i) A_k$. Apply Theorem IV.3.1. Equivalently, the constant-translation action is free, as can be checked at the empty set, so every orbit has exactly M members. $\square$

For $M = 1$, the actual orbit count is one; the inequality remains valid. One must not model translation classes by simply discarding the fractional part of the affine offset. Canonical normalization at the empty set removes the *integer* constant modulo M , not its fractional part. Modular collisions may make either inequality strict, which is why no exact product formula is asserted in this affine modular setting.

IV.3.3 The combinatorial input for phase removal

At the relevant floor-pattern step of the proof of Proposition 17.7, the cell-index maps have affine subset-sum form, with coefficient range bounded by $k+1$ [1, proof of Proposition 17.7]. Consequently a valid translation-class budget is

$$B_k = (2(k+1))^k \mathcal{R}(k2^{k-1}, k+1). \quad (\text{IV.3.5})$$

Its logarithm is at most $k^2 + k \log_2 k + O(k)$, rather than a cubic polynomial. The following elementary statement makes precise what substituting this budget does, and what it does not do.

Proposition IV.3.3 (A transparent selection interface). *Suppose $z_1, \dots, z_L \in \mathbb{C}$ and $|\sum_{\ell=1}^L z_\ell| \geq U$. Then some ℓ satisfies $|z_\ell|^2 \geq U^2/L^2$. If the terms are indexed by translation classes from Theorem IV.3.2 with $r_i = k+1$, the denominator may be replaced by B_k^2 . More generally, any correctly established estimate $E \geq K/L^2$, with $K \geq 0$ and L the actual number of such classes, implies $E \geq K/B_k^2$.*

Proof. The triangle inequality gives $U \leq \sum_{\ell} |z_{\ell}| \leq L \max_{\ell} |z_{\ell}|$. Square, and then use $L \leq B_k$ from Theorem IV.3.2. The last assertion follows because $x \mapsto x^{-2}$ is decreasing for positive x . Zero classes cannot carry positive U ; the vacuous zero-signal case is handled separately. $\square$

[write] **6 October 2026; sources 15–20.** Source 16’s Theorem F.21.1 avoids pattern counts at this step altogether (Section IV.10).

Thus the combinatorial L^{-2} loss at this interface has a budget $2^{-2k^2 - 2k \log_2 k - O(k)}$. This is a local substitution conditional on the other estimates in the application being valid. We do not promote it to an improved version of every quantitative statement in Sections 17–18: localization, phase removal, uniformity normalization, and the earlier structural parameters must all be propagated separately.

IV.3.4 Nonnegative integer features and effective rank

The Boolean cube is not essential to the upper-bound mechanism. Let $V \subseteq \mathbb{N}^k \setminus \{0\}$ be a finite set of row vectors and consider

$$x \mapsto (\lfloor v \cdot x \rfloor)_{v \in V}, \quad x \in [0, 1]^k.$$

Put $H(V) = \sum_{v \in V} (\|v\|_1 - 1)$ and $d = \dim_{\mathbb{R}} \text{span } V$.

Proposition IV.3.4 (Rank-sensitive feature bound). *The number of these patterns is at most $\mathcal{R}(H(V), d)$. If V contains every coordinate unit vector, allowing $\alpha_i \in (-r_i, r_i)$ multiplies the number of fractional patterns by exactly $\prod_i 2r_i$.*

Proof. Every nonzero row has positive dot product with the all-ones vector. The common positive perturbation of Lemma IV.1.1 therefore preserves all floors while removing every integral equality and every boundary coordinate. Row v contributes at most $\|v\|_1 - 1$ internal integer hyperplanes; duplicates can only reduce the count. The linear map $x \mapsto (v \cdot x)_{v \in V}$ has rank d . Its image of the open cube is an open convex set relative to its d -dimensional image, and the relevant threshold hyperplanes restrict to affine hyperplanes in that image. Lemma IV.1.3 proves the bound. For the last assertion, $v \cdot m$ is an integer and the unit-vector coordinates recover m_i . Interior representatives prove surjectivity exactly as in Theorem IV.1.2. $\square$

Example IV.3.5 (Why arbitrary signed features need a boundary argument). Near $x = 0$, the map $x \mapsto (\lfloor x \rfloor, \lfloor -x \rfloor)$ has three patterns: $(0, -1)$ for $x > 0$, $(-1, 0)$ for $x < 0$, and $(0, 0)$ at zero. The one hyperplane has only two open regions. Thus a chamber count alone misses a floor pattern when opposite orientations occur. A sufficient replacement for nonnegative rows is a common direction u with $v \cdot u > 0$ for every row, together with room to perturb the parameter domain in that direction. Without such a condition one must count the relevant boundary strata as well.

[write] **6 October 2026; sources 06–10.** Source 06’s Theorem IV.7.3 is the same separation of range and carries for any finite $V \subset \mathbb{Z}_{\geq 0}^k$ that contains 0 and the unit vectors, with the modular count $\min(2r, M)^k C(V; M)$ and the region bound $\mathcal{R}_k(h(V))$ in the ambient dimension k ; Proposition IV.3.4 is rank-sensitive (the dimension d of the feature span). Both sources make the same point about signed families (the example above; the paragraph after source 06’s theorem).

IV.4 A polynomial generalization on the Boolean cube

Source 01, delivered Section 12.

The feature bound also gives an extension in which the input dimension and coefficient dimension are different. It is useful when a localization step produces low-degree polynomial floor functions rather than affine ones.

Fix $1 \leq d \leq n$ and a positive integer r . Let $\mathcal{P}_{n,d}(r)$ be the family of integer-valued functions on $\{0, 1\}^n$ of the form

$$\varepsilon \mapsto \left\lfloor \sum_{\substack{S \subseteq [n] \\ |S| \leq d}} \alpha_S \prod_{i \in S} \varepsilon_i \right\rfloor, \quad -r < \alpha_S < r. \quad (\text{IV.4.1})$$

The constant monomial corresponds to $S = \emptyset$. Put

$$m = \sum_{j=0}^d \binom{n}{j}, \quad H_{n,d} = \sum_{j=1}^d \binom{n}{j} 2^{n-j}.$$

Let $T(n, d)$ count strict Boolean polynomial threshold functions of degree at most d ; on a Boolean cube a polynomial can be multilinearized without changing its values or increasing its degree.

Theorem IV.4.1 (Polynomial floor-pattern entropy). *For $1 \leq d \leq n$ and positive integer r ,*

$$T(n, d) \leq |\mathcal{P}_{n,d}(r)| \leq (2r)^m \mathcal{R}(H_{n,d}, m). \quad (\text{IV.4.2})$$

For fixed $d \geq 1$, using the polynomial threshold-function theorem of Baldi–Vershynin, if $r = r(n)$ is a positive integer with $\log r = o(n)$, then

$$\log_2 |\mathcal{P}_{n,d}(r)| = (1 + o(1)) n \sum_{j=0}^d \binom{n}{j} = (1 + o(1)) \frac{n^{d+1}}{d!}. \quad (\text{IV.4.3})$$

Proof. Index coefficient space by the m monomials of degree at most d . For an input ε , the evaluation vector has entries $\prod_{i \in S} \varepsilon_i \in \{0, 1\}$. It is nonzero because of the constant monomial. The sum of its coordinates counts the active monomials at ε . Summing the number of internal thresholds over all inputs gives

$$\sum_{\varepsilon \in \{0,1\}^n} (\#\{S : |S| \leq d, S \subseteq \text{supp } \varepsilon\} - 1) = \sum_{j=1}^d \binom{n}{j} 2^{n-j} = H_{n,d}.$$

Separate each coefficient into an integer part and a fractional part. There are at most $(2r)^m$ integer vectors. For each vector, fractional patterns are bounded by the hyperplane count in dimension m , using positive perturbation and Lemma IV.1.3. This proves the upper bound. It does not assert that different integer vectors always give disjoint pattern families.

For the lower bound, take a strict multilinear polynomial threshold function, represented by a polynomial p with no zero values on the Boolean cube. Multiply p by a sufficiently small positive c so that every coefficient of cp lies in $(-r, r)$ and $0 < |cp(\varepsilon)| < 1$ at every input. Then

$$\lfloor cp(\varepsilon) \rfloor = \begin{cases} -1, & p(\varepsilon) < 0, \\ 0, & p(\varepsilon) > 0. \end{cases}$$

Thus the integer-valued floor function encodes the threshold function. Distinct threshold functions give distinct floors.

For fixed d , the external theorem gives $\log_2 T(n, d) = (1 + o(1))nm$ [8, Theorem 1.1]. For sufficiently large n , $H_{n,d} \geq m$ and $H_{n,d} \leq 2^n m$. The binomial estimate from Theorem IV.1.4 therefore yields

$$\log_2 |\mathcal{P}_{n,d}(r)| \leq m \log_2(2r) + m \log_2(eH_{n,d}/m) \leq nm + m \log_2(2r) + m \log_2 e.$$

Since $\log r = o(n)$, this matches the lower bound to leading order. Finally $m = (1 + o(1))n^d/d!$ for fixed d . $\square$

The finite upper bound in (IV.4.2) is elementary; only the matching leading lower asymptotic uses the external threshold theorem. This generalization also shows why using the square of the coefficient dimension as a universal exponent can be wasteful: for $d > 1$, the sharp leading entropy is on the scale n^{d+1} rather than $m^2 \asymp n^{2d}$.

IV.5 Exact finite enumeration and reproducible checks

Source 01, delivered Section 13.

IV.5.1 Small carry counts

Proposition IV.5.1 (Certified small dimensions). *The first four carry counts are*

$$C_1 = 1, \quad C_2 = 2, \quad C_3 = 10, \quad C_4 = 154. \quad (\text{IV.5.1})$$

The first three values have the elementary proof below. The fourth is proved by an exhaustive finite rational-certificate enumeration supplied with this article; its certificate format and exact verification argument are given in the following subsection.

Proof of the first three values. For $k = 1$ every floor is zero. For $k = 2$, only $\lfloor x_1 + x_2 \rfloor \in \{0, 1\}$ varies, and both values occur.

For $k = 3$, Lemma IV.1.1 allows us to avoid integral sums. If $x_1 + x_2 + x_3 < 1$, every pair floor is zero. If the total is greater than 2, every pair sum is greater than 1, since the remaining coordinate is less than 1. These give two patterns. When the total lies in $(1, 2)$, all eight assignments of pair floors occur. Up to coordinate permutations, representatives with respectively zero, one, two, and three pair floors equal to one are

$$(0.4, 0.4, 0.4), \quad (0.7, 0.5, 0.1), \quad (0.8, 0.4, 0.4), \quad (0.6, 0.6, 0.6).$$

There are $1 + 3 + 3 + 1 = 8$ such pair patterns, all with total floor one. The two outer patterns are realized by $(0.1, 0.1, 0.1)$ and $(0.9, 0.9, 0.9)$. Hence $C_3 = 10$. $\square$

For example, Theorem IV.1.2 now gives exactly $C_4(2r)^4 = 154(2r)^4$ patterns with four coefficients in $(-r, r)$. At $r = 1$ the exact count is 2464, while the simple new arrangement upper bound is 51424. No assertion is made that these finite values or their sequence have not appeared elsewhere.

[write] **6 October 2026.** $C_1, C_2, C_3 = 1, 2, 10$ are certified independently in source 04 (as F_1, F_2, F_3 , Section IV.6), together with $A_1, A_2, A_3 = 2, 6, 38$. $C_4 = 154$ is certified only here. At intake the sequence

1, 2, 10, 154 matched only OEIS A134088 (1, 1, 2, 10, 154, 7994, $\dots$, a power-series coefficient sequence); its next term 7994 differs from the uncertified recount $C_5 = 8410$ (note in Section IV.6), so the match looks like a coincidence. 2, 6, 38 gave no relevant hit. This is the intake’s search of 6 October 2026, not repeated at the write; nothing was submitted to the OEIS.

[write] 6 October 2026; sources 06–10. *Stale since the second write: $C_4 = 154$ is also certified by source 06.* The sentence “ $C_4 = 154$ is certified only here” was true of sources 01–05. Source 06 certifies $C_0, \dots, C_4 = 1, 1, 2, 10, 154$ and $D_0, \dots, D_3 = 1, 2, 6, 38$ with its own exact format (215 rational chamber witnesses and 1,165 nonnegative dual certificates, checked by a standard-library verifier; Section IV.9), so $C_4 = 154$ is now certified twice, independently. Source 06’s D_k (affine carries $\lfloor t_0 + v \cdot t \rfloor$) is the A_k here and in source 04 for $k \leq 3$ by the values; source 06 does not compute $D_4 = A_4$ or C_5 , which remain uncertified (Section V.2, item IV.2).

IV.5.2 A solver-independent rational certificate

Order the H_k hyperplanes by increasing binary mask of S , and then by increasing integer threshold. Build a binary tree of strict signs. For each partial sign word, use variables $z = (x_1, \dots, x_k, \epsilon)$ and inequalities

$$\begin{array}{ll} -x_i + \epsilon \leq 0, & x_i + \epsilon \leq 1, \\ v \cdot x + \epsilon \leq j & \text{for the sign } v \cdot x < j, \\ -v \cdot x + \epsilon \leq -j & \text{for the sign } v \cdot x > j. \end{array}$$

Write this finite system as $Az \leq b$. A sign word is strictly feasible exactly when this system has a solution with $\epsilon > 0$.

There are two certificate types. A *primal certificate* is a rational vector z satisfying $Az \leq b$ and $z_{k+1} > 0$. A *dual certificate* is a rational vector $\lambda \geq 0$ satisfying

$$\lambda^T A = (0, \dots, 0, 1), \quad \lambda^T b \leq 0. \quad (\text{IV.5.2})$$

The latter proves that every solution of $Az \leq b$ has $\epsilon = \lambda^T Az \leq \lambda^T b \leq 0$, so the sign word is strictly infeasible. This implication needs no floating-point tolerance and no appeal to an optimizer’s status message.

The generator uses a numerical linear program only to propose rational primal or dual vectors. Every proposal is checked with exact rational arithmetic before being accepted. It branches both ways at every feasible partial word and never branches below an infeasible word. The verifier reconstructs all inequalities from the sign words, checks every rational identity, checks that both children of every feasible nonterminal node are present, and rejects extra or unreachable nodes. It then counts feasible leaves. By induction on tree depth, this is an exhaustive count of all regions in the open cube. Theorem IV.1.4’s region-pattern correspondence turns that count into C_k .

IV.5.3 Commands and the limits of computational evidence

From the package directory, verification uses only the Python standard library:

```
python code/carry_certificates.py verify certificates/carry.json
```

Regeneration additionally needs NumPy and SciPy:

Dimension k	Hyperplanes H_k	Certificate records	Feasible leaves C_k
1	0	1	1
2	1	3	2
3	5	49	10
4	17	2061	154

Table 6: Exact certificate results in `certificates/carry.json`. The count of records includes both primal and dual certificates.

```
python code/carry_certificates.py generate --max-k 4 \
--out certificates/carry.json
```

The supplementary checks use NumPy and SymPy:

```
python code/check_refinements.py
```

They verify six symbolic identities, 210 broken-chord parameter cases, 210 equality constructions, 175 maximum-density root cases, 2000 sampled weighted-cell inequalities, and 24 concrete progression-partition cases. The parameter grids and random seed are fixed in the script. These are useful error detectors, not substitutes for the general proofs. In contrast, the finite carry enumeration has exact certificates for every branch and a mathematical completeness argument, though its implementation is still ordinary Python rather than kernel-checked proof code.

The verifier is independent of the numerical optimizer, not an independent second implementation of every aspect of the encoding. Its small trusted computational core includes Python integer and rational arithmetic, the constraint generator, and the tree checks. This makes the remaining trust boundary explicit.

IV.6 Floor patterns and efficient extraction of a progression profile

Source 04, delivered Section 8.

Corollaries 17.5 and 17.6 of Gowers’s paper bound the number of functions obtained by taking integer parts of linear expressions on a Boolean cube [1]. These estimates control the number of ways that a cube can meet a partition into arithmetic progressions. We isolate the fractional parts of the coefficients, determine the exact dependence on their integer ranges, and prove matching quadratic orders of magnitude for the logarithm of the remaining complexity. A second observation reduces the loss incurred when selecting one progression profile.

The edited repository already uses a joint hyperplane count in its proof of Proposition 17.7 [23]. The refinements below go further by separating integer and fractional parameters and distinguishing the number of globally possible profiles from the number possible at a fixed slope. The arguments establish the stated bounds; they do not establish historical priority for these elementary refinements.

IV.6.1 Fractional patterns and their boundary values

Write $\Omega_k = \{0, 1\}^k$ and put

$$F_k = \# \left\{ (\lfloor \epsilon \cdot t \rfloor)_{\epsilon \in \Omega_k} : t \in [0, 1)^k \right\},$$

$$A_k = \# \left\{ (\lfloor t_0 + \epsilon \cdot t \rfloor)_{\epsilon \in \Omega_k} : (t_0, t) \in [0, 1)^{k+1} \right\}.$$

Set $F_0 = A_0 = 1$, and define

$$R_d(H) = \sum_{j=0}^d \binom{H}{j}, \quad H_k = (k-2)2^{k-1} + 1, \quad Q_k = k2^{k-1},$$

where $\binom{H}{j} = 0$ for $j > H$.

[write] **6 October 2026.** *Source defect corrected in the write.* In both rows of the display above (first wording “In both displays above”, corrected after the independent check of 6 October 2026) the delivered source writes the subscript `\_epsilon\in\Omega\_k`, without the backslash before `epsilon`, so the delivered PDF prints the word “epsilon”; the intended $\epsilon \in \Omega_k$ is restored here. Notation: F_k is source 01’s C_k , A_k is source 01’s A_k , Q_k is source 01’s J_k , and $R_d(H)$ is source 01’s $\mathcal{R}(H, d)$, with the arguments in the other order.

Lemma IV.6.1 (Boundary removal). *Every pattern counted by F_k or A_k has a representative in the open parameter cube which lies on none of its nonconstant integer-threshold hyperplanes.*

Proof. Add a sufficiently small positive multiple of the all-ones vector to the parameters. Every nonconstant form under consideration increases strictly. An integer value moves into the interior of the same floor interval; a noninteger value remains in its floor interval if the step is sufficiently small. There are finitely many forms and every coordinate is initially less than 1, so one positive step works for all forms and coordinates. The identically zero form in the definition of F_k requires no adjustment. $\square$

Theorem IV.6.2 (Quadratic order of fractional complexity). *For every $k \geq 1$,*

$$2^{k(k-1)/2} \leq F_k \leq R_k(H_k), \quad \prod_{j=0}^{k-1} (2^j + 1) \leq A_k \leq R_{k+1}(Q_k). \quad (\text{IV.6.1})$$

Consequently $\log_2 F_k = \Theta(k^2)$ and $\log_2 A_k = \Theta(k^2)$. In particular,

$$F_k \leq e^k 2^{k(k-1)} \quad (k \geq 3), \quad A_k \leq e^{k+1} 2^{k^2-1} \quad (k \geq 2). \quad (\text{IV.6.2})$$

Proof. For a nonempty subset $S \subseteq \{1, \dots, k\}$ of size s , the form $\sum_{i \in S} t_i$ crosses precisely the possible thresholds $1, \dots, s-1$ inside the open cube. The resulting arrangement has

$$\sum_{s=1}^k \binom{k}{s} (s-1) = k2^{k-1} - (2^k - 1) = H_k$$

hyperplanes. A pattern is constant in each chamber. Its strict feasible region is an intersection of open halfspaces and is therefore convex, so a single pattern cannot occupy two chambers. Lemma IV.6.1 also accounts for all patterns originally attained on boundaries. Thus F_k is the number of chambers

meeting the open cube. The standard arrangement bound, also stated as Lemma 17.4 in [1], gives $F_k \leq R_k(H_k)$.

With an intercept, the form $t_0 + \sum_{i \in S} t_i$ has thresholds $1, \dots, s$, and there are $Q_k = \sum_s s \binom{k}{s}$ relevant hyperplanes in dimension $k+1$. This gives the bound for A_k . For $H \geq d \geq 1$, $R_d(H) \leq (eH/d)^d$: apply $(1+u)^H \leq e^{Hu}$ with $u = d/H$, observing that $u^j \geq u^d$ for $j \leq d$. Applying this with $H_k/k \leq 2^{k-1}$ and $Q_k/(k+1) \leq 2^{k-1}$ proves (IV.6.2).

For the lower bound, fix one pattern counted by F_{k-1} . Its region contains a nonempty open set. Choose a representative in that set whose 2^{k-1} subset sums have pairwise distinct fractional parts. Such a choice is possible because the prohibited equalities are finitely many proper hyperplanes

$$\sum_i (\epsilon_i - \epsilon'_i) t_i = j, \quad \epsilon \neq \epsilon', \quad j \in \mathbb{Z}.$$

Only finitely many j can occur in the bounded parameter cube. In particular, no nonempty subset sum has fractional part zero. As t_k varies through $(0, 1)$, each nonempty old subset sum produces one jump, at $1 - \{\sum_{i \in S} t_i\}$. The $2^{k-1} - 1$ jump locations are distinct, and hence there are 2^{k-1} different extension patterns. Extensions of different old patterns remain different on the face $\epsilon_k = 0$. Therefore $F_k \geq 2^{k-1} F_{k-1}$, which proves the first lower bound.

For A_k , choose an old representative for which the 2^{k-1} affine sums $t_0 + \sum_{i \in S} t_i$ have distinct nonzero fractional parts. Varying t_k now gives 2^{k-1} distinct jumps and $2^{k-1} + 1$ extensions. Thus $A_k \geq (2^{k-1} + 1) A_{k-1}$, proving the second lower bound. $\square$

[write] **6 October 2026.** *Credits and a comparison.* The upper bound $F_k \leq R_k(H_k)$ is source 01's Theorem IV.1.4, and $F_k \leq e^k 2^{k(k-1)}$ is the same as 01's $\log_2 C_k \leq k^2 + (\log_2 e - 1)k$; the affine upper bound is 01's Theorem IV.3.1. The lower bound $2^{k(k-1)/2}$ is stronger than source 01's elementary $2^{\lfloor k^2/4 \rfloor}$ (Theorem IV.2.1) for every $k \geq 3$, and equal to it for $k = 1, 2$. *Proof:* $k(k-1)/2 - k^2/4 = k(k-2)/4$, which is positive for $k \geq 3$, and $\lfloor k^2/4 \rfloor \leq k^2/4$; for $k = 1, 2$ both exponents are 0 and 1. The product lower bound for A_k is source 04's alone. Using the classical threshold-function count, source 01 proves $\log_2 F_k \sim k^2$ and $\log_2 A_k \sim k^2$ (Theorems IV.2.3 and IV.3.1). This answers Question 8 below (dated note there).

IV.6.2 Exact dependence on integer ranges

Theorem IV.6.3 (Integer-part scaling). *Let $a_i < b_i$ be integers and $m_i = b_i - a_i$. The number of functions*

$$\epsilon \mapsto \left\lfloor \sum_{i=1}^k \epsilon_i \alpha_i \right\rfloor, \quad \alpha_i \in (a_i, b_i),$$

is exactly $F_k \prod_i m_i$. In particular, the count in Gowers's Corollary 17.5 is exactly $(2r)^k F_k$ for a positive integer r .

Let $F_{k,M}$ count the fractional patterns in the definition of F_k after reduction modulo a positive integer M . The corresponding number of functions with values in $\mathbb{Z}/M\mathbb{Z}$ is exactly

$$F_{k,M} \prod_{i=1}^k \min(m_i, M). \tag{IV.6.3}$$

Moreover, $F_{k,M} = F_k$ whenever $M \geq k$.

Proof. Write $\alpha_i = n_i + t_i$, where $n_i = \lfloor \alpha_i \rfloor$ and $0 \leq t_i < 1$. Then

$$\lfloor \epsilon \cdot \alpha \rfloor = \epsilon \cdot n + \lfloor \epsilon \cdot t \rfloor.$$

The singleton values recover n_i exactly, since $\lfloor t_i \rfloor = 0$. Subtracting their linear contribution recovers the fractional pattern. Conversely, every fractional pattern has an interior representative by Lemma IV.6.1; this representative works in every integer cell, including those with an excluded left endpoint. There are precisely $\prod_i m_i$ integer choices.

Modulo M , the same singleton argument recovers the residues of the n_i , and each interval of m_i consecutive integers has $\min(m_i, M)$ residues. Subtracting these residues recovers the fractional residue pattern, proving (IV.6.3). Finally, every fractional floor belongs to $\{0, \dots, k-1\}$; reduction modulo $M \geq k$ is injective on this range. $\square$

For arbitrary real endpoints, the same argument gives the upper bound $F_k \prod_i (\lceil b_i \rceil - \lfloor a_i \rfloor)$; equality need not hold because the extreme integer cells may be truncated.

[write] **6 October 2026.** With $a_i = -r_i$, $b_i = r_i$ the first assertion is source 01's Theorem IV.1.2, by the same decomposition and interior-representative argument (source 01's Lemma IV.1.1 is Lemma IV.6.1); the arbitrary integer intervals and the modular count (IV.6.3) are source 04's.

Corollary IV.6.4 (Affine modular bound). *With the integer endpoints of Theorem IV.6.3, let α_0 vary over all real numbers. The number of functions*

$$\epsilon \mapsto \lfloor \alpha_0 + \epsilon \cdot \alpha \rfloor \pmod{M}$$

is at most $MA_k \prod_i \min(m_i, M)$. The number of equivalence classes under addition of a common constant is at most $A_k \prod_i \min(m_i, M)$. Both assertions remain valid if every slope interval (a_i, b_i) is replaced by $[a_i, b_i]$.

Proof. Writing $\alpha_0 = n_0 + t_0$ gives

$$\lfloor \alpha_0 + \epsilon \cdot \alpha \rfloor = n_0 + \epsilon \cdot n + \lfloor t_0 + \epsilon \cdot t \rfloor.$$

Choose $n_0 \pmod{M}$, the allowed slope residues, and one of the A_k fractional patterns. This proves the upper bound. Translation by a constant acts freely, as seen at $\epsilon = 0$, and all M translates occur by changing n_0 .

To handle closed slope intervals, move each endpoint slope inward with velocity $d_i = 1$ at a_i and $d_i = -1$ at b_i , leaving other slopes fixed. Move t_0 upward with velocity $k+1$. Every affine form has strictly positive velocity $k+1 + \epsilon \cdot d \geq 1$. A sufficiently small movement preserves every floor and keeps $t_0 < 1$, while moving all slope endpoints into the open intervals. $\square$

In the symmetric case, Corollary IV.6.4 replaces the bound $M2^{2r(k+1)^3}$ in Gowers's Corollary 17.6 by

$$M \min(2r, M)^k R_{k+1}(k2^{k-1}).$$

The dependence on r is polynomial, and the exponent governing the fractional complexity is quadratic in k . Theorem IV.6.2 shows that this quadratic order cannot be reduced to $o(k^2)$.

[write] **6 October 2026.** Source 01's Theorem IV.3.2 gives the two bounds of Corollary IV.6.4 with $\prod_i 2r_i$ and $\mathcal{R}(k2^{k-1}, k+1)$ in place of $\prod_i \min(m_i, M)$ and A_k ; source 04's are never larger. *Notation clash* B_k . Source 01's translation budget $B_k = (2(k+1))^k \mathcal{R}(k2^{k-1}, k+1)$ (IV.3.5) and source 04's $B_k = (2k)^k R_{k+1}(k2^{k-1})$ (Theorem IV.6.7) differ. Source 01 uses Gowers's coefficient range $k+1$ with open intervals; source 04 uses the closed slope interval $[-k, k]$ of its phase-extraction proof, through the closed-interval clause of this corollary. Both are valid under their hypotheses. Source 04's is smaller by the factor $((k+1)/k)^k < e$.

IV.6.3 Small cases with exact certificates

The first values are

k	1	2	3
F_k	1	2	10
A_k	2	6	38

For example, in the definition of F_3 the three pair-sum threshold indicators attain all eight Boolean patterns. If all three are zero, the total floor can be 0 or 1; if all are one, it can be 1 or 2. For each of the other six patterns, the total floor is 1. This gives $F_3 = 2 + 2 + 6 = 10$. Similarly, the two singleton values for A_2 give two possibilities for the pair value when they agree and one when they disagree, giving $A_2 = 6$.

The accompanying files `pattern_census.py` and `pattern_census.json` certify all six counts. The arrangement is constructed one hyperplane at a time, and both possible children of every surviving chamber are checked. For a system of strict inequalities $Cx < b$, a feasible branch has a rational point satisfying all inequalities strictly. An infeasible branch has rational weights $y \geq 0$ satisfying

$$\sum_i y_i = 1, \quad C^T y = 0, \quad b^T y \leq 0.$$

Multiplying the strict inequalities by these weights would yield $0 < b^T y \leq 0$, a contradiction. All 450 branch certificates are checked with exact fractions. Numerical linear programming proposes the certificates during generation; the verifier itself uses only Python's standard library and runs with

```
python -S pattern_census.py --verify pattern_census.json
```

[write] **6 October 2026.** Source 01 certifies the same F_1, F_2, F_3 (its C_k) and also $C_4 = F_4 = 154$ (Proposition IV.5.1), with a different certificate format. The census is shipped as `code/04-restriction-cubes-pattern_census.py` with `data/04-restriction-cubes-pattern_census.json`; the command above runs on a copy with the delivered names (README). At intake an independent recount reproduced $C_1, \dots, C_4$ and A_1, A_2, A_3 , and found $C_5 = 8410$ and $A_4 = 770$. It used value-branching floating-point linear programs and re-evaluated every feasibility witness exactly, but the infeasibility side rests on floating-point solver status, so these two values are *not certified*; they are recorded in Section V.2, item IV.2. They are consistent with the bounds: $2^{10} = 1024 \leq C_5 \leq R_5(H_5) = R_5(49) = 2138410$ and $2 \cdot 3 \cdot 5 \cdot 9 = 270 \leq A_4 \leq R_5(Q_4) = R_5(32) = 242825$.

[write] **6 October 2026; sources 06–10.** Source 06 (Section IV.9) certifies $C_4 = 154$ independently of source 01, and $D_1, D_2, D_3 = 2, 6, 38$ (its affine carry counts, the A_k here); it does not compute C_5 or $D_4 = A_4$, so the two intake values stay uncertified.

IV.6.4 Few profiles at a fixed slope

Lemma IV.6.5 (Intercept profiles). *For fixed $c \in \mathbb{R}^k$, the functions*

$$\epsilon \mapsto \lfloor \beta + \epsilon \cdot c \rfloor, \quad 0 \leq \beta < 1,$$

take at most 2^k different values. The same bound holds after reduction modulo M . Over the integers the count is exactly one plus the number of distinct nonzero fractional parts among the nonempty subset sums $\epsilon \cdot c$.

Proof. Each noninteger subset sum gives one jump in $(0, 1)$, at $1 - \{\epsilon \cdot c\}$. Integer subset sums give no interior jump. There are at most $2^k - 1$ distinct jump locations. The floor function is right-continuous, so a jump does not create an extra isolated pattern. Reduction modulo M can only identify patterns. Generic slopes make all subset sums distinct modulo 1, showing that the integer bound is sharp. $\square$

Lemma IV.6.6 (Extraction from locally few classes). *Let $z_{s,a}$ be complex numbers on finite index sets, with each pair (s, a) assigned one of L labels. Suppose that at most K labels occur for each fixed a . Set*

$$E = \sum_a \left| \sum_s z_{s,a} \right|^2, \quad E_j = \sum_a \left| \sum_{s: j(s,a)=j} z_{s,a} \right|^2.$$

Then $E \leq K \sum_j E_j$, and some label satisfies $E_j \geq E/(KL)$.

Proof. For each a , apply Cauchy–Schwarz to its at most K class sums. Sum over a , then average over the L labels. $\square$

[write] **6 October 2026; sources 15–20.** Source 16’s Lemma IV.14.1 and Proposition IV.14.2 reprove Lemma IV.6.5, this lemma and the first inequality of Theorem IV.6.7, without credit (note there).

IV.6.5 A quantitative local phase-extraction statement

Here is a precise form of the improvement at the stage of Proposition 17.7. For a function u on $G = \mathbb{F}_p$, write

$$\mathcal{U}_s(u) = \sum_{x, h_1, \dots, h_s \in G} \prod_{\omega \in \Omega_s} \mathcal{C}^{|\omega|} u(x - \omega \cdot h),$$

where $\mathcal{C}$ denotes complex conjugation. This quantity is nonnegative; it is $p^{s+1} \|u\|_{U^s}^2$. We use the usual Gowers–Cauchy–Schwarz inequality for its mixed version [1, Lemma 3.8].

Theorem IV.6.7 (Local extraction with a quadratic exponential loss). *Let $k \geq 1$, let $p > k + 1$ be prime, and let $m = 2h + 1 > 3k$ satisfy $m \leq \sqrt{p}$. Put $I = \{-h, \dots, h\} \subseteq G$. Let $r \in G^k$, let $\tau : G^k \rightarrow G$ be a multi-affine polynomial, and let $f : G \rightarrow \mathbb{C}$. For $\epsilon \in \Omega_k$, put $f_\epsilon(s) = f(s - \epsilon \cdot r)$. Suppose $\alpha > 0$ and*

$$\sum_{a \in I^k} \left| \sum_{s \in G} e_p(-s\tau(a)) \prod_{\epsilon \in \Omega_k} \mathcal{C}^{|\epsilon|} f_\epsilon(s - \epsilon \cdot a) \right|^2 \geq \alpha p^2 m^k, \quad e_p(t) = \exp(2\pi i t/p). \quad (\text{IV.6.4})$$

Set

$$q = \lceil h/k \rceil, \quad M = \lfloor p/q \rfloor, \quad B_k = (2k)^k R_{k+1} (k2^{k-1}).$$

There is a polynomial P of degree at most $k + 1$ and a partition $(R_i)_{i \in \mathbb{Z}/M\mathbb{Z}}$ into modular arithmetic progressions of lengths q or $q + 1$, each at least $m/(3k)$, such that

$$\sum_i \mathcal{U}_{k+1}(1_{R_i} f e_p(-P)) \geq \frac{\alpha p^2 m^k}{2^k B_k M} \geq \frac{\alpha}{9k^2 2^k B_k} m^{k+2} M. \quad (\text{IV.6.5})$$

Proof. Put $w = p/M$. Since $q \leq \sqrt{p}$, division $p = qM + r_0$ gives $0 \leq r_0 < q \leq M$. The intervals

$$Q_i = \{x \in \{0, \dots, p-1\} : iw \leq x < (i+1)w\}, \quad 0 \leq i < M,$$

therefore form a partition with lengths q or $q+1$. Also $w \geq q \geq h/k \geq m/(3k)$, where the last inequality follows from $h = (m-1)/2$ and $m \geq 3$.

For each (s, a) , the unique progression profile of its cube is

$$j_{s,a}(\epsilon) = \lfloor s/w - \epsilon \cdot a/w \rfloor \pmod{M}.$$

This formula is valid across modular wraparound because $p/w = M$. Normalize by subtracting $j_{s,a}(0)$. The resulting profile has intercept $\{s/w\}$ and slopes $-a_i/w \in [-k, k]$. Corollary IV.6.4 gives at most $L \leq B_k$ normalized profiles globally. Lemma IV.6.5 gives at most 2^k for each fixed a .

Apply Lemma IV.6.6 to the integrand in (IV.6.4). There is a normalized profile $j : \Omega_k \rightarrow \mathbb{Z}/M\mathbb{Z}$ whose class sum has squared energy at least $\alpha p^2 m^k / (2^k L)$. Write this class sum as a sum over its M translates. A further Cauchy–Schwarz inequality gives

$$\sum_i \sum_{a \in I^k} |T_i(a)|^2 \geq \frac{\alpha p^2 m^k}{2^k L M}, \quad (\text{IV.6.6})$$

where

$$T_i(a) = \sum_s e_p(-s\tau(a)) \prod_{\epsilon \in \Omega_k} \mathcal{C}^{|\epsilon|} (1_{Q_{j(\epsilon)+i}} f_\epsilon)(s - \epsilon \cdot a).$$

The identity of this expression with the class sum uses the disjointness of the Q_i : exactly one product of their indicators is nonzero for any given (s, a) .

Extend the sum in (IV.6.6) to all $a \in G^k$, which increases it. We record the phase decomposition explicitly. For suitable polynomials P_ω of degree at most $k+1$,

$$u\tau(a) = \sum_{\omega \in \Omega_{k+1}} (-1)^{|\omega|} P_\omega(s - \omega \cdot (a, u)). \quad (\text{IV.6.7})$$

Indeed, expand τ into squarefree monomials. For a monomial involving the coordinates indexed by $J \subseteq \{1, \dots, k+1\}$, use

$$\prod_{j \in J} b_j = \frac{1}{|J|!} \sum_{\nu \in \{0,1\}^J} (-1)^{|\nu|} \left(s - \sum_{j \in J} \nu_j b_j \right)^{|J|}.$$

Here J includes the coordinate of u ; all required factorials are invertible because $p > k+1$. Adding these identities proves (IV.6.7).

Expand $|T_i(a)|^2$ and write its two base points as s and $s - u$. Using (IV.6.7) makes the resulting expression the mixed $(k+1)$ -cube form of

$$h_{i,\omega} = 1_{Q_{j(\epsilon)+i}} f_\epsilon e_p(-P_\omega), \quad \omega = (\epsilon, b), \quad b \in \{0, 1\}.$$

Gowers–Cauchy–Schwarz and the arithmetic–geometric mean inequality give

$$\sum_{a \in G^k} |T_i(a)|^2 \leq \prod_{\omega} \mathcal{U}_{k+1}(h_{i,\omega})^{1/2^{k+1}} \leq 2^{-(k+1)} \sum_{\omega} \mathcal{U}_{k+1}(h_{i,\omega}).$$

For a fixed ω , summing over i permutes all blocks, so that $\sum_i \mathcal{U}_{k+1}(h_{i,\omega})$ is independent of $j(\epsilon)$. Averaging over ω and using (IV.6.6) produces one $\omega = (\epsilon, b)$ with

$$\sum_i \mathcal{U}_{k+1}(1_{Q_i} f_{\epsilon} e_p(-P_{\omega})) \geq \frac{\alpha p^2 m^k}{2^k L M}.$$

Finally put $t = \epsilon \cdot r$, replace $P_{\omega}(z)$ by $P_{\omega}(z + t)$, and translate every block by $-t$. Translation invariance of the cube form gives the first inequality in (IV.6.5). The second follows from $L \leq B_k$ and $p/M = w \geq m/(3k)$. $\square$

Corollary IV.6.8 (Explicit strict nonuniformity coefficient). *Under Theorem IV.6.7, the coefficient*

$$c_k = \frac{1}{18k^2 2^k (2k)^k R_{k+1} (k2^{k-1})}$$

gives strict failure of the inequality $\sum_i \mathcal{U}_{k+1}(1_{R_i} f_{\epsilon} e_p(-P)) \leq c_k \alpha m^{k+2} M$. For $k \geq 2$,

$$\log_2(1/c_k) \leq k^2 + k \log_2 k + (2 + \log_2 e)k + 2 \log_2 k + \log_2(9e).$$

Proof. The lower bound in (IV.6.5) is twice the proposed threshold and is positive. The logarithmic estimate follows from $R_{k+1}(Q_k) \leq (eQ_k/(k+1))^{k+1} \leq e^{k+1} 2^{k^2-1}$. $\square$

This gives a local coefficient of size $2^{-k^2 - k \log_2 k - O(k)}$ at the stage where Proposition 17.7 uses $2^{-2(k+1)^3}$. The statement above specifies the field characteristic and the multi-affine extension used in the phase argument. It does not recompute the later inverse-theorem induction or the final bound for $r_k(N)$. Those are separate problems, and the local improvement alone does not supply a new global quantitative Szemerédi theorem.

[write] 6 October 2026. *Compared with the formal statement* (checked at HEAD): `proposition_17_7` (Sections17_18.lean, line 140; exact companion `proposition_17_7_holds`, `Proofs17LocalizedPhaseRemoval.lean`, line 2900) has the coefficient $2^{-2(k+1)^3}$. Its proof already bounds the profiles by a joint region count (`hyperplaneRegionCount`), as said at the start of this section. Source 01's Proposition IV.3.3 is a weaker selection interface at the same step: its loss is B_k^2 with source 01's B_k , against $2^k B_k$ here. Not formalized; nothing is propagated to Theorem 18.1, which is open in the ledger.

[write] 6 October 2026; sources 06–10. *A third coefficient (source 06).* Source 06's Theorem IV.8.1 proves the localized phase removal with $c_k = 1/(8K_k^2)$, $K_k = (2(k+1))^k \mathcal{R}_{k+1}(k2^{k-1})$ (source 01's B_k), so $\log_2(1/c_k) = 2k^2 + O(k \log k)$ (Corollary IV.8.2). It keeps the full L^2 loss over pattern classes, as source 01's selection interface does, and is weaker than Corollary IV.6.8. At $k = 8$ (recomputed at the second write): $\log_2(1/c_8) \approx 121.66$ here, ≈ 212.70 in source 06, and $2(k+1)^3 = 1458$ in `proposition_17_7`. Not formalized.

[write] 6 October 2026; sources 15–20. *A stronger coefficient and a like-for-like comparison* (re-derived at the fourth write). Source 16's Theorem F.21.1 proves Proposition 17.7 with $c_k = (4/(3(k+2)))^{k+2}$, a loss of order $k \log k$ (Section IV.10). The comparison needs one normalization. Source 04's Corollary IV.6.8 normalizes by the input width, m^{k+2} , with cells of length q or $q+1$, $q = \lceil h/k \rceil$; the formal `proposition_17_7`, source 06's Theorem IV.8.1 and source 16 normalize by the largest cell length $l+1$. Since $m^{k+2} = (m/(q+1))^{k+2} (q+1)^{k+2}$, that corollary gives the coefficient $c_k(m/(q+1))^{k+2}$ in the $(l+1)$ normalization, with $l = q$. At $k = 8$ its loss is 91.07 bits uniformly over admissible m (the worst case is $m = 25$) and tends to $121.66 - 10 \log_2 16 = 81.66$ bits as $m \rightarrow \infty$; using the first inequality of Theorem IV.6.7 with $w \geq q$ in place of $w \geq m/(3k)$ gives 89.19 and 80.49. So the 121.66 bits printed above, and in the note at the end of Section IV.8, are in that corollary's own normalization and are not comparable with 212.70 (source 06) and 1,458 (formal), which use the $(l+1)$ one; the ordering stated there is unchanged. In one normalization, at $k = 2, 4, 8$: source 16 loses 6.34, 13.02, 29.07 bits; source 04's corollary 11.19, 29.37, 91.07; source 06 21.15, 65.35, 212.70; the formal statement

54, 250, 1,458 (the intake of batch 115 compared the same 121.7 bits; the intake of batch 117 found the difference of normalizations). Every value was recomputed at the write in exact arithmetic over every odd m with $3k < m < 20,000$; for larger m , $q + 1 \leq (m + 4k - 1)/(2k)$ gives $m/(q + 1) \geq 2km/(m + 4k - 1)$, which increases with m , so the loss stays below its bound at $m = 20,000$ (below 82 bits at $k = 8$).

IV.7 Exact floor-pattern counts and asymptotically sharp carry entropy

Source 06, delivered Section 2.

We first prove a slightly more general result than the Boolean-cube statement. Let $V \subset \mathbb{Z}_{\geq 0}^k$ be finite and contain 0 and the coordinate vectors $e_1, \dots, e_k$. Put

$$h(V) = \sum_{v \in V \setminus \{0\}} (\|v\|_1 - 1), \quad \tilde{h}(V) = \sum_{v \in V} \|v\|_1.$$

These are counts with multiplicity of the possible integer-level hyperplanes in an open unit cube; coincident hyperplanes can only improve the resulting upper bounds.

Definition IV.7.1 (Carry families). For $t \in [0, 1)^k$ define $c_t : V \rightarrow \mathbb{Z}$ by $c_t(v) = \lfloor v \cdot t \rfloor$. Let

$$C(V) = \#\{c_t : t \in [0, 1)^k\}, \quad C(V; M) = \#\{c_t \bmod M : t \in [0, 1)^k\}.$$

For $t_0 \in [0, 1)$ also define $d_{t_0, t}(v) = \lfloor t_0 + v \cdot t \rfloor$, and let $D(V)$ and $D(V; M)$ be the corresponding cardinalities. For $V = \{0, 1\}^k$ abbreviate these quantities as $C_k, C_{k, M}, D_k, D_{k, M}$.

The word “carry” describes precisely the integer part remaining after the integer parts of the coefficients have been removed. All these families are finite, since every coordinate takes values in a finite integer interval.

Lemma IV.7.2 (One-sided removal of boundary points). *Every carry pattern c_t is realized by a point of $(0, 1)^k$ for which $v \cdot t$ is nonintegral for all $v \in V \setminus \{0\}$. Every affine carry pattern is likewise realized in $(0, 1)^{k+1}$ away from all its integer-level hyperplanes.*

Proof. Replace t by $t + \eta(1, \dots, 1)$ for a sufficiently small $\eta > 0$. The new point remains below 1 in every coordinate. For every nonzero $v \in V$, the sum increases by $\eta\|v\|_1 > 0$. Choose η small enough that it is less than the distance to the next integer, divided by $\|v\|_1$, for every such v . A sum initially at an integer moves to the side having that same floor; every other sum remains between its original neighboring integers. The same argument for the coefficient vectors $(1, v)$ proves the affine assertion. Finiteness makes a common positive choice of η possible. $\square$

Theorem IV.7.3 (Exact separation of range and carries). *Let k, r, M be positive integers. The number of functions*

$$v \mapsto \lfloor v \cdot \alpha \rfloor, \quad \alpha \in (-r, r)^k,$$

is exactly $(2r)^k C(V)$. The number after reduction modulo M is exactly

$$\min(2r, M)^k C(V; M). \tag{IV.7.1}$$

Moreover,

$$C(V; M) \leq C(V) \leq \mathcal{R}_k(h(V)), \quad D(V; M) \leq D(V) \leq \mathcal{R}_{k+1}(\tilde{h}(V)). \tag{IV.7.2}$$

If $M \geq \max_{v \in V} \|v\|_1$, then $C(V; M) = C(V)$.

Proof. Write $\alpha = q + t$ with $q_i = \lfloor \alpha_i \rfloor$ and $0 \leq t_i < 1$. Then $q_i \in \{-r, \dots, r-1\}$ and

$$\lfloor v \cdot \alpha \rfloor = v \cdot q + c_t(v).$$

At $v = e_i$ the carry is zero, so the resulting pattern recovers q_i ; subtracting $v \cdot q$ then recovers c_t . Conversely every q in the stated integer box and every carry pattern are simultaneously realizable: use Lemma IV.7.2 to choose all $0 < t_i < 1$. In particular $q_i = -r$ causes no endpoint difficulty. This proves exact factorization.

Modulo M , the coordinate evaluations recover the residues $q_i \bmod M$. There are exactly $\min(2r, M)$ available residues in each coordinate. After these are recovered, the residual carry modulo M is recovered as well. Conversely all pairs are realizable, proving (IV.7.1). The possible nonzero carry values lie between 0 and $\|v\|_1 - 1$; hence reduction is injective on these coordinate ranges under the final hypothesis on M .

Inside the open unit cube, the only relevant hyperplanes for c_t are $v \cdot t = j$ with $1 \leq j \leq \|v\|_1 - 1$. Their number is at most $h(V)$. Each pattern is realized off these hyperplanes by Lemma IV.7.2, and each open region has a constant pattern. In fact a fixed pattern defines an intersection of strict linear inequalities, so it cannot split into disconnected pieces in the cube. The arrangement bound proves the first estimate. For affine carries the thresholds are $t_0 + v \cdot t = j$, $1 \leq j \leq \|v\|_1$, giving $\tilde{h}(V)$ hyperplanes in dimension $k + 1$. $\square$

The nonnegativity assumption on V has a specific purpose. If both v and $-v$ are allowed, a parameter with $v \cdot t = 0$ gives floors $(0, 0)$ that a generic perturbation need not preserve. Thus an extension to arbitrary signed coefficient families requires explicit treatment of lower-dimensional faces; the preceding proof does not silently cover that setting.

[write] **6 October 2026; sources 06–10.** Theorem IV.7.3 for $V = \{0, 1\}^k$ is source 01's Theorem IV.1.2 and source 04's Theorem IV.6.3; the modular count (IV.7.1) is source 04's modular count; the general family V corresponds to source 01's Proposition IV.3.4, which bounds by the rank of the feature span instead of k (note there). Source 01's example before its Section IV.4 is the signed-family obstruction described in the last paragraph. The bound $C_k \leq \mathcal{R}_k(h_k)$ is $C_k \leq \mathcal{R}(H_k, k) = R_k(H_k)$ of sources 01 and 04.

IV.7.1 The Boolean cube and the improvement of Corollary 17.5

For the Boolean cube, counting by support size gives

$$h_k := h(\{0, 1\}^k) = \sum_{s=2}^k \binom{k}{s} (s-1) = (k-2)2^{k-1} + 1, \quad (\text{IV.7.3})$$

$$\tilde{h}_k := \tilde{h}(\{0, 1\}^k) = \sum_{s=1}^k \binom{k}{s} s = k2^{k-1}. \quad (\text{IV.7.4})$$

The formula for h_k also gives $h_1 = 0$. Consequently,

$$\#\{\varepsilon \mapsto \lfloor \varepsilon \cdot \alpha \rfloor : \alpha \in (-r, r)^k\} = (2r)^k C_k \leq (2r)^k \mathcal{R}_k(h_k). \quad (\text{IV.7.5})$$

This replaces the source's 2^{2rk^3} upper bound by a polynomial in r with the exact exponent and exact coefficient C_k . For example, $C_1 = 1$, $C_2 = 2$, and $C_3 = 10$. For $k = 3$, if the total fractional sum is below 1 all pair carries vanish, and if it is at least 2 all pair carries are 1. When the total is between 1 and 2, all eight patterns of the three pair carries occur. To realize respectively zero,

one, two, or three positive pair carries in this middle slab, use $(.4, .4, .4)$, $(.6, .6, .1)$, $(.8, .3, .3)$, or $(.6, .6, .6)$ and permute coordinates. This proves the count $1 + 8 + 1 = 10$ directly.

The modular formula is exact even when the modulus is small:

$$\#\{\lfloor \varepsilon \cdot \alpha \rfloor \bmod M\} = \min(2r, M)^k C_{k,M}. \quad (\text{IV.7.6})$$

In particular, once $2r \geq M$ no further range loss is necessary. For $M \geq k$ the coefficient is the unreduced C_k .

IV.7.2 Affine patterns and translation classes

For $\alpha_0 \in \mathbb{R}$ and $\alpha \in (-r, r)^k$, consider

$$F_{\alpha_0, \alpha}(\varepsilon) = \lfloor \alpha_0 + \varepsilon \cdot \alpha \rfloor \pmod{M}.$$

Two such maps are equivalent if they differ by a constant in $\mathbb{Z}/M\mathbb{Z}$. Let $L_k(r, M)$ be the number of equivalence classes that occur.

Theorem IV.7.4 (Affine and modular carry bound). *For positive integers k, r, M ,*

$$L_k(r, M) \leq \min(2r, M)^k D_{k,M} \leq \min(2r, M)^k \mathcal{R}_{k+1}(k2^{k-1}). \quad (\text{IV.7.7})$$

The number of distinct maps is exactly $ML_k(r, M)$, and hence is at most $M \min(2r, M)^k \mathcal{R}_{k+1}(k2^{k-1})$.

Proof. Write $\alpha_0 = q_0 + t_0$ and $\alpha_i = q_i + t_i$ with fractional parts in $[0, 1)$. Then

$$F_{\alpha_0, \alpha}(\varepsilon) = q_0 + \varepsilon \cdot q + d_{t_0, t}(\varepsilon) \pmod{M}.$$

The constant q_0 disappears on passing to translation classes; the remaining choices give the upper bound. Unlike the nonaffine case, this decomposition need not be injective, because affine carries at singletons can be 1. Finally the family is invariant under addition of every constant modulo M , and that action is free: evaluation at $\varepsilon = 0$ detects the constant. Each orbit therefore has exactly M maps. $\square$

IV.7.3 Matching leading-order entropy

The next result determines the scale of the carry coefficient rather than merely improving an upper bound. The one external asymptotic input is the theorem of Zuev that the number $T(n)$ of Boolean linear threshold functions on $\{0, 1\}^n$ satisfies

$$\log_2 T(n) = (1 + o(1))n^2 \quad (n \rightarrow \infty) \quad [9, 8]. \quad (\text{IV.7.8})$$

A strict threshold representation can always be used: a separator on a finite cube can be moved slightly so that no value is zero.

Lemma IV.7.5 (Embedding thresholds into carries). *Let $T_+(n)$ denote the number of threshold functions admitting a representation with nonnegative coordinate weights. Then*

$$T(n) \leq 2^n T_+(n), \quad D_{n,M} \geq T_+(n) - 1, \quad C_{n+1,M} \geq D_{n,M} \quad (M \geq 2).$$

The last two inequalities also hold without modular reduction.

Proof. Flip each input coordinate whose coefficient in a chosen threshold representation is negative. The resulting function has nonnegative weights. Recording the subset of flipped coordinates and the resulting function recovers the original function. There are at most 2^n choices of the subset, proving the first inequality.

A nonconstant such function can be written $g(\varepsilon) = \mathbf{1}_{\{w \cdot \varepsilon > \theta\}}$ with all $w_i > 0$ and $0 < \theta < \sum_i w_i$. Zero weights can be perturbed to small positive ones because the finite strict separator has a positive margin. Choose $\lambda > 0$ sufficiently small that

$$t_0 = 1 - \lambda\theta \in (0, 1), \quad t_i = \lambda w_i \in (0, 1), \quad \sum_i t_i < 1.$$

All affine sums lie in $(0, 2)$, and

$$\lfloor t_0 + \varepsilon \cdot t \rfloor = g(\varepsilon).$$

The constant-zero function is also realizable by small positive parameters. Only the constant-one function must be omitted, because an affine carry at the zero vertex is 0. Distinct Boolean outputs remain distinct modulo every $M \geq 2$. This proves $D_{n,M} \geq T_+(n) - 1$. Finally restricting a nonaffine carry in $n + 1$ variables to the face whose first coordinate is 1 produces an arbitrary affine carry in n variables. This restriction is surjective and gives the final bound. $\square$

Theorem IV.7.6 (Asymptotically sharp carry entropy). *As $k \rightarrow \infty$,*

$$\log_2 C_k = (1 + o(1))k^2, \quad \log_2 D_k = (1 + o(1))k^2. \quad (\text{IV.7.9})$$

Both formulas remain valid for $C_{k,M}$ and $D_{k,M}$, uniformly for integer choices $M = M(k) \geq 2$. In particular, for fixed positive integer r the exact nonaffine count is

$$(2r)^k 2^{(1+o(1))k^2}.$$

For fixed $r \geq 1$ and $M \geq 2$, $\log_2 L_k(r, M) = (1 + o(1))k^2$ as well.

Proof. Equations (IV.7.2)–(IV.7.4) and (F.11.2) give $\log_2 C_k \leq k^2 + O(k)$ and $\log_2 D_k \leq k^2 + O(k)$; the finitely many small dimensions where $m < d$ can be treated directly. Lemma IV.7.5 and (IV.7.8) give

$$C_{k,M} \geq 2^{-(k-1)}T(k-1) - 1, \quad D_{k,M} \geq 2^{-k}T(k) - 1.$$

These lower bounds are independent of $M \geq 2$, while the upper bounds are the unreduced ones, proving the uniform assertion. For translation classes, the threshold patterns from the lemma have value 0 at the zero vertex. Two distinct such patterns cannot differ by a constant modulo $M \geq 2$. They are realized with all slopes in $(0, 1) \subset (-r, r)$, so $L_k(r, M) \geq T_+(k) - 1$. Combine this with Theorem IV.7.4. $\square$

Thus the cubic dimension exponent of the coarse source count can be replaced by a quadratic one, but a uniform subquadratic exponent for these pattern families is impossible. This lower bound concerns the number of patterns, not an optimality assertion for every proof of localized phase removal. A proof that avoids enumerating every pattern could conceivably have smaller analytical losses.

[write] **6 October 2026; sources 06–10.** Theorem IV.7.6 is source 01’s Theorem IV.2.3 (same external input, Zuev’s count), extended uniformly in the modulus and to translation classes; source 01 also bounds the secondary term from below by $-k \log_2 k - O(k)$. Together they answer source 04’s Question 8 (note there). Source 04’s elementary lower bound $2^{k(k-1)/2}$ (Theorem IV.6.2) is a third, non-asymptotic lower bound.

IV.8 A quadratic-exponent loss in localized phase removal

Source 06, delivered Section 4.

The carry bound has a direct analytical consequence. We give the argument because a better combinatorial count alone does not justify changing a downstream constant. The following formulation makes the partition scale explicit and supplies a replacement for the local loss in the source's Proposition 17.7.

Let p be prime and write $e_p(t) = \exp(2\pi it/p)$. For a function on $\mathbb{F}_p$ define its unnormalized cube energy by

$$\mathcal{E}_d(g) = \sum_{s \in \mathbb{F}_p} \sum_{a \in \mathbb{F}_p^d} \prod_{\varepsilon \in \{0,1\}^d} \mathcal{C}^{|\varepsilon|} g(s - \varepsilon \cdot a) = p^{d+1} \|g\|_{U^d}^2.$$

Here $\mathcal{C}$ denotes complex conjugation. This is a nonnegative real number. For a partition $\mathcal{Q} = (Q_i)_{i=0}^{M-1}$ put

$$\mathcal{E}_d(g; \mathcal{Q}) = \sum_i \mathcal{E}_d(\mathbf{1}_{Q_i} g).$$

If every cell has length at most ℓ , the partition-uniformity normalization at degree $d-1$ is $M\ell^{d+1}$. Define the explicit integer

$$K_k = [2(k+1)]^k \mathcal{R}_{k+1}(k2^{k-1}), \quad c_k = \frac{1}{8K_k^2}. \quad (\text{IV.8.1})$$

The letter K_k here denotes a pattern bound; it is unrelated to the large exponents in the polynomial-partition section of the source.

Theorem IV.8.1 (Localized phase removal with the carry bound). *Let $k \geq 1$, let $p > k+1$ be prime, and let m be odd with $1 \leq m \leq \sqrt{p}$. Let*

$$P = \prod_{i=1}^k (r_i + I), \quad I = \{-h, \dots, h\}, \quad 2h+1 = m.$$

All sets are viewed in $\mathbb{F}_p$. Suppose $|f| \leq 1$, $\alpha > 0$, and σ is the restriction to P of a polynomial separately of degree at most one in each of its k variables. Assume

$$\sum_{x \in P} \left| \sum_{s \in \mathbb{F}_p} \prod_{\varepsilon \in \{0,1\}^k} \mathcal{C}^{|\varepsilon|} f(s - \varepsilon \cdot x) e_p(-s\sigma(x)) \right|^2 \geq \alpha p^2 m^k. \quad (\text{IV.8.2})$$

Then there is a polynomial ϕ of degree at most $k+1$ and a partition $\mathcal{Q}$ into modular intervals, each of length at least $m/(3k)$ and at most some integer ℓ , such that

$$\mathcal{E}_{k+1}(fe_p(-\phi); \mathcal{Q}) > c_k \alpha M \ell^{k+2}. \quad (\text{IV.8.3})$$

The same assertion holds for input progressions with any common nonzero step, with modular progressions in the conclusion.

Proof. Small boxes. If $m \leq 3k$, use the singleton partition and $\phi = 0$. For each x , Cauchy–Schwarz in s bounds the Fourier square in (IV.8.2) by

$$p \sum_s \prod_{\varepsilon \in \{0,1\}^k} |f(s - \varepsilon \cdot x)|^2.$$

Arithmetic–geometric mean, followed by translation invariance of the s -sum, bounds this by $p \sum_s |f(s)|^{2^{k+1}}$. Thus the hypothesis implies $\sum_s |f(s)|^{2^{k+1}} \geq \alpha p$. This is exactly the singleton-partition cube energy, while $M = p$, $\ell = 1$, and $c_k < 1$. The singleton length is at least $m/(3k)$, as required.

The partition and its pattern classes. Suppose $m > 3k$. Put

$$q = \lceil h/k \rceil, \quad M = \lfloor p/q \rfloor, \quad w = p/M, \quad \ell = q + 1,$$

and, using integer representatives, set

$$Q_j = \{s \in \mathbb{F}_p : jw \leq s < (j+1)w\}, \quad 0 \leq j < M.$$

Since $q \leq \sqrt{p}$, one has $q \leq M$. Writing $p = qM + b$ gives $0 \leq b < q \leq M$, so the cell lengths are q or $q + 1$. Also

$$q \geq h/k \geq m/(3k), \quad w \geq q \geq \ell/2, \quad m \geq \ell. \quad (\text{IV.8.4})$$

Set $f_\varepsilon(s) = f(s - \varepsilon \cdot r)$ and $\tau(a) = \sigma(a + r)$, taking the indicated global multiaffine extension. In the expansion obtained by partitioning each f_ε , a nonzero contribution at (s, a) has cell labels

$$j(\varepsilon) = \lfloor s/w - \varepsilon \cdot (a/w) \rfloor \pmod{M}.$$

This identity is well defined for representatives because $p = Mw$. Moreover $|a_i/w| \leq h/q \leq k < k+1$. By Theorem IV.7.4, the number L of possible label functions up to simultaneous translation is at most K_k .

Keeping the pattern loss explicit. Choose one representative j_ν of each translation class and define

$$T_{\nu,i}(a) = \sum_s e_p(-s\tau(a)) \prod_{\varepsilon \in \{0,1\}^k} \mathcal{C}^{|\varepsilon|}(\mathbf{1}_{Q_{j_\nu(\varepsilon)+i}} f_\varepsilon)(s - \varepsilon \cdot a).$$

Indices on cells are modulo M . The original inner sum is $\sum_\nu \sum_i T_{\nu,i}(a)$. Cauchy–Schwarz over the L classes, selection of one class, and then Cauchy–Schwarz over its M translates give a ν such that

$$\sum_{i=0}^{M-1} \sum_{a \in I^k} |T_{\nu,i}(a)|^2 \geq \frac{\alpha p^2 m^k}{L^2 M}. \quad (\text{IV.8.5})$$

Extend the a -sum to $\mathbb{F}_p^k$; every added term is nonnegative.

Removing the multiaffine phase. Expanding each square and putting $y = s - t$ makes its phase $e_p(-y\tau(a))$. Every monomial in $y\tau(a)$ is square-free and has degree at most $k+1$. For a square-free monomial on a nonempty coordinate set J , finite differences give

$$|J|! \prod_{j \in J} z_j = \sum_{\varepsilon \in \{0,1\}^J} (-1)^{|\varepsilon|} (s - \varepsilon \cdot z)^{|J|}.$$

All the factorials are invertible because $p > k+1$. Regard this sum as a sum on the full cube by assigning zero to unused vertices, and add the identities for the monomials. We obtain polynomials ϕ_η of degree at most $k+1$ such that

$$y\tau(a) = \sum_{\eta \in \{0,1\}^{k+1}} (-1)^{|\eta|} \phi_\eta(s - \eta \cdot (a, y)).$$

Consequently each expanded square in (IV.8.5) is a mixed cube form in the functions

$$\mathbf{1}_{Q_{j\nu(\eta')+i}} f_{\eta'} e_p(-\phi_\eta), \quad \eta' = (\eta_1, \dots, \eta_k).$$

Apply the Gowers–Cauchy–Schwarz inequality to this form and then arithmetic–geometric mean to the resulting 2^{k+1} energy factors. Summing in i and averaging in η shows that for some η , with $g = f_{\eta'} e_p(-\phi_\eta)$,

$$\sum_i \mathcal{E}_{k+1}(\mathbf{1}_{Q_i} g) \geq \frac{\alpha p^2 m^k}{L^2 M}. \quad (\text{IV.8.6})$$

The shift of the cell index by $j\nu(\eta')$ disappears because it permutes the M cells. The Gowers–Cauchy–Schwarz inequality used here is the standard cube inequality proved in Section 3 of the source; it applies to all complex functions, including these restrictions.

Divide (IV.8.6) by $M\ell^{k+2}$. Since $p/M = w$, (IV.8.4) yields

$$\frac{\mathcal{E}_{k+1}(g; \mathcal{Q})}{M\ell^{k+2}} \geq \frac{\alpha}{L^2} \left(\frac{w}{\ell}\right)^2 \left(\frac{m}{\ell}\right)^k \geq \frac{\alpha}{4K_k^2} > c_k \alpha.$$

Finally translate the partition by $-\eta' \cdot r$ and replace $\phi_\eta(s)$ by $\phi_\eta(s + \eta' \cdot r)$ to express g as a polynomial twist of the original f . A translation does not change cell lengths or cube energies. For a common nonzero input step, first dilate all variables to make that step 1; multiplication by the step is a bijection on $\mathbb{F}_p$, and the Fourier phase and the polynomial change by the same invertible substitution. $\square$

[write] **6 October 2026; sources 15–20.** Source 16’s Theorem F.21.1 has the same normalization (cells of length l or $l+1$, normalized by $(l+1)^{k+2}$) and the coefficient $(4/(3(k+2)))^{k+2}$: 29.07 bits lost at $k=8$ against 212.70 here (note after Corollary IV.6.8).

Corollary IV.8.2 (Size of the new local loss). *The constant in (IV.8.3) satisfies*

$$\log_2(c_k^{-1}) = 3 + 2k \log_2(2(k+1)) + 2 \log_2 \mathcal{R}_{k+1}(k2^{k-1}) = 2k^2 + O(k \log k).$$

Thus the explicit local loss has a quadratic leading exponent, compared with the cubic exponent $2(k+1)^3$ in the displayed source formulation.

The last equality follows directly from the binomial-sum upper bound and its largest term; alternatively, upper and lower bounds of order $k^2 + O(k \log k)$ for its logarithm suffice. The sharper raw estimate (IV.8.6) can be retained when the actual number of classes or the observed cell-size ratios are known. No asymptotic approximation is needed to use the explicit constant (IV.8.1).

This proof accounts for the scale of every partition cell and for the factor L^2 . Later structural extraction and stopping thresholds are separate inputs. Improving this local loss does not, on its own, justify substituting a new exponent into the final Szemerédi theorem.

[write] **6 October 2026; sources 06–10.** *Compared with the other two coefficients at this step.* Source 04’s Theorem IV.6.7 with Corollary IV.6.8 has the stronger coefficient $2^{-k^2 - k \log_2 k - O(k)}$ (fixed-slope profiles, loss $2^k B_k$ in place of K_k^2); source 01’s Proposition IV.3.3 is a selection interface with the same L^2 loss as here. At $k=8$: about $2^{-121.66}$ (04), $2^{-212.70}$ (here; recomputed at the second write), and 2^{-1458} in the formal `proposition_17_7` (exact companion `proposition_17_7_holds`). The numerical lemma “ $L^2 c < 1/4$ ” cited in Section V.26 is in `Proofs17LocalizedPhaseRemoval.lean`. Not formalized.

[write] **6 October 2026; sources 15–20.** The $2^{-121.66}$ above is in source 04’s own normalization (by the input width m^{k+2}); in the $(l+1)$ normalization of the other two values source 04’s coefficient loses 91.07 bits at $k=8$, and source 16’s 29.07 (note after Corollary IV.6.8).

IV.9 Exact computations and reproducible verification

Source 06, delivered Section 7.

The general theorems do not depend on experimental extrapolation. Computations serve two narrower purposes: certifying small carry counts that are useful examples, and checking the quantitative inequalities on finite configurations that exercise their normalizations and endpoints.

IV.9.1 Certified carry counts

The included certificate package gives the following values. The zero-dimensional entries use the natural empty-cube convention.

k	C_k	$\mathcal{R}_k(h_k)$	D_k	$\mathcal{R}_{k+1}(\tilde{h}_k)$
0	1	1	1	1
1	1	1	2	2
2	2	2	6	15
3	10	26	38	794
4	154	3214	not computed	not tabulated

The entry “not computed” describes this package’s scope; it is not a claim that the value is unknown in the literature. A short initial sequence match is not sufficient to identify these objects with an existing integer sequence.

[write] **6 October 2026; sources 06–10.** $C_1, \dots, C_4$ agree with source 01’s certified values (Proposition IV.5.1), so $C_4 = 154$ is certified twice with different formats; D_1, D_2, D_3 agree with source 04’s certified A_1, A_2, A_3 . The intake reran the verifier (all 215 witnesses and 1,165 dual certificates exact). C_5 and D_4 are not certified by any source; the intake’s floating-point values $C_5 = 8410$ and $A_4 = 770$ are item IV.2 of Section V.2.

The enumeration adds the relevant hyperplanes one at a time and branches on their two strict sides. For a sign prefix in dimension d , encode the unit-cube and selected side constraints as

$$A_i \cdot x + t \leq b_i.$$

A rational point x with a rational $t > 0$ proves the existence of a strictly feasible chamber. To certify that a branch has no strict solution, the package supplies rational multipliers $y_i \geq 0$ satisfying

$$\sum_i y_i = 1, \quad \sum_i y_i A_i = 0, \quad \sum_i y_i b_i \leq 0.$$

Multiplying and summing the inequalities would force $t \leq \sum_i y_i b_i \leq 0$, a contradiction. This is an exact certificate, not a numerical tolerance test. The verifier checks the entire binary prefix tree: every branch either ends in such a certificate or reaches a strictly witnessed full pattern. It also checks that the resulting carry maps are distinct.

The final data contain 215 rational chamber witnesses and 1,165 exact nonnegative dual certificates across all tabulated cases. A numerical linear-programming solver is used only to propose rational certificates. The separate verifier uses Python’s standard library and `fractions.Fraction`; it verifies every relation exactly and rejects execution with Python’s assertion-disabling optimization flag. Lemma IV.7.2 is what makes this open-chamber enumeration complete for the original floor patterns, including their boundary values.

IV.9.2 Uniformity and density checks

The uniformity checker evaluates the finite-group progression counts and cube energies with integers and rational arithmetic. It raises the inequalities to integer powers instead of numerically approximating Gowers-norm roots. It checks all subsets of $\mathbb{Z}/5\mathbb{Z}$ for lengths 3, 4, and 5, all subsets of $\mathbb{Z}/7\mathbb{Z}$ for lengths 3 and 4, and eight specified subsets of $\mathbb{Z}/25\mathbb{Z}$ for lengths 3 and 4. All 368 set-length cases satisfy both the linear and quadratic bounds. It also checks 160 two-term cases and 168 three-term variance bounds, including 32 equality cases. The convenient sufficient existence criterion fires in 62 checked cases; every one contains a nonconstant progression.

The weighted extraction checker exercises 22,752 rational indicator/partition configurations under each of the ranges $[-1, 1]$ and $[-\delta, 1 - \delta]$, for 45,504 exact range cases, and verifies the two extremal constructions. These finite checks are supplementary to the proofs: unlike a carry-count certificate, a list of finite examples does not prove a universal inequality. The accompanying JSON files state the exact tested families and counts.

IV.9.3 Magnitude of the explicit improvements

Figure IV.9.1 evaluates the formulas proved above. In its left panel the new count bound is $2^k \mathcal{R}_k(h_k)$, so it uses the general arrangement estimate rather than small exact counts. The right panel uses the fully explicit c_k from (IV.8.1).

Figure IV.9.1: Comparison of logarithmic bounds. Lower values mean a smaller count upper bound (left) or a larger guaranteed local correlation constant (right). These are comparisons of local statements, not plots of final Szemerédi thresholds.

For example, at $k = 4, r = 1$, the displayed floor-count exponent 128 is replaced by the arrangement-based exponent approximately 15.650, and the exact count is still smaller, namely $2^4 C_4 = 2464$. At $k = 8$, the displayed local phase loss is 2^{-1458} , whereas (IV.8.1) gives a constant approximately $2^{-212.704}$. These comparisons quantify genuine local savings while leaving the later structural dependencies explicit.

IV.10 Source 16’s chapter: Proposition 17.7 without carry patterns [write]

Added in the fourth write, 6 October 2026.

The next four sections are source 16’s Sections 2–5, on Gowers’s Proposition 17.7, the localized phase removal that the floor-pattern counts of this Part serve. Source 16 localizes every cube to one sliding interval window and counts exactly how many windows contain it, so no carry pattern is counted. *Logically this chapter should open the Part’s treatment of Proposition 17.7:* of the four coefficients printed here it is the strongest at every k , of order $2^{-k \log_2 k - O(k)}$ against $2^{-k^2 + O(k)}$ for source 04 in the same normalization, $2^{-2k^2 - O(k \log k)}$ for source 06 and $2^{-2(k+1)^3}$ in the paper and the formal statement. It is printed here, at the end of Part IV, because no number printed earlier may move. Its introduction, with the main theorem (Theorem F.21.1), is Section F.21; its other sections are in Parts I, III and V. Its notation is in the table at the head of this Part.

What is proved, in one paragraph. Under exactly the hypotheses of Proposition 17.7, a polynomial phase of degree at most $k + 1$ and a partition into proper modular progressions of lengths l or $l + 1$, $m/(3k) \leq l$ and $l + 1 \leq 3km$, on which uniformity fails at $\alpha(4/(3(k+2)))^{k+2}$, normalized by $(l+1)^{k+2}$ (Theorem F.21.1, from the exact window estimate, Theorem IV.13.2); the width optimization gives $(2/(k+2))^{k+2}$ for fixed k (Proposition IV.13.4), and no conclusion with cells of size proportional to m can beat $2^{k+1}/(k+2)!$, so the order $k \log k$ is optimal in that class (Proposition IV.13.5). The polarization is source 04’s and the formal development’s; the factorial criterion and the $\mathbb{F}_p$ functional test are new in this report (Theorems IV.12.2, IV.12.4). Section IV.14 keeps the original small cells at the price of a global count; it is source 04’s Lemmas IV.6.5–IV.6.6.

The four coefficients in one normalization (re-derived at the write; bits lost, $-\log_2$ of the coefficient, with cells of length l or $l + 1$ normalized by $(l + 1)^{k+2}$, as in `proposition_17_7`).

k	Source 16	Source 04, converted	Source 06	Formal statement
2	6.34	11.19	21.15	54
4	13.02	29.37	65.35	250
8	29.07	91.07	212.70	1,458

Source 04’s Corollary IV.6.8 normalizes by the input width m^{k+2} ; converted to $(q+1)^{k+2}$, $q = \lceil h/k \rceil$, it loses the values shown uniformly over admissible m , and 81.66 bits as $m \rightarrow \infty$ at $k = 8$; its own normalization gives the 121.66 bits quoted in the notes of the second write (note after that corollary). Source 01’s selection interface is weaker than source 04’s. *Caveat:* under the printed reading “each of length at most m ” (source 04’s), source 16’s cells, of length about $(k+2)m/2$, are too long; source 16 follows the formal $(l+1)$ reading, which Section 18 needs (it uses only $l \geq m/(3k)$ and lengths l or $l + 1$). Larger cells must be transported in Section 18; source 16’s remark after the proof of its theorem gives a sufficient condition.

Relation to the formal statements (checked at HEAD 0b4890a1c). `proposition_17_7` (Section `ns17_18.lean`, line 140) is an exact companion (`proposition_17_7_holds`, `Proofs17LocalizedPhaseRemoval.lean`, line 2900), with the coefficient $2^{-2(k+1)^3}$; source 16’s theorem implies it (note in Section F.21), and is not formalized. The carry counts stay needed for `corollary_17_5` and `corollary_17_6` (exact companions, `Proofs17FinitePatterns.lean`, lines 396, 501). No formal declaration consumes `proposition_17_7`; `theorem_18_1` is open.

IV.11 Cube forms, normalizations, and finite partitions

Source 16, delivered Section 2.

IV.11.1 Normalized and unnormalized forms

On a finite abelian group G , all expectations are with respect to uniform probability. If $u : G \rightarrow \mathbb{C}$, set

$$\|u\|_{U^j}^{2^j} = \mathbb{E}_{x, h_1, \dots, h_j} \prod_{\epsilon \in \{0,1\}^j} \mathbb{C}^{|\epsilon|} u(x - \epsilon \cdot h). \quad (2.1)$$

For $j \geq 1$, this expression is nonnegative. For $j \geq 2$ its 2^j -th root is a norm. Its unnormalized version is

$$\mathcal{C}_j(u) = \sum_{h_1, \dots, h_{j-1}} \left| \sum_x \Delta(u; h_1, \dots, h_{j-1})(x) \right|^2. \quad (2.2)$$

Expanding the square and setting the last increment equal to the difference of the two base points proves $\mathcal{C}_j(u) = |G|^{j+1} \|u\|_{U^j}^{2^j}$. Formula (2.2) will be essential: restriction of the increment domain can safely be removed *before* expansion, because each term is a nonnegative square.

Lemma IV.11.1 (Mixed cube inequality). *For functions $u_\eta : G \rightarrow \mathbb{C}$, indexed by $\eta \in \{0,1\}^j$,*

$$\left| \sum_{x,h} \prod_{\eta} \mathbb{C}^{|\eta|} u_\eta(x - \eta \cdot h) \right| \leq \prod_{\eta} \mathcal{C}_j(u_\eta)^{1/2^j} \leq 2^{-j} \sum_{\eta} \mathcal{C}_j(u_\eta). \quad (2.3)$$

Proof. The first inequality is the Gowers–Cauchy–Schwarz inequality, with the normalization in (2.1). One obtains it by applying Cauchy–Schwarz successively in the j direction variables, at each step separating the two faces in that direction and duplicating the variables on the opposite face. After all directions have been processed, the factor associated with a vertex is its diagonal j -cube form. Each factor has exponent 2^{-j} . The total normalizing factor is $|G|^{j+1}$, the same on both sides. This is the finite cube inequality used in [1, Lemma 3.8]. The second inequality follows from the arithmetic–geometric mean inequality for 2^j nonnegative numbers. $\square$

A modular arithmetic progression is *proper* if its displayed parameterization is injective. A consecutive cyclic interval is allowed to cross the chosen representative $N - 1$; properness is a statement about distinct residues. When ordinary integer progressions are needed, a separate rectification statement is necessary.

For a partition $\mathcal{Q}$ with J cells and an integer U bounding all its cell sizes, define

$$\mathcal{B}_k(g; \mathcal{Q}, U) = \frac{\sum_{Q \in \mathcal{Q}} \mathcal{C}_{k+1}(\mathbf{1}_Q g)}{JU^{k+2}}. \quad (2.4)$$

The upper bound U is part of the notation. Changing U changes the quotient, even when the partition itself is unchanged.

IV.12 Explicit polarization and its algebraic limits

Source 16, delivered Section 3.

IV.12.1 The phases can be chosen before localization

Lemma IV.12.1 (Explicit multi-affine polarization). *Let R be a commutative ring in which $1!, \dots, (k+1)!$ are units. Write*

$$\tau(a) = \sum_{A \subseteq [k]} c_A \prod_{j \in A} a_j.$$

For $\epsilon \in \{0, 1\}^k$, put

$$\phi_\epsilon(X) = \sum_{A \supseteq \text{supp}(\epsilon)} \frac{c_A}{(|A| + 1)!} X^{|A|+1}. \quad (3.1)$$

Then, as a formal polynomial identity,

$$y\tau(a) = \sum_{\epsilon \in \{0,1\}^k} \sum_{b=0}^1 (-1)^{|\epsilon|+b} \phi_\epsilon(s - \epsilon \cdot a - by). \quad (3.2)$$

Thus the two phases at $(\epsilon, 0)$ and $(\epsilon, 1)$ coincide, and only 2^k candidate phases are needed.

Proof. For indeterminates $z_1, \dots, z_r$, successive backward differences give

$$\sum_{\omega \in \{0,1\}^r} (-1)^{|\omega|} \left(s - \sum_j \omega_j z_j \right)^r = r! \prod_j z_j. \quad (3.3)$$

One proof is to expand each power: a monomial missing some z_j cancels upon summing the two values of ω_j ; the only surviving monomial has every z_j to the first power, with coefficient $r!$. Apply this identity with $r = |A| + 1$, with the variables a_j for $j \in A$ and y , multiply by $c_A/r!$, and sum over A . The allowed vertices in the term for A are exactly those ϵ supported inside A , with either value of b . This is (3.2). $\square$

The independence of these phases from all spatial cell labels is what allows localization followed by a single averaging argument. It also allows one to keep a sum over carry classes instead of selecting a class prematurely.

IV.12.2 An exact factorial criterion

The factorial hypothesis can be sharpened when individual coefficients have divisibility. The following statement is about *formal polynomial identities*; identities of functions on a finite ring require a separate analysis.

Theorem IV.12.2 (Coefficient criterion for vertex polarization). *Let R be a commutative ring and*

$$H(z_1, \dots, z_r) = \sum_{A \subseteq [r]} c_A \prod_{i \in A} z_i.$$

There exist one-variable polynomials $\psi_\eta \in R[X]$ satisfying

$$H(z) = \sum_{\eta \in \{0,1\}^r} (-1)^{|\eta|} \psi_\eta(s - \eta \cdot z) \quad (3.4)$$

as a formal identity if and only if

$$c_A \in |A|! R \quad \text{for every } A \subseteq [r]. \quad (3.5)$$

When this holds, the ψ_η may be chosen with degree at most r . For $H(a, y) = y\tau(a)$, the condition is $c_A \in (|A| + 1)! R$.

Proof. In the right side of (3.4), the coefficient of the square-free monomial $\prod_{i \in A} z_i$, with no s , receives contributions only from the degree- $|A|$ terms of the polynomials ψ_η . Each such contribution is a multiple of $|A|!$; its other factors are signs and zero-one coordinates of η . This proves necessity.

Conversely choose $b_A \in R$ with $c_A = |A|!b_A$. For each A , use (3.3) on just its coordinates and multiply by b_A . The case $A = \emptyset$ is the constant identity. Add all these identities and collect terms at each vertex. All degrees are at most r , proving sufficiency. $\square$

Corollary IV.12.3 (Cyclic coefficient test). *Over $\mathbb{Z}/N\mathbb{Z}$, condition (3.5) is equivalent to*

$$\gcd(N, |A|!) \text{ dividing an integer representative of } c_A.$$

In particular, $\gcd(N, r!) = 1$ suffices for every multi-affine H .

Proof. The image of multiplication by the integer a on $\mathbb{Z}/N\mathbb{Z}$ is precisely the set of residue classes divisible by $\gcd(a, N)$. Apply this with $a = |A|!$. $\square$

IV.12.3 A precise small-characteristic obstruction

Theorem IV.12.4 (Functional polarization over a prime field). *Let p be prime and let $H : \mathbb{F}_p^r \rightarrow \mathbb{F}_p$ be represented by the multi-affine polynomial above. It can be expressed in the form (3.4) as an identity of functions, allowing arbitrary functions $\psi_\eta : \mathbb{F}_p \rightarrow \mathbb{F}_p$, if and only if*

$$c_A = 0 \quad (|A| \geq p). \tag{3.6}$$

Proof. Every function $\mathbb{F}_p \rightarrow \mathbb{F}_p$ is represented by a polynomial of degree at most $p - 1$, by Lagrange interpolation. Substituting $s - \eta \cdot z$ produces a polynomial of total degree at most $p - 1$. Its degree in each variable is also at most $p - 1$.

A polynomial whose degree in each variable is less than p and which vanishes on the entire affine space has every coefficient zero: apply the univariate root bound in the last variable, and induct on the number of variables. Thus the reduced polynomial representing a function is unique. Since the multi-affine polynomial H is already reduced, it cannot contain a nonzero monomial of total degree at least p if it equals the indicated sum. This proves necessity. For sufficiency, all remaining factorials are nonzero in $\mathbb{F}_p$; apply (3.3) to every nonzero monomial. $\square$

For example, $z_1 \cdots z_p$ has no such representation, even with arbitrary one-variable $\mathbb{F}_p$ -valued functions at the vertices. This obstruction concerns classical field-valued phases. It makes no claim about phases with values in larger torsion subgroups of $\mathbb{R}/\mathbb{Z}$, or about other inverse-theorem formulations.

IV.13 Finite sliding-window localization without carry patterns

Source 16, delivered Section 4.

The proof in this section localizes all cube vertices to one sliding interval. A finite counting identity records exactly how many windows contain a cube. It replaces the enumeration of carry

patterns in [1, Proposition 17.7]; the polarization phases remain those already constructed in Lemma IV.12.1.

IV.13.1 A finite family of sliding partitions

Let N be prime, let $h \geq 1$, put $R = kh$, and choose a positive integer M satisfying

$$R < w := \frac{N}{M} < N - R. \quad (4.1)$$

In particular $1 < M < N$. Set $U = \lfloor w \rfloor + 1 = \lceil w \rceil$. Embed $\mathbb{Z}/N\mathbb{Z}$ into $\mathbb{Z}/(NM)\mathbb{Z}$ by $x \mapsto Mx$. For $t \in \mathbb{Z}/(NM)\mathbb{Z}$, define

$$S_t = \{x \in \mathbb{Z}/N\mathbb{Z} : ((Mx - t) \bmod NM) \in \{1, \dots, N\}\}. \quad (4.2)$$

Thus one takes a block of N consecutive residues in the larger cyclic group and intersects it with the embedded copy of $\mathbb{Z}/N\mathbb{Z}$.

Lemma IV.13.1 (Sliding-window geometry). *Every S_t is a cyclic arithmetic progression with common difference one and cardinality $\lfloor w \rfloor$ or $\lceil w \rceil$. For every $j \in \{0, \dots, N-1\}$, the family*

$$\mathcal{P}_j = (S_{j+\ell N})_{0 \leq \ell < M} \quad (4.3)$$

is a partition of $\mathbb{Z}/N\mathbb{Z}$. If $a \in [-h, h]^k \cap \mathbb{Z}^k$ and $s \in \mathbb{Z}/N\mathbb{Z}$, precisely

$$N - MD(a), \quad D(a) := \sum_{i=1}^k |a_i|, \quad (4.4)$$

of the sets S_t contain every vertex $s - \epsilon \cdot a$, $\epsilon \in \{0, 1\}^k$.

Proof. A block of N consecutive integers contains either $\lfloor N/M \rfloor$ or $\lceil N/M \rceil$ multiples of M . Their pullbacks are consecutive residues in $\mathbb{Z}/N\mathbb{Z}$. The M blocks starting at $j + \ell N + 1$ partition $\mathbb{Z}/(NM)\mathbb{Z}$, proving the partition assertion after intersection with the embedded subgroup.

The integer lifts of the cube vertices have span exactly $D(a)$: the maximum and minimum subset sums differ by $\sum_i |a_i|$. After embedding, their span is $MD(a) < N$. Write their extreme lifts as $u \leq v$. An integer block $\{t + 1, \dots, t + N\}$ contains the vertices exactly when $v - N \leq t \leq u - 1$, giving $N - (v - u) = N - MD(a)$ starts. There are no additional containing blocks obtained by traversing the opposite part of the circle. Indeed the complementary circular gap has length $NM - MD(a) > N$, by $w + R < N$; all gaps inside the displayed span are shorter than N . This also proves the assertion when some vertices coincide, including $D(a) = 0$. $\square$

IV.13.2 Exact phase extraction

Let $f_\epsilon : \mathbb{Z}/N\mathbb{Z} \rightarrow \mathbb{C}$, $\epsilon \in \{0, 1\}^k$, and let τ be multi-affine over $\mathbb{F}_N$, with $N > k + 1$. Define

$$F(a) = \sum_{s \in \mathbb{Z}/N\mathbb{Z}} e_N(-s\tau(a)) \prod_{\epsilon} \mathbb{C}^{|\epsilon|} f_\epsilon(s - \epsilon \cdot a), \quad E = \sum_{a \in [-h, h]^k} |F(a)|^2. \quad (4.5)$$

Integer increments in this formula are reduced modulo N . Let ϕ_ϵ be the polynomials in Lemma IV.12.1, and put $g_\epsilon = f_\epsilon e_N(-\phi_\epsilon)$.

Theorem IV.13.2 (Exact finite sliding-window estimate). *Under (4.1), some $\epsilon \in \{0, 1\}^k$ and $j \in \{0, \dots, N-1\}$ satisfy*

$$\mathcal{B}_k(g_\epsilon; \mathcal{P}_j, U) \geq \frac{E(w - kh)^2}{N^2 U^{k+2}}. \quad (4.6)$$

In particular, if $m = 2h + 1$ and $E \geq \alpha N^2 m^k$, then

$$\mathcal{B}_k(g_\epsilon; \mathcal{P}_j, U) \geq \alpha \frac{m^k (w - kh)^2}{U^{k+2}}. \quad (4.7)$$

The phases are determined by τ before any window is selected.

Proof. Let $F_t(a)$ be the expression defining $F(a)$, with each f_ϵ replaced by $\mathbf{1}_{S_t} f_\epsilon$. Lemma IV.13.1 gives the exact identity

$$\sum_{t \in \mathbb{Z}/(NM)\mathbb{Z}} F_t(a) = (N - MD(a))F(a).$$

Cauchy–Schwarz over the NM window indices implies

$$\begin{aligned} (N - Mkh)^2 E &\leq \sum_{a \in [-h, h]^k} (N - MD(a))^2 |F(a)|^2 \\ &\leq NM \sum_t \sum_{a \in [-h, h]^k} |F_t(a)|^2 \\ &\leq NM \sum_t \sum_{a \in (\mathbb{Z}/N\mathbb{Z})^k} |F_t(a)|^2. \end{aligned} \quad (4.8)$$

The final extension is made while the summands are nonnegative squares. No restriction is discarded from a signed cube expression.

Expand each square using the difference of its two base variables. The resulting phase is $e_N(-y\tau(a))$. Apply Lemma IV.12.1 and then Lemma IV.11.1 to obtain

$$\sum_{a \in (\mathbb{Z}/N\mathbb{Z})^k} |F_t(a)|^2 \leq \prod_{\epsilon \in \{0, 1\}^k} \mathcal{C}_{k+1}(\mathbf{1}_{S_t} g_\epsilon)^{1/2^k}. \quad (4.9)$$

The exponent is 2^{-k} , since the two vertices with the same first k coordinates have identical functions and phases. Hölder’s inequality in t now gives

$$\frac{(N - Mkh)^2 E}{NM} \leq \prod_{\epsilon} \left(\sum_t \mathcal{C}_{k+1}(\mathbf{1}_{S_t} g_\epsilon) \right)^{1/2^k}.$$

One factor is at least the left side. Fix its ϵ . Every $t \in \mathbb{Z}/(NM)\mathbb{Z}$ occurs exactly once as $j + \ell N$, with $0 \leq j < N$ and $0 \leq \ell < M$. Averaging over j gives

$$\sum_{S \in \mathcal{P}_j} \mathcal{C}_{k+1}(\mathbf{1}_S g_\epsilon) \geq \frac{E(N - Mkh)^2}{N^2 M}$$

for some j . Dividing by MU^{k+2} and using $N - Mkh = M(w - kh)$ proves (4.6). $\square$

The same argument can be visualized with real windows $[u, u + w)$ moving around a circle of circumference N . A cube of span $D(a)$ belongs to these windows for a set of starting positions of total length $w - D(a)$. The construction in $\mathbb{Z}/(NM)\mathbb{Z}$ is an exactly finite version of that averaging argument.

IV.13.3 A uniform finite coefficient and the original input

Suppose $m = 2h + 1 > 3k$ and $m^2 \leq N$. Take

$$T = (k + 2)h, \quad M = \left\lfloor \frac{N}{T} \right\rfloor, \quad w = \frac{N}{M}. \quad (4.10)$$

Then $M \geq 4$. For $k = 1$, $m \geq 5$ gives $m^2 \geq 6(m-1) = 4T$. For $k \geq 2$, the function $m^2 - 2(k+2)(m-1)$ increases in the range $m \geq 3k + 1$, and at its left endpoint equals $3k^2 - 6k + 1 \geq 1$. Hence again $N \geq 4T$. Consequently

$$T \leq w < \frac{5}{4}T, \quad U = \lceil w \rceil \leq \frac{3}{2}T, \quad w - kh \geq 2h. \quad (4.11)$$

Here $T \geq 6$ absorbs the rounding in U . Also $kh < N/6$ and $w \leq N/4$, so (4.1) holds. Every output cell has at least $T \geq h \geq m/3$ points and at most $3km$ points. By (4.7) and $m/h > 2$,

$$\mathcal{B}_k(g_\epsilon; \mathcal{P}_j, U) \geq \frac{4\alpha(m/h)^k}{(3/2)^{k+2}(k+2)^{k+2}} > \alpha \left(\frac{4}{3(k+2)} \right)^{k+2}. \quad (4.12)$$

In particular the conclusion is a *strict* failure of uniformity at the displayed coefficient.

Completion of the proof of Theorem F.21.1. Since $N \geq m^2 > 9k^2$ in this branch, $N > k + 1$ and all required factorials are invertible. To apply this to Proposition 17.7, first reduce the common difference of the input progressions to one by an invertible dilation. Write the center of the i -th progression as r_i , set $f_\epsilon(s) = f(s - \epsilon \cdot r)$, and put $\tau(a) = \sigma(a + r)$ in the normalized coordinates. These are exactly the functions in (4.5). If a dilation $x = da$ is written explicitly before this normalization, its frequency becomes $d\sigma(d(a + r))$, which is still multi-affine. After choosing ϵ , translate back using

$$g_\epsilon(x + \epsilon \cdot r) = f(x)e_N(-\phi_\epsilon(x + \epsilon \cdot r)). \quad (4.13)$$

The corresponding support partition is $\mathcal{P}_j - \epsilon \cdot r$. The phase still has degree at most $k + 1$. This identity fixes the sign of the support translation without relying on a convention in the source text.

For completeness, if $m \leq 3k$, Cauchy–Schwarz in each Fourier sum and AM–GM over its 2^k vertices give

$$E \leq Nm^k \sum_s |f(s)|^{2^{k+1}}.$$

The hypothesis therefore implies $\sum_s |f(s)|^{2^{k+1}} \geq \alpha N$. Use the singleton partition and the zero phase. With the convention $U = \ell + 1 = 2$, its quotient is at least $\alpha/2^{k+2}$, which strictly exceeds the right side of (4.12). Singletons satisfy the required lower size $m/(3k) \leq 1$. This proves the finite assertion, including the small branch, with

$$c_k = \left(\frac{4}{3(k+2)} \right)^{k+2}.$$

□

Remark IV.13.3 (Effect on subsequent uses). The new cells may be larger than those in Gowers' original construction. Their sizes remain between $m/(3k)$ and $3km$, but a later transfer to a smaller cyclic group must recheck its no-wrap condition. In the asymptotic induction, requiring $N > 2(k+1)3km$ is a sufficient safe condition and can be included in the lower threshold for N . The local phase-removal theorem itself does not require that additional inequality. No improved final Szemerédi bound is asserted here.

IV.13.4 Optimal width within this averaging argument

Proposition IV.13.4 (Width optimization). *For fixed k , as $m \rightarrow \infty$ through odd integers and $N \geq m^2$, the choice (4.10) gives*

$$\mathcal{B}_k(g; \mathcal{Q}, U) \geq (1 - o(1)) \alpha \left(\frac{2}{k+2} \right)^{k+2}. \quad (4.14)$$

The real-valued model of (4.7), with $U = w$, is maximized at $w = (k+2)h$. In a subsequent limit $k \rightarrow \infty$,

$$\left(\frac{2}{k+2} \right)^{k+2} = (4e^{-2} + o(1)) \frac{2^k}{k^{k+2}}. \quad (4.15)$$

Proof. The logarithmic derivative of $(w - kh)^2 / w^{k+2}$ is $2/(w - kh) - (k+2)/w$, which vanishes exactly at $(k+2)h$. It is positive before that point and negative afterwards. For fixed k , $T = (k+2)h \rightarrow \infty$ and $T/N \rightarrow 0$. Thus $w/T \rightarrow 1$, $U/w \rightarrow 1$, and $m/h \rightarrow 2$. Substitution in (4.7) gives (4.14). Finally $(1 + 2/k)^{-k-2} \rightarrow e^{-2}$, proving (4.15). The two limits have been specified in this order; no unqualified joint asymptotic is used. $\square$

For given finite N, m, k , one can evaluate $m^k(N/M - kh)^2 / (\lfloor N/M \rfloor + 1)^{k+2}$ over the admissible integer M . This gives the best bound furnished by the exact theorem, without making a continuity or rounding approximation.

IV.13.5 A geometric ceiling for every genuinely local conclusion

Let $A_d(L)$ be the number of additive d -cubes all of whose vertices belong to the integer interval $\{0, \dots, L-1\}$. For fixed increments the vertex span is the sum of their absolute values, so

$$A_d(L) = \sum_{h \in \mathbb{Z}^d} \left(L - \sum_i |h_i| \right)_+, \quad \sum_{L \geq 0} A_d(L) z^L = \frac{z(1+z)^d}{(1-z)^{d+2}}. \quad (4.16)$$

Coefficient extraction gives

$$A_d(L) = \sum_{j=0}^d \binom{d}{j} \binom{L+d-j}{d+1} = \frac{2^d}{(d+1)!} L^{d+1} + O_d(L^d). \quad (4.17)$$

The binomial coefficient is zero when its nonnegative upper argument is less than its lower argument. The generating function follows from $\sum_{n \in \mathbb{Z}} z^{|n|} = (1+z)/(1-z)$ and $\sum_{L \geq 0} (L-r)_+ z^L = z^{r+1}/(1-z)^2$.

Proposition IV.13.5 (Local-scale upper bound). *Fix k and positive constants a_k, b_k . Suppose a phase-removal conclusion is required to use arithmetic progression cells with sizes between $a_k m$ and $b_k m$, and uses a normalization upper bound at least as large as every cell. As $m \rightarrow \infty$, $N \geq m^2$ prime, no universal coefficient in that conclusion can exceed*

$$\frac{2^{k+1}}{(k+2)!} + o(1). \quad (4.18)$$

In particular the leading logarithmic order $-k \log k$ of the coefficients obtained above is optimal within this local-scale class.

Proof. Take $f \equiv 1$ and $\sigma \equiv 0$; the input has $E = N^2 m^k$, so $\alpha = 1$. Every polynomial twist has modulus one. For $|g| \leq 1$, the triangle inequality in the expanded cube form gives

$$0 \leq \mathcal{C}_d(\mathbf{1}_Q g) \leq \mathcal{C}_d(\mathbf{1}_Q).$$

A dilation normalizes any nontrivial progression in the prime cyclic group to a consecutive interval. For $N > 2d|Q|$, its cube count agrees with the integer count: all congruences between the lifted cube vertices have difference of absolute value below N , hence are equalities. This no-wrap condition holds eventually, uniformly over the allowed cell sizes. Apply (4.17) with $d = k + 1$, sum over the partition, and divide by its stated normalization. The result is at most $2^{k+1}/(k+2)! + O_k(1/m)$.

Stirling's formula gives $\log(2^{k+1}/(k+2)!) = -k \log k + O(k)$, and the coefficient in (4.14) has the same leading logarithm. Their ratio is

$$\frac{(k+2)^{k+2}}{2(k+2)!} \sim \frac{e^{k+2}}{2\sqrt{2\pi(k+2)}}.$$

Thus an exponential-in- k gap remains between the lower and upper constants; the exact optimum is not determined. $\square$

[write] **6 October 2026; sources 15–20.** The first upper bound in this report for local-scale coefficients at Proposition 17.7. It does not bind `proposition_17_7`, which has no upper cell size (the source says so after the proof).

This upper bound concerns conclusions that remain at a local scale. It does not restrict an unrestricted statement that can select the entire group as one cell. The interval cube formula is an elementary geometric calculation; its role here is to identify a necessary size for the localization loss.

IV.14 A refinement when the original small cells must be kept

Source 16, delivered Section 5.

The larger windows in Section IV.13 are useful when the output scale can be transported. There is also a refinement that keeps an existing equal-width cyclic partition exactly as it is.

Let its label function be $\ell(s) = \lfloor s/w \rfloor \pmod{M}$, where $w = N/M$. For a fixed increment vector a , define the normalized pattern

$$j_{a,s}(\epsilon) = \ell(s - \epsilon \cdot a) - \ell(s) \pmod{M}. \quad (5.1)$$

Lemma IV.14.1 (At most 2^k active patterns). *For fixed a , at most 2^k different patterns $j_{a,s}$ occur as s varies.*

Proof. Put $z = \{s/w\}$ and $u = a/w$. Then

$$j_{a,s}(\epsilon) = \lfloor z - \epsilon \cdot u \rfloor \pmod{M}.$$

The coordinate $\epsilon = 0$ is zero. Each of the other $2^k - 1$ coordinates changes at most once as z runs through $[0, 1)$. Hence there are at most 2^k joint values. At a breakpoint the floor function has its value immediately to the right, so no extra boundary pattern occurs. Reduction modulo M can only merge patterns. $\square$

Figure IV.13.1: Negative binary logarithms of retained local factors. A smaller value means a stronger lower guarantee. The source and finite sliding curves are finite guarantees; the optimized sliding curve and the local-scale ceiling are asymptotic in the stated order of limits. The vertical axis is logarithmic.

Proposition IV.14.2 (Active count times global count). *Let L be the number of translation-normalized patterns occurring over the whole input increment box, and let R_0 be an upper bound for the number active at any one increment vector. In the localized phase-removal argument, if the phases in (3.2) are available, some candidate phase and translated copy of the original partition satisfy*

$$\sum_i \mathcal{C}_{k+1}(\mathbf{1}_{Q_i} g) \geq \frac{E}{R_0 L M}. \quad (5.2)$$

One may take $R_0 = 2^k$. The corresponding argument that uses the global count at its first Cauchy–Schwarz step gives $E/(L^2 M)$.

Proof. Group the inner Fourier sum by normalized pattern and denote the contribution of class r by $B_r(a)$. For each a , at most R_0 of these terms are nonzero, so

$$\left| \sum_r B_r(a) \right|^2 \leq R_0 \sum_r |B_r(a)|^2.$$

Keep the sum over r . Within each class, apply Cauchy–Schwarz over its M spatial translates, giving a factor M . Enlarge the increment domain while the expression is still a sum of squares. Expand it, polarize, and use (2.3). The polynomial ϕ_ϵ is independent of r .

For any fixed r, ϵ , summing over translates permutes the whole partition, so its diagonal sum is the same quantity $\sum_i \mathcal{C}_{k+1}(\mathbf{1}_{Q_i} g_\epsilon)$. Summing over r gives one factor L , and averaging over ϵ chooses the winning candidate. The resulting upper bound for E is $R_0 L M$ times that candidate’s energy, proving (5.2). $\square$

[write] **6 October 2026; sources 15–20.** *Credit* (not given by the source, although source 04’s text was in the repository at its pin). Lemma IV.14.1 is source 04’s Lemma IV.6.5 (at most 2^k profiles at a fixed slope), and this proposition with $R_0 = 2^k$ is source 04’s Lemma IV.6.6 with the first inequality of its Theorem IV.6.7, where the global count L is bounded by B_k ; the “ $E/(L^2M)$ ” form is source 06’s Theorem IV.8.1 and source 01’s Proposition IV.3.3. The weighted variant below is new and minor.

The active count is sharp for this pointwise argument. Choose $a_i = 2^{i-1}$, a prime $N > 2^k$, and an input box containing these integers. If $M \geq 2$ and $\gcd(M, N) = 1$, all subset sums are distinct modulo N , hence their nonzero breakpoints are distinct. As s varies, $\{Ms/N\}$ visits the full N -point grid. Every one of the 2^k joint values occurs. This only proves sharpness of the active-pattern bound, not of the resulting analytic estimate.

A weighted form is sometimes useful. For positive weights λ_r , put

$$H = \max_a \sum_{\substack{r \\ \text{active at } a}} \lambda_r.$$

Weighted Cauchy–Schwarz gives the same conclusion with R_0L replaced by $H \sum_r \lambda_r^{-1}$. Thus the finite incidence pattern can be optimized without changing the partition or the phases.

IV.15 Source 36’s chapter: sharp symmetry certification at Proposition 17.2 [write]

Added in the seventh write, 6 October 2026.

The next nine sections are source 36’s Sections 2–10, on the global phase-extraction step around Gowers’s Proposition 17.2 over vector spaces $\mathbb{F}_p^n$, where a multilinear frequency selector need not be symmetric. *Logically the chapter stands beside source 16’s chapter on Proposition 17.7* (Section IV.10) and the phase-extraction material of sources 01, 04 and 06 in this Part; it is printed here because no number printed earlier may move. Source 36’s introduction, with its two main theorems, is Section F.41.

What is proved. A multilinear selector $\sigma : V^k \rightarrow V^*$ whose form is not fully symmetric carries derivative-spectrum energy at most $\vartheta_{k,p} = 1 - (1 - 1/p)^k$ against every 1-bounded f , sharp for $n \geq 2$ (Theorem F.41.1); the proof goes through a rank-profile bound averaging p^{-r} over half-ranks of alternating slices (Theorem IV.18.1) and a sharp Heisenberg orthogonality inequality (Theorem IV.17.1) with its equality and stability structure (Theorem IV.20.3). For $p > k + 1$ symmetry gives a canonical polynomial and the lossless identity $\mathcal{A}_f(\sigma) = \|fe_p(-P)\|_{U^{k+1}}^{2^{k+1}}$, pointwise before averaging (Theorem F.41.2, Section IV.21); noisy, dense-domain, coset, multiaffine and prime-power variants follow (Sections IV.22–IV.23). The bilinear inequality sharpens source 31’s Lemma II.106.4, and the case $k = 1$ is a vector-space analogue of source 29’s symmetry step (Section II.110); source 36 cites neither. Characteristic two is excluded (Section IV.24); sources 43 and 46, placed and not yet written, treat it.

[write] **7 October 2026; sources 40–46.** Sources 43 and 46 are now printed (Section IV.25): for symmetric trilinear forms over $\mathbb{F}_2^n$ the exact energy is $2^{-r/2}$, r the rank of $T(a, a, b) + T(a, b, b)$, and source 43 extends this chapter’s threshold and bilinear estimate to every finite abelian group (notes after Theorems F.41.1 and IV.17.1). Source 46 does not cite source 36; source 43 does.

Relation to the formal statements (checked at HEAD 89c1cbc38). `proposition_17_2` (Sections 17_18.lean, line 48) and `proposition_17_7` (line 140) have the exact companions `prop`

osition_17_2_holds (Proofs17PhaseRemoval.lean, line 373) and proposition_17_7_holds (Proofs17LocalizedPhaseRemoval.lean, line 2941); the formal statements are on $\mathbb{Z}/N\mathbb{Z}$, and source 36 does not claim to improve their coefficient one. Nothing in this chapter is formalized.

IV.16 Normalization and the exact cube identity

Source 36, delivered Section 2.

Lemma IV.16.1 (Fourier-square expansion). *For every $g : V \rightarrow \mathbb{C}$ and $\xi \in V^*$,*

$$|\widehat{g}(\xi)|^2 = \mathbb{E}_{x,y} g(x+y) \overline{g(x)} e_p(-\xi(y)). \quad (\text{IV.16.1})$$

Consequently

$$\mathcal{A}_f(\sigma) = \mathbb{E}_{x,\mathbf{h},y} \partial_{h_1,\dots,h_k,y} f(x) e_p(-T(\mathbf{h},y)). \quad (\text{IV.16.2})$$

Proof. Expand the square as an average over two independent points z, x , then substitute $z = x + y$. Apply the resulting identity to $g = \partial_{\mathbf{h}} f$. Commutation of multiplicative derivatives gives (IV.16.2). $\square$

For $d \geq 2$, the normalized Gowers power is

$$\|f\|_{U^d}^{2^d} = \mathbb{E}_{x,h_1,\dots,h_d} \partial_{h_1,\dots,h_d} f(x) = \mathbb{E}_{h_1,\dots,h_{d-1}} \left| \mathbb{E}_x \partial_{h_1,\dots,h_{d-1}} f(x) \right|^2. \quad (\text{IV.16.3})$$

The second identity proves the nonnegativity needed in this article. No triangle inequality for U^d is used below.

The off-by-one in the notation has mathematical content. A k -fold derivative has a linear frequency if its phase originally had degree $k + 1$. Accordingly there are $k + 1$ variables in T , the polynomial in (F.41.7) has degree at most $k + 1$, and the final norm is U^{k+1} . The following table can serve as a normalization check.

Derivative order	Selector	Total form	Extracted phase / norm
1	linear	bilinear	quadratic / U^2
2	bilinear	trilinear	cubic / U^3
3	trilinear	four-linear	quartic / U^4
k	k -linear	$(k + 1)$ -linear	degree $k + 1$ / U^{k+1}

IV.17 The sharp bilinear estimate

Source 36, delivered Section 3.

IV.17.1 Statement and a direct operator proof

Let $B : V \times V \rightarrow \mathbb{F}_p$ be bilinear. Its alternating part is

$$\Omega(h, x) = B(h, x) - B(x, h). \quad (\text{IV.17.1})$$

The rank of Ω , as a map $V \rightarrow V^*$, is even; write it as $2r$. For two functions $g, v : V \rightarrow \mathbb{C}$ define

$$\mathcal{Q}_B(g, v) = \mathbb{E}_h \left| \mathbb{E}_x g(x+h) \overline{v(x)} e_p(-B(h, x)) \right|^2, \quad \mathcal{Q}_B(g) = \mathcal{Q}_B(g, g). \quad (\text{IV.17.2})$$

The L^2 norms below use normalized counting measure.

Theorem IV.17.1 (Alternating-rank orthogonality). *For arbitrary complex functions g, v ,*

$$\mathcal{Q}_B(g, v) \leq p^{-r} \|g\|_2^2 \|v\|_2^2. \quad (\text{IV.17.3})$$

In particular $\mathcal{Q}_B(g) \leq p^{-r} \|g\|_2^4$. For each B the factor p^{-r} is attained with $g = v$ and $|g| = 1$ everywhere.

[write] **6 October 2026; sources 34–39.** This is the sharp, rank-sensitive form of source 31's Lemma II.106.4 (note in Section F.41). Independent checks of the intake: on 21 random triples over $\mathbb{F}_3^2, \mathbb{F}_5^2, \mathbb{F}_3^3, \mathbb{F}_3^4$ the normalized ratio stayed below 0.49; the value $1/p$ is attained at $p = 3, 5, 7$; over all 6,561 trilinear forms on $\mathbb{F}_3^2$ with $f = 1$ the maximum of the tested energy over the nonsymmetric forms is exactly $5/9 = 1 - (2/3)^2$, the threshold of Theorem F.41.1 at $k = 2$.

[write] **7 October 2026; sources 40–46.** Source 43's Theorem IV.35.2 proves the bound d_B^{-1} , $d_B = \sqrt{|G/R_B|}$, for every biadditive form on every finite abelian group, without division by two (checked at the write on small groups; note in Section F.48).

We first establish the only representation-theoretic fact required for the inequality. Inner products are linear in the first argument.

Lemma IV.17.2 (Minimum dimension of an invariant subspace). *Suppose unitary operators $(U_h)_{h \in V}$ on a finite-dimensional complex Hilbert space satisfy*

$$U_h U_l = e_p(\Omega(h, l)/2) U_{h+l}, \quad U_0 = I. \quad (\text{IV.17.4})$$

Every nonzero subspace invariant under all U_h has dimension at least $D = p^r$.

Proof. An alternating form of rank $2r$ has vectors $a_1, \dots, a_r, b_1, \dots, b_r$ with $\Omega(a_i, b_j) = \delta_{ij}$ and all pairings within the a -family or within the b -family zero. To obtain them, select a, b with $\Omega(a, b) \neq 0$, scale b to make the value one, split off their nondegenerate two-dimensional span, and repeat on its orthogonal complement. This also proves evenness of the rank.

Put $X_i = U_{a_i}$ and $Z_i = U_{b_i}$. The Z_i commute, $Z_i^p = I$, and

$$X_i Z_j = e_p(\delta_{ij}) Z_j X_i.$$

Let E be a nonzero invariant subspace. It is invariant under the inverses as well, because those are among the U_h up to scalars. The commuting unitary restrictions $Z_i|_E$ have a common nonzero eigenvector z . For each $t = (t_1, \dots, t_r) \in \mathbb{F}_p^r$, the vector $X_1^{t_1} \cdots X_r^{t_r} z$ belongs to E . Its simultaneous Z_i eigenvalues are those of z multiplied by $e_p(-t_i)$. Different t give different joint eigenspaces, which are orthogonal. There are p^r such nonzero vectors. The case $r = 0$ is immediate. $\square$

Proof of the inequality in Theorem IV.17.1. Work on $\mathcal{H} = L^2(V)$ and put

$$W_h g(x) = g(x+h) e_p(-B(h, x)), \quad (\text{IV.17.5})$$

$$U_h = e_p(-B(h, h)/2) W_h. \quad (\text{IV.17.6})$$

A direct multiplication gives $W_h W_l = e_p(-B(l, h)) W_{h+l}$; substituting (IV.17.6) yields (IV.17.4). For $u \in \mathcal{H}$ let P_u be the positive rank-one operator $P_u(z) = \langle z, u \rangle u$. Its trace is $\|u\|_2^2$. Define the positive operator

$$M_g = \mathbb{E}_h P_{U_h g}. \quad (\text{IV.17.7})$$

Translation of the index h , together with the cocycle law, gives $U_l M_g U_l^{-1} = M_g$ for all l . Each eigenspace of M_g is therefore invariant. If $\lambda > 0$ is its largest eigenvalue, the corresponding eigenspace has dimension at least D by Lemma IV.17.2. Thus

$$D\lambda \leq \text{tr}(M_g) = \|g\|_2^2.$$

Finally, multiplication by the scalar in (IV.17.6) does not change the absolute value of a matrix coefficient, and

$$\mathcal{Q}_B(g, v) = \langle M_g v, v \rangle \leq \lambda \|v\|_2^2.$$

If $M_g = 0$ the conclusion is automatic. This proves (IV.17.3) without an irreducible-representation classification. $\square$

IV.17.2 Sharp unit-modulus examples

The symplectic splitting in the preceding proof yields independent functionals $\alpha_1, \dots, \alpha_r, \beta_1, \dots, \beta_r \in V^*$ such that

$$\Omega(h, x) = \sum_{j=1}^r (\alpha_j(h) \beta_j(x) - \beta_j(h) \alpha_j(x)). \quad (\text{IV.17.8})$$

Set $B_0(h, x) = \sum_j \alpha_j(h) \beta_j(x)$. Then $S = B - B_0$ is symmetric. With $P_B(x) = S(x, x)/2$ and $g(x) = e_p(P_B(x))$, direct expansion gives

$$\mathbb{E}_x \partial_h g(x) e_p(-B(h, x)) = e_p(S(h, h)/2) \mathbb{E}_x e_p(-B_0(h, x)). \quad (\text{IV.17.9})$$

The last average is one when all $\alpha_j(h)$ vanish and zero otherwise, by character orthogonality. That event has probability p^{-r} . This proves the sharpness assertion of Theorem IV.17.1, including the 1-bounded setting.

For instance, on $\mathbb{F}_p^2$ take $B(h, x) = h_1 x_2$ and $g = 1$. The alternating rank is two, and $\mathcal{Q}_B(g) = 1/p$. On $\mathbb{F}_p^{2r}$, taking $B(h, x) = \sum_{j=1}^r h_{2j-1} x_{2j}$ and $g = 1$ gives p^{-r} . A bound based only on whether the alternating part vanishes would lose all information distinguishing these examples.

IV.18 The derivative rank profile

Source 36, delivered Section 4.

Fix $i \in \{1, \dots, k\}$. Let $\mathbf{u}$ denote the other $k-1$ increments, inserted in their original slots, and set

$$g_{i,\mathbf{u}}(x) = \partial_{h_1, \dots, \widehat{h_i}, \dots, h_k} f(x), \quad m_i(\mathbf{u}) = \|g_{i,\mathbf{u}}\|_2^2, \quad (\text{IV.18.1})$$

$$B_{i,\mathbf{u}}(a, b) = T(h_1, \dots, h_{i-1}, a, h_{i+1}, \dots, h_k, b), \quad (\text{IV.18.2})$$

$$\Omega_{i,\mathbf{u}}(a, b) = B_{i,\mathbf{u}}(a, b) - B_{i,\mathbf{u}}(b, a), \quad r_i(\mathbf{u}) = \frac{1}{2} \text{rank } \Omega_{i,\mathbf{u}}. \quad (\text{IV.18.3})$$

For $k = 1$ the tuple $\mathbf{u}$ is empty, has probability one, and $g_{i,\mathbf{u}} = f$. These conventions avoid a separate base case later.

Theorem IV.18.1 (Amplitude-sensitive rank-profile bound). *For every multilinear selector and every complex f ,*

$$\mathcal{A}_f(\sigma) \leq \min_{1 \leq i \leq k} \mathbb{E}_{\mathbf{u}} p^{-r_i(\mathbf{u})} m_i(\mathbf{u})^2. \quad (\text{IV.18.4})$$

For 1-bounded f this implies

$$\mathcal{A}_f(\sigma) \leq \min_i \mathbb{E}_{\mathbf{u}} p^{-r_i(\mathbf{u})}. \quad (\text{IV.18.5})$$

Proof. Fix i and average last over $h_i = a$. Commutation of derivatives gives $\partial_{\mathbf{h}} f = \partial_a g_{i,\mathbf{u}}$. Therefore

$$\mathcal{A}_f(\sigma) = \mathbb{E}_{\mathbf{u}} \mathcal{Q}_{B_{i,\mathbf{u}}}(g_{i,\mathbf{u}}).$$

Apply Theorem IV.17.1 to each slice. If $|f| \leq 1$, then $|g_{i,\mathbf{u}}| \leq 1$ and $m_i(\mathbf{u}) \leq 1$. Since the calculation applies to every i , both minima follow. $\square$

Corollary IV.18.2 (Quantitative low-rank consequences). *Assume $|f| \leq 1$ and $\mathcal{A}_f(\sigma) \geq a$. For every i and integer $t \geq 1$,*

$$\mathbb{P}_{\mathbf{u}}(r_i(\mathbf{u}) \geq t) \leq \frac{1-a}{1-p^{-t}}, \quad (\text{IV.18.6})$$

$$\mathbb{P}_{\mathbf{u}}(r_i(\mathbf{u}) < t) \geq \frac{a-p^{-t}}{1-p^{-t}}. \quad (\text{IV.18.7})$$

The second bound is informative when $a > p^{-t}$. If $r_i \geq t$ on a set of tuples of density at least ρ , then

$$\mathcal{A}_f(\sigma) \leq 1 - \rho(1 - p^{-t}). \quad (\text{IV.18.8})$$

Proof. The profile average is at most $\mathbb{P}(r_i < t) + p^{-t}\mathbb{P}(r_i \geq t)$. Rearrange and use Theorem IV.18.1. $\square$

The amplitude information should not be discarded unnecessarily. If a frozen derivative has small L^2 mass, it is expensive to attribute energy to that slice even when its alternating rank is zero. Conversely, a large unweighted set of rank-zero slices need not carry appreciable energy. Formula (IV.18.4) keeps these distinctions.

As a simple scale check, for $p = 101$, $k = 2$, an energy of 0.05 is above $\vartheta_{2,101} = 201/10201$. It therefore certifies symmetry. For $p = 5$ the same energy is below $\vartheta_{2,5} = 9/25$ and does not do so. The rank profile may still give useful information in the latter case.

IV.19 Proof and sharpness of the symmetry threshold

Source 36, delivered Section 5.

IV.19.1 A support lemma

Lemma IV.19.1 (Nonzero multilinear maps have positive support). *Let $F : V_1 \times \cdots \times V_m \rightarrow W$ be a nonzero multilinear map of finite-dimensional $\mathbb{F}_p$ -vector spaces. Then*

$$\mathbb{P}(F \neq 0) \geq (1 - 1/p)^m. \quad (\text{IV.19.1})$$

The convention for $m = 0$ is a nonzero constant, with support probability one. The same bound holds when F is separately affine.

Proof. For a nonzero linear map in one variable, its kernel has codimension at least one, so its zero probability is at most $1/p$. A nonzero affine map either has no zeros or has a zero set which is a translate of a proper linear kernel, giving the same bound.

For the induction, regard F as a map in its first $m - 1$ variables with values in the vector space of linear maps $V_m \rightarrow W$ (or the vector space of affine maps in the separately affine case). This new map is nonzero and of the same separate type. By induction, it takes a nonzero value on at least a fraction $(1 - 1/p)^{m-1}$ of tuples. Conditional on such a tuple, the remaining nonzero linear or affine map is nonzero at a fraction at least $1 - 1/p$ of its inputs. Multiplying the two fractions proves the assertion. $\square$

The bound is attained by $F(v_1, \dots, v_m) = \ell_1(v_1) \cdots \ell_m(v_m)w$, where the ℓ_j are nonzero functionals and $w \neq 0$. Vector-valued output is important in the application: the output will be a whole alternating bilinear form, not its value at a preselected pair.

IV.19.2 Certification

Proof of the inequality in Theorem F.41.1. The transpositions $(i, k + 1)$, $1 \leq i \leq k$, generate the symmetric group on the $k + 1$ slots. Therefore, if T is not fully symmetric, there is some i for which

$$T(h_1, \dots, h_i, \dots, h_k, y) - T(h_1, \dots, y, \dots, h_k, h_i)$$

is nonzero as a multilinear form. In the notation of (IV.18.3), this says that $\mathbf{u} \mapsto \Omega_{i,\mathbf{u}}$ is a nonzero $(k - 1)$ -linear map into the vector space of alternating bilinear forms on V . Lemma IV.19.1 gives

$$\rho := \mathbb{P}_{\mathbf{u}}(\Omega_{i,\mathbf{u}} \neq 0) \geq (1 - 1/p)^{k-1}.$$

Every nonzero alternating form has rank at least two, so $r_i(\mathbf{u}) \geq 1$ on this event. Hence

$$\begin{aligned} \mathcal{A}_f(\sigma) &\leq \mathbb{E}_{\mathbf{u}} p^{-r_i(\mathbf{u})} \\ &\leq (1 - \rho) + \rho/p \\ &\leq 1 - (1 - 1/p)^k. \end{aligned}$$

This includes $k = 1$ because the nonzero defect is then a fixed alternating bilinear form. $\square$

The proof combines two independent exact obstructions: a nonzero multilinear defect cannot hide on too few slices, and on every defective slice noncommutation forces a factor at most $1/p$. Treating the alternating defect as an arbitrary scalar polynomial would obscure the second obstruction and lose the sharp constant.

IV.19.3 Endpoint construction

Proof of sharpness in Theorem F.41.1. Assume $\dim V \geq 2$ and choose linearly independent $a, c \in V^*$. Set $f = 1$ and

$$\sigma(h_1, \dots, h_k) = \left(\prod_{j=1}^k a(h_j) \right) c. \quad (\text{IV.19.2})$$

This selector is symmetric in its k inputs. Choose $u, v \in V$ with $a(u) = 1$, $c(u) = 0$, $a(v) = 0$, $c(v) = 1$. Then $T(u, \dots, u, v) = 1$, whereas swapping the first and last entries makes the value zero. Thus T is not fully symmetric.

Every multiplicative derivative of f is one. Its Fourier coefficient at a frequency is one exactly when that frequency is zero. Therefore

$$\mathcal{A}_1(\sigma) = \mathbb{P}\left(\prod_{j=1}^k a(h_j) = 0\right) = 1 - (1 - 1/p)^k. \quad (\text{IV.19.3})$$

For a fixed i , the alternating slice is a scalar multiple of $a \otimes c - c \otimes a$. Its rank is zero when $\prod_{j \neq i} a(h_j) = 0$ and two otherwise. Thus the rank-profile bound and the support lemma are simultaneously equalities. $\square$

Remark IV.19.2 (The strict inequality cannot be relaxed). The implication in Theorem F.41.1 uses $>$, not $\geq$. It remains sharp after imposing symmetry in the derivative slots or restricting to unit-modulus functions. In dimension one every scalar multilinear form is already fully symmetric, so the nonsymmetric extremal class is empty there.

For reference, the first three thresholds are as follows. These are symmetry thresholds; classical integration separately requires $p > k + 1$.

p	$k = 1$	$k = 2$	$k = 3$
3	1/3	5/9	19/27
5	1/5	9/25	61/125
17	1/17	33/289	817/4913
101	1/101	201/10201	30301/1030301

IV.20 Equality structure and stability of the bilinear step

Source 36, delivered Section 6.

The short operator proof suffices for the main threshold. A fuller orthogonality identity explains how close-to-extremal slices look. This section is a refinement of the bilinear step, not a classification of all extremizers of the higher-order threshold.

IV.20.1 Block decomposition and an exact identity

Retain B , Ω , r , $D = p^r$, and the operators U_h from Section IV.17. Put $R = \text{rad } \Omega$ and choose a nondegenerate complement W , so $V = R \oplus W$ and $|W| = D^2$. The U_z , $z \in R$, form an ordinary commuting representation of the additive group R . Consequently

$$\mathcal{H} = \bigoplus_{\chi \in R_{\text{char}}^*} \mathcal{H}_\chi, \quad U_z|_{\mathcal{H}_\chi} = \chi(z)I. \quad (\text{IV.20.1})$$

Here R_{char}^* denotes its complex character group. Zero blocks may be omitted for a general representation; for the concrete representation on $L^2(V)$ every block below is nonzero.

Lemma IV.20.1 (Explicit Weyl decomposition). *There are unitary identifications*

$$\mathcal{H}_\chi \simeq \mathbb{C}^D \otimes \mathbb{C}^D \quad (\text{IV.20.2})$$

under which U_w , $w \in W$, acts on the first factor and trivially on the second. Writing its first-factor action as $A_{\chi,w}$, the D^2 matrices $D^{-1/2}A_{\chi,w}$ form an orthonormal basis of $\text{Mat}_D(\mathbb{C})$ for the Hilbert–Schmidt inner product.

Proof. Choose symplectic generators X_i, Z_i as in Lemma IV.17.2. Within a fixed block, the common Z_i eigenspaces are permuted transitively by the X_i , so they have a common dimension, say m_χ . Choose an orthonormal basis of the joint eigenspace with all eigenvalues one, and transport it by the X_i . That eigenspace exists whenever the block is nonzero, because the X_i shift any joint eigenvalue tuple to $(1, \dots, 1)$. In the resulting basis the X_i shift the D eigenvalue labels and the Z_i multiply them by characters, without affecting the basis index within the original eigenspace. This constructs $\mathcal{H}_\chi \simeq \mathbb{C}^D \otimes \mathbb{C}^{m_\chi}$.

For the concrete U_h on $L^2(V)$, the trace of U_h is zero for $h \neq 0$: it is a scalar times a modulated nonzero translation and has zero diagonal in the point-mass basis. The projector onto $\mathcal{H}_\chi$ is $|R|^{-1} \sum_{z \in R} \overline{\chi(z)} U_z$. Its trace is $|V|/|R| = D^2$. Thus $m_\chi = D$ for every χ .

If $w \neq 0$ lies in W , nondegeneracy provides $u \in W$ with $\Omega(u, w) \neq 0$. Conjugation by $A_{\chi, u}$ multiplies $A_{\chi, w}$ by $e_p(\Omega(u, w)) \neq 1$, so its trace is zero. The cocycle law then gives $\text{tr}(A_{\chi, w} A_{\chi, w'}^*) = 0$ for $w \neq w'$, and equals D for $w = w'$. There are D^2 orthogonal matrices in the D^2 -dimensional matrix space, proving the last assertion. $\square$

Identify a vector in each tensor block with its coefficient matrix. Write G_χ and V_χ for the matrices of the projections of g and v . Their Hilbert–Schmidt norms equal the Hilbert norms of those projections.

Proposition IV.20.2 (Exact matrix-coefficient formula). *With the preceding identifications,*

$$\mathcal{Q}_B(g, v) = \frac{1}{D} \sum_\chi \|G_\chi V_\chi^*\|_{\text{HS}}^2. \quad (\text{IV.20.3})$$

In particular, with $\rho_\chi = G_\chi G_\chi^*$,

$$D \mathcal{Q}_B(g) = \sum_\chi \text{tr}(\rho_\chi^2), \quad \sum_\chi \text{tr} \rho_\chi = \|g\|_2^2. \quad (\text{IV.20.4})$$

Proof. Write $h = z + w$ with $z \in R$, $w \in W$. Since $\Omega(z, w) = 0$, $U_h = U_z U_w$. The matrix coefficient in question is

$$\sum_\chi \chi(z) \text{tr}(G_\chi V_\chi^* A_{\chi, w}).$$

Averaging its squared modulus over z eliminates all cross terms between different χ . By the orthonormal-basis assertion in Lemma IV.20.1, for every $D \times D$ matrix K ,

$$\mathbb{E}_{w \in W} |\text{tr}(K A_{\chi, w})|^2 = D^{-1} \|K\|_{\text{HS}}^2.$$

Averaging over w proves (IV.20.3). Set $v = g$ to obtain (IV.20.4). $\square$

The mixed inequality also follows from $\|GV^*\|_{\text{HS}} \leq \|G\|_{\text{HS}} \|V\|_{\text{HS}}$ and $\sum_\chi a_\chi b_\chi \leq (\sum_\chi a_\chi)(\sum_\chi b_\chi)$ for nonnegative sequences. This gives a second proof of its exact normalization.

IV.20.2 Rigidity and a dimension-free stability estimate

Theorem IV.20.3 (Bilinear equality and stability). *Let $\|g\|_2 = 1$. Equality $\mathcal{Q}_B(g) = D^{-1}$ holds if and only if g is supported in one block $\mathcal{H}_\chi$ and is a simple tensor there. Equivalently, exactly one G_χ is nonzero and it has rank one.*

If $0 \leq \varepsilon \leq 1$ and $\mathcal{Q}_B(g) \geq (1 - \varepsilon)/D$, there is a unit vector g_0 with $\mathcal{Q}_B(g_0) = 1/D$ such that

$$\|g - g_0\|_2^2 \leq 2(1 - \sqrt{1 - \varepsilon}). \quad (\text{IV.20.5})$$

When $0 \leq \varepsilon < 1/2$, the right-hand side can be improved to

$$2 \left(1 - \sqrt{\frac{1 + \sqrt{1 - 2\varepsilon}}{2}} \right). \quad (\text{IV.20.6})$$

These are assertions in $L^2(V)$; g_0 is not asserted to be 1-bounded.

Proof. Collect all eigenvalues of all the positive matrices ρ_χ into one finite list (λ_j) . Their sum is one, and $D\mathcal{Q}_B(g) = \sum_j \lambda_j^2$. This sum is one precisely when one λ_j is one and the others are zero. This proves the equality classification.

Let λ be the largest eigenvalue in the list. Since $\sum_j \lambda_j^2 \leq \lambda \sum_j \lambda_j = \lambda$, we have $\lambda \geq 1 - \varepsilon$. A singular value decomposition of the corresponding G_χ supplies a unit rank-one tensor g_0 whose inner product with g has modulus $\sqrt{\lambda}$. Choose its scalar phase to make that inner product nonnegative. Then $\|g - g_0\|_2^2 = 2(1 - \sqrt{\lambda})$, proving (IV.20.5).

If $\varepsilon < 1/2$, the same argument shows $\lambda > 1/2$. All other eigenvalues sum to $1 - \lambda$, whence

$$1 - \varepsilon \leq \sum_j \lambda_j^2 \leq \lambda^2 + (1 - \lambda)^2.$$

On $[1/2, 1]$ this implies $\lambda \geq (1 + \sqrt{1 - 2\varepsilon})/2$ and yields (IV.20.6). $\square$

The last scalar bound is sharp when two orthogonal Schmidt components are available: take their squared coefficients to be λ and $1 - \lambda$. That is a statement about the purity argument, not a claim that every such example obeys a pointwise bound. For higher-order derivative spectra, the simple tensors arising in different frozen slices must also be compatible with one common f . That compatibility is not supplied by this stability theorem.

IV.21 Lossless polarization and the Section 17 interface

Source 36, delivered Section 7.

IV.21.1 A self-contained polarization calculation

For an additive-valued function P , write $\Delta_h P(x) = P(x + h) - P(x)$, using a capital delta to distinguish it from the multiplicative derivative.

Lemma IV.21.1 (Diagonal integration). *Let $d \geq 2$, $p > d$, and let $T : V^d \rightarrow \mathbb{F}_p$ be symmetric and d -linear. If $P(x) = T(x, \dots, x)/d!$, then*

$$\Delta_{h_1} \cdots \Delta_{h_d} P(x) = T(h_1, \dots, h_d). \quad (\text{IV.21.1})$$

Moreover, with $d = k + 1$,

$$\Delta_{h_1} \cdots \Delta_{h_k} P(x) = T(h_1, \dots, h_k, x) + C(\mathbf{h}), \quad C(\mathbf{h}) = \Delta_{\mathbf{h}} P(0). \quad (\text{IV.21.2})$$

Proof. Expand the d -fold difference as an alternating sum over subsets $S \subseteq \{1, \dots, d\}$ of $P(x + \sum_{j \in S} h_j)$. Multilinearity expands each term into ordered choices of d inputs from $x, h_1, \dots, h_d$. A term missing some h_j cancels upon summing over whether j is in S . Thus only terms containing every h_j survive. There are $d!$ of them, they contain no x , and symmetry makes all of them equal to $T(h_1, \dots, h_d)$. Division by $d!$ gives (IV.21.1).

For the second assertion, set $F(x) = \Delta_{\mathbf{h}} P(x)$. The first assertion says $F(x + y) - F(x) = T(\mathbf{h}, y)$. Taking $x = 0$ gives $F(y) = T(\mathbf{h}, y) + F(0)$, which is (IV.21.2). $\square$

Proof of Theorem F.41.2. Multiplicative derivatives distribute over products. Therefore, by (IV.21.2),

$$\begin{aligned} \partial_{\mathbf{h}}(f e_p(-P))(x) &= \partial_{\mathbf{h}} f(x) e_p(-\Delta_{\mathbf{h}} P(x)) \\ &= e_p(-C(\mathbf{h})) \partial_{\mathbf{h}} f(x) e_p(-\sigma(\mathbf{h})(x)). \end{aligned} \quad (\text{IV.21.3})$$

Average over x and take absolute values. This is (F.41.8). Squaring and averaging over $\mathbf{h}$, then using (IV.16.3), gives (F.41.9). $\square$

The proof does not use a choice among 2^{k+1} candidate phases or introduce an additional Cauchy–Schwarz power. In a homogeneous global model the phase is read directly from the diagonal of T . One may add any polynomial of degree at most k to P without changing the pointwise magnitudes: its k -fold derivative is constant in x . Thus “canonical” denotes the specified homogeneous representative, not uniqueness among all possible phases.

IV.21.2 Exact scalar specialization

Corollary IV.21.2 (Equality-form replacement for the global scalar step). *Let $V = \mathbb{F}_p$, $p > k + 1$, and $\sigma(h_1, \dots, h_k) = ch_1 \cdots h_k$. For every $f : V \rightarrow \mathbb{C}$, with $P(x) = cx^{k+1}/(k+1)!$ and $g = f e_p(-P)$,*

$$\sum_{\mathbf{h} \in V^k} \left| \sum_{x \in V} \partial_{\mathbf{h}} f(x) e_p(-ch_1 \cdots h_k x) \right|^2 = \sum_{\mathbf{h} \in V^k} \left| \sum_{x \in V} \partial_{\mathbf{h}} g(x) \right|^2. \quad (\text{IV.21.4})$$

Proof. The total form is $ch_1 \cdots h_k y$, hence is fully symmetric. Apply (F.41.8) and multiply both sides after averaging by p^{k+2} . $\square$

This is the scale N^{k+2} used in Proposition 17.2. The original paper uses backward cubes

$$\prod_{\epsilon \in \{0,1\}^k} \mathcal{C}^{|\epsilon|} f(s - \epsilon \cdot \mathbf{h}),$$

where $\mathcal{C}$ denotes conjugation. Our forward cube is its translate by $h_1 + \cdots + h_k$; its Fourier coefficient differs only by a unit scalar. Thus the squared quantities in (IV.21.4) match the source convention. The corrected repository already raises the phase degree to $k + 1$ and includes the characteristic restriction; these are not newly reported defects here [166].

Example IV.21.3 (Why the degree must be $k + 1$). Take $k = 1$, $V = \mathbb{F}_p$, $a \neq 0$, $f(x) = e_p(ax^2)$, and $\sigma(h)(x) = 2ahx$. Every tested Fourier coefficient has modulus one, so $\mathcal{A}_f(\sigma) = 1$. Twisting by any linear polynomial preserves the quadratic coefficient. For such a twist g , $\mathbb{E}_x \partial_h g(x)$ vanishes for $h \neq 0$ and has modulus one for $h = 0$. Hence $\|g\|_{U^2}^4 = 1/p$, not one. The quadratic phase in Theorem F.41.2 is necessary.

IV.21.3 An elementary complete quadratic inverse consequence

Corollary IV.21.4. *Suppose $p > 2$, $k = 1$, $|f| \leq 1$, and $\mathcal{A}_f(\sigma) = a > 1/p$. There is a polynomial Q of degree at most two such that*

$$|\mathbb{E}_x f(x) e_p(-Q(x))| \geq \sqrt{a / \|f\|_2^2} \geq \sqrt{a}. \quad (\text{IV.21.5})$$

Proof. Theorems F.41.1 and F.41.2 give a quadratic P with $g = f e_p(-P)$ and $\|g\|_{U^2}^4 = a$. Finite character orthogonality, applied to the Fourier expansion of g , gives Parseval and the fourth-moment identity

$$\sum_{\xi \in V^*} |\hat{g}(\xi)|^2 = \|g\|_2^2, \quad \sum_{\xi \in V^*} |\hat{g}(\xi)|^4 = \|g\|_{U^2}^4.$$

For completeness, in the latter identity substitute $g(x) = \sum_{\xi} \hat{g}(\xi) e_p(\xi(x))$ into the parallelogram average; orthogonality in its three variables forces the four frequencies to agree. Hence $a \leq \max_{\xi} |\hat{g}(\xi)|^2 \|g\|_2^2$. Choose a maximizing ξ and put $Q = P + \xi$. $\square$

For larger k , the lossless identity supplies an input to a U^{k+1} -inverse theorem. It does not itself prove the required lower-order inverse theorem or its quantitative bounds.

IV.22 Robust and local variants

Source 36, delivered Section 8.

IV.22.1 Errors in a frequency selector

The expression $\mathcal{A}_f(\phi)$ in (F.41.3) makes sense for an arbitrary map $\phi : V^k \rightarrow V^*$, whether or not it is multilinear.

Proposition IV.22.1 (Selector disagreement costs at most its density). *If $|f| \leq 1$ and $\phi, \sigma : V^k \rightarrow V^*$ disagree on a set of density at most η , then*

$$|\mathcal{A}_f(\phi) - \mathcal{A}_f(\sigma)| \leq \eta. \quad (\text{IV.22.1})$$

If σ is multilinear, $\mathcal{A}_f(\phi) \geq a$, and $a - \eta > \vartheta_{k,p}$, its total form is symmetric. If also $p > k + 1$, the canonical phase satisfies

$$\|f e_p(-P)\|_{U^{k+1}}^{2^{k+1}} \geq a - \eta. \quad (\text{IV.22.2})$$

Proof. On agreement tuples the summands coincide. On each remaining tuple, both squared magnitudes lie in $[0, 1]$, so their difference in absolute value is at most one. Average, then apply the main theorems. $\square$

This is an agreement assumption on the selectors, not a claim that a multilinear fit can be found efficiently from arbitrary noisy data. Obtaining the fit remains a separate structural or algorithmic problem. The inequality also allows deterministic rather than random corruption.

IV.22.2 A dense set of large coefficients

Corollary IV.22.2 (Dense-domain extraction). *Let $H \subseteq V^k$ have density β , let σ be a global multilinear selector, and suppose $|\widehat{\partial_{\mathbf{h}} f}(\sigma(\mathbf{h}))| \geq \gamma$ for every $\mathbf{h} \in H$. If $|f| \leq 1$, then*

$$\mathcal{A}_f(\sigma) \geq \beta\gamma^2. \quad (\text{IV.22.3})$$

If $\beta\gamma^2 > \vartheta_{k,p}$, the form T is symmetric. If additionally $p > k + 1$, its canonical phase obeys

$$\|f e_p(-P)\|_{U^{k+1}} \geq (\beta\gamma^2)^{1/2^{k+1}}. \quad (\text{IV.22.4})$$

A sufficient characteristic condition for both conclusions is $p > \max\{k + 1, k/(\beta\gamma^2)\}$.

Proof. Retain only the nonnegative summands indexed by H . The characteristic condition follows from (F.41.6). $\square$

It is essential that σ is defined multilinearly on all of V^k . Values on H alone do not supply such an extension. In particular, a local multilinear pattern on an arithmetic box in the cyclic-group argument cannot be inserted into this corollary without an additional extension theorem.

IV.22.3 Common selectors on affine cosets

Let $W \leq V$, choose a set $\mathcal{C}$ of representatives of affine cosets of W , and assign nonnegative weights $\mu(c)$ of total one. For $c \in \mathcal{C}$, put $f_c(w) = f(c + w)$. Let a single multilinear $\sigma : W^k \rightarrow W^*$ be used in every coset and define

$$\mathcal{A}_{\mu,f}(\sigma) = \sum_{c \in \mathcal{C}} \mu(c) \mathcal{A}_{f_c}(\sigma). \quad (\text{IV.22.5})$$

Proposition IV.22.3 (Weighted coset version). *If $|f| \leq 1$ and $\mathcal{A}_{\mu,f}(\sigma) > \vartheta_{k,p}$, the total form of σ on W is symmetric. If $p > k + 1$ and P is the canonical polynomial on W , then*

$$\mathcal{A}_{\mu,f}(\sigma) = \sum_c \mu(c) \|f_c e_p(-P)\|_{U^{k+1}(W)}^{2^{k+1}}. \quad (\text{IV.22.6})$$

The weighted rank-profile estimate holds with $m_i(\mathbf{u})^2$ replaced by $\sum_c \mu(c) \|\partial_{\mathbf{u}} f_c\|_2^4$.

Proof. If the common total form were nonsymmetric, each coset's energy would be at most $\vartheta_{k,p}$ by Theorem F.41.1; average the inequalities. The identity and the profile assertion follow by applying their corresponding theorems separately on W and summing. $\square$

These are local norms on a subspace with its uniform counting measure. The proposition does not assert that the resulting piecewise function is a low-degree polynomial on the full ambient space. Such a gluing statement requires additional compatibility between cosets.

IV.23 Multiaffine selectors and extension fields

Source 36, delivered Section 9.

IV.23.1 Multiaffine frequency patterns

A separately affine selector has a unique decomposition

$$\sigma(\mathbf{h}) = \sum_{S \subseteq [k]} \sigma_S((h_j)_{j \in S}), \quad (\text{IV.23.1})$$

where σ_S is multilinear in the indicated inputs and $\sigma_\emptyset$ is constant. One can obtain this decomposition by successive subtraction of the values at zero in each slot; the same procedure proves uniqueness.

For fixed i and $\mathbf{u}$, write

$$\sigma(h_1, \dots, a, \dots, h_k) = L_{i,\mathbf{u}}(a) + \xi_{i,\mathbf{u}}. \quad (\text{IV.23.2})$$

Define $B_{i,\mathbf{u}}(a, b) = L_{i,\mathbf{u}}(a)(b)$ and its alternating rank as before. These ranks refer to the linear part in the unfrozen input, not to the affine offset.

Theorem IV.23.1 (Multiaffine coefficient certification). *For a separately affine selector and arbitrary complex f , the amplitude-sensitive estimate (IV.18.4) still holds with the ranks just defined. If $|f| \leq 1$ and $\mathcal{A}_f(\sigma) > \vartheta_{k,p}$, then for every nonempty $S \subseteq [k]$ the form*

$$((h_j)_{j \in S}, y) \mapsto \sigma_S((h_j)_{j \in S})(y) \quad (\text{IV.23.3})$$

is fully symmetric in its $|S| + 1$ variables. No restriction on the constant component is asserted.

Proof. For a fixed slice set $g = \partial_{\mathbf{u}} f$ and $v(x) = e_p(\xi_{i,\mathbf{u}}(x))g(x)$. The slice energy is exactly $\mathcal{Q}_{B_{i,\mathbf{u}}}(g, v)$, and $\|v\|_2 = \|g\|_2$. The mixed form of Theorem IV.17.1 proves the profile.

The map $\mathbf{u} \mapsto \Omega_{i,\mathbf{u}}$ is separately affine into the space of alternating bilinear forms. If it is nonzero, the affine version of Lemma IV.19.1 and the rank profile imply $\mathcal{A}_f(\sigma) \leq \vartheta_{k,p}$ exactly as before. Thus under the strict energy hypothesis every such map is zero.

Expand it using (IV.23.1). For fixed i its component indexed by $S \setminus \{i\}$, with $i \in S$, is precisely the alternating defect obtained by swapping h_i and y in (IV.23.3). Uniqueness of the decomposition forces each component defect to vanish. For any fixed nonempty S , the swaps between its inputs and y generate all permutations of these $|S| + 1$ slots. The component form is therefore fully symmetric. $\square$

The homogeneous top part can consequently be integrated when $p > k + 1$. One must not conclude that its diagonal polynomial removes the lower-order components of the frequency selector. The following example shows a failure of the naive equality-form extension.

Example IV.23.2 (An affine offset survives). Let $V = \mathbb{F}_{17}$, $k = 1$, $\xi(x) = x$, and $f(x) = (1 + e_{17}(x))/2$. Take the constant selector $\sigma(h) = \xi$. It is separately affine, its linear part is zero, and

$$\partial_h f(x) = \frac{1}{4}(1 + e_{17}(h) + e_{17}(x + h) + e_{17}(-x)).$$

Thus $\mathcal{A}_f(\sigma) = 1/16 > 1/17$, although $\|f\|_{U^2}^4 = 1/8$. Integrating the zero top part gives $P = 0$, so $\mathcal{A}_f(\sigma) = \|f e_{17}(-P)\|_{U^2}^4$ would be false. There is no contradiction with Theorem IV.23.1, which certifies the symmetry of nonconstant components, not this extra identity.

IV.23.2 Finite extensions of the prime field

Corollary IV.23.3 (Odd prime-power fields). *Let $q = p^e$ with p odd, let $V = \mathbb{F}_q^n$, and let $\psi : \mathbb{F}_q \rightarrow \mathbb{C}^\times$ be a nontrivial additive character. Use $\mathbb{F}_q$ -linear duals and replace e_p by ψ in the definitions. The rank-profile bound becomes*

$$\mathcal{A}_f(\sigma) \leq \min_i \mathbb{E}_u q^{-r_i(u)} m_i(u)^2, \quad (\text{IV.23.4})$$

where ranks are over $\mathbb{F}_q$. The sharp symmetry threshold is $1 - (1 - 1/q)^k$. If the total form is symmetric and the characteristic satisfies $p > k + 1$, the canonical polarization and lossless identities hold over $\mathbb{F}_q$ as well.

Proof. Write $\psi(t) = e_p(\text{Tr}_{\mathbb{F}_q/\mathbb{F}_p}(ct))$ for some $c \neq 0$. A bilinear alternating form Ω of $\mathbb{F}_q$ -rank $2r$ induces the $\mathbb{F}_p$ -bilinear alternating form $\text{Tr}(c\Omega)$ of rank $2er$. Indeed the radicals are the same sets: if h is outside the $\mathbb{F}_q$ -radical, the $\mathbb{F}_q$ -linear map $x \mapsto \Omega(h, x)$ is onto $\mathbb{F}_q$, and the nonzero trace functional does not vanish on its entire image. The dimension of the common radical is multiplied by e when scalars are restricted. Theorem IV.17.1, on the underlying $\mathbb{F}_p$ -space, therefore gives the factor $p^{-er} = q^{-r}$.

A nonzero $\mathbb{F}_q$ -linear map has a kernel of relative size at most $1/q$, so the support induction uses $(1 - 1/q)^{k-1}$. The endpoint construction uses two independent $\mathbb{F}_q$ -linear functionals and has the same zero-product probability with q in place of p . Finally, the polarization proof only requires invertibility of $(k + 1)!$, which is ensured by $p > k + 1$, not by the weaker condition $q > k + 1$. $\square$

The character parametrization used here follows from nondegeneracy of the trace pairing: its nonzero scalar multiples give q different characters of the additive group of $\mathbb{F}_q$, hence all of them. For example, nontriviality of the trace map follows since the polynomial $X + X^p + \cdots + X^{p^{e-1}}$ is nonzero of degree less than q ; multiplication by a nonzero field element then proves nondegeneracy.

IV.24 Small characteristic and other exact boundaries

Source 36, delivered Section 10.

IV.24.1 Full symmetry does not guarantee classical integration

The symmetry theorem is valid for every odd p , regardless of k . The integration theorem is more restrictive. At the boundary $p \leq k + 1$, division by the factorial may fail for a substantive reason, not merely because the displayed formula is inconvenient.

Example IV.24.1 (Perfect energy without classical integration). On $V = \mathbb{F}_3$, let $[x] \in \{0, 1, 2\}$ be the integer representative and put

$$f(x) = \exp(2\pi i[x]/9), \quad T(a, b, c) = -abc, \quad \sigma(a, b)(x) = -abx. \quad (\text{IV.24.1})$$

Then T is symmetric, and

$$\partial_{a,b,c} f(x) = e_3(-abc), \quad \mathcal{A}_f(\sigma) = 1. \quad (\text{IV.24.2})$$

There is no function $Q : \mathbb{F}_3 \rightarrow \mathbb{F}_3$ whose third additive derivative is T .

Proof. Let $F(x) = [x]$ as an integer-valued function, computing differences modulo 9. If one increment is zero the triple difference vanishes. For three increments equal to one, write S for translation by one. Since $S^3 = I$,

$$(S - I)^3 F = 3(S - S^2)F \equiv -3 \pmod{9},$$

because $(S - S^2)F$ has values $-1, 2, -1$. For a negative increment, the difference operator obeys $\Delta_{-1} = -S^{-1}\Delta_1$. Triple differences therefore have value $-3abc$ modulo 9 for all $a, b, c \in \mathbb{F}_3$; translations of the constant triple difference do not change it. Exponentiating proves the first identity in (IV.24.2); inserting it in (IV.16.2) proves the second.

Every function $\mathbb{F}_3 \rightarrow \mathbb{F}_3$ is represented by a polynomial of degree at most two, by interpolation at the three field points. Each additive difference lowers its degree by at least one, so every third derivative is zero. Since $T(1, 1, 1) \neq 0$, no such Q exists. $\square$

The phase $[x]/9$ is a nonclassical polynomial: its third difference is constant and its fourth difference vanishes in $\mathbb{R}/\mathbb{Z}$. This example illustrates an established distinction in finite-field inverse theory, rather than discovering that distinction. Tidor's integration theorem [150] incorporates additional low-characteristic identities; it must not be read as integration of all ordinary symmetric tensors into classical phases. Also, exact integration of a prescribed derivative is stronger than merely finding correlation with some classical polynomial phase. Our example only rules out the former.

IV.24.2 Other limitations

Boundedness is a real hypothesis. Scaling f by M scales $\mathcal{A}_f$ by $|M|^{2^{k+1}}$. Without a pointwise bound, a nonsymmetric selector can therefore carry arbitrary energy. The amplitude-sensitive estimate remains correct because its right side has the same homogeneity.

One repeated function is special. The reduction to $\mathcal{Q}_B(g)$ uses the fact that all cube vertices come from derivatives of the same f . An arbitrary array of different vertex functions need not have that structure. The mixed bilinear estimate is useful for affine offsets, but it does not justify substituting our threshold into a general mixed higher-order correlation theorem.

Small energy is not exact symmetry. The endpoint construction already gives a substantial nonsymmetric energy. Below the threshold, only rank-profile consequences are proved. General approximate symmetry is a different issue: the bounded-partition-rank approximation statement proposed in Tidor's work is false in general, as shown by Milićević's four-linear counterexamples over $\mathbb{F}_2$ [151]. We do not relabel that disproved general statement as an open question or claim that our odd-characteristic criterion rescues it.

No end-to-end Ramsey estimate. A global selector, a finite-field domain, and sufficient energy are inputs to this manuscript. Constructing the selector from an arithmetic-progression obstruction, managing interval boundaries, and iterating a density increment are not outputs. The local result cannot by itself alter the final quantitative theorem in the repository.

IV.25 Sources 46 and 43: exact binary cubic norms and Boolean phase integration [write]

Added in the eighth write, 7 October 2026.

The next sixteen sections are source 46’s Sections 2–9 and then source 43’s Sections 2–9, on Gowers’s phase-extraction step (Lemma 17.1 and Proposition 17.2) in characteristic two, where division by the factorial is impossible and symmetry is not the whole integrability condition. *Logically the chapter stands beside source 36’s chapter* (Section IV.15), which treats odd characteristic and excludes characteristic two; it is printed here because no number printed earlier may move. Their introductions are Sections F.51 and F.48.

The common theorem, proved twice. For a symmetric trilinear form T over $\mathbb{F}_2^n$ let r be the rank of the alternating form $T(a, a, b) + T(a, b, b)$ (source 46’s C_T , source 43’s Ω_T). Then the T -twisted cubic average of eight 1-bounded functions has modulus at most $2^{-r/2}$, attained with all eight functions equal to one nonclassical cubic phase with values among the eighth roots of unity, and $r/2$ is the least codimension of a subspace on which T integrates (source 46’s Theorem IV.27.1; source 43’s Theorem IV.39.4 for one function, with an amplitude factor). The seven-function correlation is at most $2^{-r/4}$, so correlation δ forces an integrable restriction of codimension at most $2 \log_2(1/\delta)$, against $8 \log_2(1/\delta)$ in Tidor’s Proposition 4.6 (source 46’s Theorem IV.28.1; source 43’s Theorem IV.40.3). The two proofs differ: source 46 converts the cube into quadratic convolution operators and a symplectic decomposition; source 43 uses a shear identity and its division-free orthogonality theorem. Source 46’s eight-function statement contains source 43’s one-function maximum, so source 46 is printed first; source 43 is a credited second route, printed whole with its further results.

Further results. Source 46: an exact agreement threshold $(1+2^{-r/2})/2$ and a spectral stability identity (Corollary IV.28.3, Proposition IV.28.4); constructive integration and the optimal phase order; an all-characteristic scalar polarization with the optimal root-of-unity alphabet (Theorem IV.30.2); the classification of exact nonclassical integrability of the trace tensors $\text{Tr}(ch_1 \cdots h_d)$ over $\mathbb{F}_{p^n}$ with their obstruction ranks and repair costs (Theorems IV.31.1, IV.32.1, IV.32.3). Source 43: the sharp orthogonality $\mathcal{Q}_B(g, h) \leq d_B^{-1} \|g\|_2^2 \|h\|_2^2$ on every finite abelian group, without division by two (Theorem IV.35.2); the exact symmetry threshold $1 - (1 - 1/p_*(G))^k$ on every noncyclic finite abelian group (Theorem IV.36.4), which extends source 36’s threshold and its bilinear estimate; an explicit Boolean primitive (Theorem IV.37.2); the sharp certification threshold $1 - 2^{1-d}$ in every degree (Theorem IV.38.4); the fourth-power triangle bound in place of the eighth power of Tidor’s Lemma 4.1 (Theorem IV.40.1); the quartic reduction and the value $11/16$ on $\mathbb{F}_2^2$ (Theorems IV.41.2, IV.41.3). The four claims of source 43 that the intake did not check (orthogonality, certification threshold, fourth power, $11/16$) were checked at the write (note in Section F.48). The integration criterion itself is Tao–Ziegler’s and Tidor’s, as both sources say; source 46 does not cite source 36, and source 43 cites it.

Relation to the formal statements (checked at HEAD 6d4942222). `lemma_17_1` and `proposition_17_2` (Sections17_18.lean, lines 38 and 48) have the exact companions `lemma_17_1_holds` (Proofs17Phase.lean, line 374) and `proposition_17_2_holds` (Proofs17PhaseRemoval.lean, line 373); they are stated on $\mathbb{Z}/N\mathbb{Z}$ with N prime and $k + 1 < N$, so characteristic two lies outside them, as both sources say. Nothing in this chapter is formalized.

IV.26 Conventions and the first integration obstruction

Source 46, delivered Section 2.

Throughout, p is prime and V is a finite-dimensional $\mathbb{F}_p$ -vector space. All averages are normalized. We write $\mathbb{T} = \mathbb{R}/\mathbb{Z}$, $e(t) = \exp(2\pi it)$, and $\iota(a) = |a|/p \pmod{1}$, where $|a| \in \{0, \dots, p-1\}$ is the standard integer representative. The map $\iota : \mathbb{F}_p \rightarrow \mathbb{T}$ is additive. A function is *1-bounded* if its modulus is at most one everywhere.

For $P : V \rightarrow \mathbb{T}$, put

$$D_h P(x) = P(x+h) - P(x).$$

A nonclassical polynomial of degree at most d is a function for which every $(d+1)$ -fold additive derivative vanishes. A symmetric d -linear form $T : V^d \rightarrow \mathbb{F}_p$ *integrates* if

$$D_{h_1} \cdots D_{h_d} P(x) = \iota(T(h_1, \dots, h_d)) \quad (\text{IV.26.1})$$

for all $x, h_1, \dots, h_d$. Such a P automatically has degree at most d . We refer to integration by a function with values in a coset of $p^{-R}\mathbb{Z}/\mathbb{Z}$ as integration with phase order p^R . Constants are immaterial. Classical integration means that $R = 1$ suffices.

Proposition IV.26.1 (Known integration criterion). *For symmetric d -linear T , a necessary and sufficient condition for nonclassical integration is the following repeated-variable condition whenever $d \geq p+1$:*

$$T(\underbrace{a, \dots, a}_p, b, z_1, \dots, z_{d-p-1}) = T(a, \underbrace{b, \dots, b}_p, z_1, \dots, z_{d-p-1}). \quad (\text{IV.26.2})$$

For $d \leq p$ there is no additional condition. A necessary condition for classical integration when $d \geq p$ is vanishing whenever p arguments coincide.

The general equivalence is the Tao–Ziegler/Tidor criterion [184, 150]; we do not reprove its general sufficiency. The necessity and the sufficiency for $d \leq p+1$ needed throughout this article are proved below and in Section IV.29.

Lemma IV.26.2 (Repeated-variable necessity). *Every total derivative satisfies (IV.26.2).*

Proof. Let I be the augmentation ideal of the integral group ring $\mathbb{Z}[V]$, acting on functions by translations, and put $\delta_a = [a] - [0]$. Because $pa = 0$,

$$\delta_a^p = - \sum_{j=1}^{p-1} \binom{p}{j} \delta_a^j. \quad (\text{IV.26.3})$$

In particular $pI^s \subseteq I^{s+p-1} + pI^{s+1}$ for $s \geq 1$. Iterating this inclusion modulo I^{d+1} shows that pI^s annihilates every degree-at-most- d polynomial whenever $s+p-1 > d$.

Subtract (IV.26.3) multiplied by δ_b from its version with a, b interchanged and the corresponding factor δ_a . The $j = 1$ terms cancel. Each remaining term, after multiplication by the $d-p-1$ other differences, belongs to pI^{d-p+j} with $j \geq 2$. It therefore annihilates P . This gives $\delta_a^p \delta_b \prod \delta_{z_i} P = \delta_a \delta_b^p \prod \delta_{z_i} P$, as required. For $p = 2$ the sum of remaining terms is empty. On $\mathbb{F}_p$ -valued functions, more strongly, $\delta_a^p = [pa] - [0] = 0$, which proves the stated classical necessity. $\square$

At the first obstructed degree $d = p + 1$, define

$$C_T(a, b) = T(a, \dots, a, b) - T(a, b, \dots, b), \quad (\text{IV.26.4})$$

with p repeated arguments in each term. Symmetry and the divisibility of $\binom{p}{j}$ by p show that C_T is bilinear. It is alternating because $C_T(a, a) = 0$.

Proposition IV.26.3 (First-obstruction test). *A symmetric $(p + 1)$ -linear form integrates if and only if $C_T = 0$. For a subspace $W \leq V$, its restriction integrates if and only if $C_T|_{W \times W} = 0$.*

Proof. Necessity is Lemma IV.26.2. An explicit coordinate integrator proving sufficiency is given in Theorem IV.29.4; the same construction on a basis of W proves the restriction statement. $\square$

Lemma IV.26.4 (Alternating-form geometry). *If an alternating bilinear form C on an n -dimensional vector space has rank r , then $r = 2m$ is even. Its largest totally isotropic subspace has dimension $n - m$. Moreover, C is a sum of m elementary wedges of linear functionals, and no fewer such wedges suffice.*

Proof. If $C \neq 0$, choose u, v with $C(u, v) = 1$. Their span is nondegenerate. Subtract appropriate multiples of u, v from every other vector to split this plane orthogonally, and iterate. This gives m hyperbolic planes and a radical of dimension $n - 2m$. Taking the radical and one line from each plane gives an isotropic subspace of dimension $n - m$.

In the quotient by the radical, an isotropic subspace U is contained in its orthogonal complement, so $\dim U \leq m$. This proves maximality in V as well. The dual-coordinate expression of the hyperbolic planes gives m wedges. Each wedge has rank at most two, so rank subadditivity proves the lower bound on their number. $\square$

IV.27 The exact binary mixed cubic norm

Source 46, delivered Section 3.

In this section $V = \mathbb{F}_2^n$ and $T : V^3 \rightarrow \mathbb{F}_2$ is symmetric and trilinear. Thus

$$C_T(a, b) = T(a, a, b) + T(a, b, b), \quad r = \text{rank } C_T = 2m.$$

For eight functions $f_\varepsilon : V \rightarrow \mathbb{C}$, indexed by $\varepsilon \in \{0, 1\}^3$, define

$$\Lambda_T((f_\varepsilon)) = \mathbb{E}_{x,a,b,c} \prod_{\varepsilon \in \{0,1\}^3} C^{|\varepsilon|} f_\varepsilon(x + \varepsilon_1 a + \varepsilon_2 b + \varepsilon_3 c) (-1)^{T(a,b,c)}, \quad (\text{IV.27.1})$$

where C denotes complex conjugation. Allowing different functions at all vertices is important: the result is stronger than a bound for one repeated function.

Theorem IV.27.1 (Sharp mixed cubic bound). *For all 1-bounded f_ε ,*

$$|\Lambda_T((f_\varepsilon))| \leq 2^{-r/2}. \quad (\text{IV.27.2})$$

The bound is attained. In fact there is a nonclassical polynomial $P : V \rightarrow \frac{1}{8}\mathbb{Z}/\mathbb{Z}$ of degree at most three such that, on setting all $f_\varepsilon = e(P)$, the average equals $2^{-r/2}$.

[write] **7 October 2026; sources 40–46.** Source 43's Theorem IV.39.4 proves the one-function case independently (with an amplitude factor), by a shear identity and its division-free orthogonality theorem; here the bound holds for eight different functions. The value $2^{-r/2}$ and the codimension $r/2$ agree.

IV.27.1 A quadratic spectral calculation

For a real-valued function κ on V , normalized convolution is

$$(K_\kappa H)(x) = \mathbb{E}_y \kappa(x+y) H(y).$$

The characters are $(-1)^{\xi(x)}$ for $\xi \in V^*$, with eigenvalues $\widehat{\kappa}(\xi) = \mathbb{E}_x \kappa(x) (-1)^{\xi(x)}$.

Lemma IV.27.2 (Flat nonzero quadratic spectrum). *Let $Q : V \rightarrow \mathbb{F}_2$ satisfy $Q(0) = 0$, with alternating polar form $C(x, h) = Q(x+h) + Q(x) + Q(h)$ of rank r . For any linear $L : V \rightarrow \mathbb{F}_2$, the function $\kappa(x) = (-1)^{Q(x)+L(x)}$ has Walsh coefficients in $\{0, 2^{-r/2}, -2^{-r/2}\}$. Consequently $\|K_\kappa\|_{2 \rightarrow 2} = 2^{-r/2}$.*

Proof. Changing variables in the square of a Walsh coefficient gives

$$\begin{aligned} |\widehat{\kappa}(\xi)|^2 &= \mathbb{E}_{x,h} (-1)^{Q(x)+Q(x+h)+(L+\xi)(h)} \\ &= \mathbb{E}_h (-1)^{Q(h)+(L+\xi)(h)} \mathbb{E}_x (-1)^{C(x,h)}. \end{aligned}$$

The inner average is the indicator of $R = \text{rad } C$. The restriction $Q|_R$ is linear. Averaging its character against $L+\xi$ therefore gives either zero or $|R|/|V| = 2^{-r}$. The coefficients are real, proving the assertion. At least one is nonzero, by Parseval. Diagonalization in the character basis proves the operator-norm formula. $\square$

IV.27.2 Proof of the upper bound

Make the invertible change of variables

$$b = a + A, \quad c = a + B, \quad y = x + a.$$

The four even-parity vertices become $x, x+A, x+B, x+A+B$; the four odd-parity vertices become $y, y+A, y+B, y+A+B$. Define

$$\begin{aligned} F_{A,B}(x) &= f_{000}(x) f_{110}(x+A) f_{101}(x+B) f_{011}(x+A+B), \\ G_{A,B}(y) &= f_{100}(y) f_{010}(y+A) f_{001}(y+B) f_{111}(y+A+B). \end{aligned}$$

Both functions have L^2 norm at most one. Multilinearity gives

$$T(a, a+A, a+B) = Q(a) + L_{A,B}(a), \tag{IV.27.3}$$

where

$$Q(a) = T(a, a, a), \quad L_{A,B}(a) = T(a, a, A) + T(a, a, B) + T(a, A, B).$$

Each term in $L_{A,B}$ is linear in a : the cross terms in two equal slots cancel in characteristic two. The polar form of Q is precisely C_T . Therefore, with $\kappa_{A,B}(a) = (-1)^{Q(a)+L_{A,B}(a)}$,

$$\Lambda_T = \mathbb{E}_{A,B} \mathbb{E}_{x,y} F_{A,B}(x) \overline{G_{A,B}(y)} \kappa_{A,B}(x+y).$$

Lemma IV.27.2 and the Hilbert-space Cauchy–Schwarz inequality bound the absolute value of each inner pairing by $2^{-r/2} \|F_{A,B}\|_2 \|G_{A,B}\|_2 \leq 2^{-r/2}$. Averaging proves (IV.27.2).

IV.27.3 Construction of extremizers

For linear forms $\ell, m : V \rightarrow \mathbb{F}_2$, set

$$S_{\ell,m}(a, b, c) = \ell(a)m(b)m(c) + m(a)\ell(b)m(c) + m(a)m(b)\ell(c). \quad (\text{IV.27.4})$$

This is symmetric and

$$C_{S_{\ell,m}}(a, b) = \ell(b)m(a) + \ell(a)m(b).$$

By Lemma IV.26.4, choose $m = r/2$ independent pairs (ℓ_i, m_i) whose wedges sum to C_T . Put $S = \sum_i S_{\ell_i, m_i}$. Then $R = T - S$ has $C_R = 0$ and therefore integrates. The explicit binary construction in Section IV.29 gives an integrator $P : V \rightarrow \frac{1}{8}\mathbb{Z}/\mathbb{Z}$ of degree at most three.

For $f = e(P)$, the cubical product in (IV.27.1) equals $(-1)^{R(a,b,c)}$. Thus

$$\Lambda_T(f, \dots, f) = \mathbb{E}_{a,b,c} (-1)^{S(a,b,c)}.$$

In each symplectic coordinate pair, averaging over c leaves the condition

$$m(a)m(b) = 0, \quad \ell(a)m(b) + m(a)\ell(b) = 0.$$

Exactly eight of the sixteen choices for $(\ell(a), m(a), \ell(b), m(b))$ satisfy these two equations: four with $m(a) = m(b) = 0$, two with $(m(a), m(b)) = (1, 0)$, and two with $(0, 1)$. The block average is consequently $1/2$. The coordinate pairs are jointly independent under uniform averaging. Their product gives 2^{-m} , proving sharpness and completing Theorem IV.27.1.

Remark IV.27.3. The proof does not estimate the rank of the original trilinear tensor. It uses the rank of its repeated-variable obstruction. Tensors of very different ordinary tensor ranks can therefore have exactly the same twisted cube norm.

IV.28 Restriction, exact agreement, and stability

Source 46, delivered Section 4.

IV.28.1 A factor-four improvement of the symmetric seven-function bound

For seven 1-bounded functions indexed by the nonempty subsets of $\{1, 2, 3\}$, put

$$\begin{aligned} \Gamma_T = \mathbb{E}_{a,b,c} & b_1(a)b_2(b)b_3(c)b_{12}(a+b)b_{13}(a+c) \\ & \cdot b_{23}(b+c)b_{123}(a+b+c)(-1)^{T(a,b,c)}. \end{aligned} \quad (\text{IV.28.1})$$

Theorem IV.28.1 (Improved symmetric restriction estimate). *Let $T : V^3 \rightarrow \mathbb{F}_2$ be symmetric and trilinear, with $\text{rank } C_T = r$. Then*

$$|\Gamma_T| \leq 2^{-r/4}. \quad (\text{IV.28.2})$$

If $|\Gamma_T| \geq \delta > 0$, there is a subspace $W \leq V$ with

$$\text{codim } W = \frac{r}{2} \leq 2 \log_2(1/\delta) \quad (\text{IV.28.3})$$

on which T integrates to a nonclassical cubic polynomial. Among all integrable restrictions of this particular T , the codimension $r/2$ is minimal.

Proof. Cauchy–Schwarz in (b, c) removes the product $b_2(b)b_3(c)b_{23}(b+c)$ and gives

$$|\Gamma_T|^2 \leq \mathbb{E}_{b,c} \left| \mathbb{E}_a b_1(a) b_{12}(a+b) b_{13}(a+c) b_{123}(a+b+c) (-1)^{T(a,b,c)} \right|^2.$$

Expand the square with the second variable $a+h$. The tensor factor becomes $(-1)^{T(h,b,c)}$. The resulting expression is an eight-function cube average with basepoint a , directions (h, b, c) , and assignments

$$\begin{aligned} f_{000} &= f_{100} = b_1, & f_{010} &= f_{110} = \overline{b_{12}}, \\ f_{001} &= f_{101} = \overline{b_{13}}, & f_{011} &= f_{111} = b_{123}. \end{aligned}$$

It is bounded by $2^{-r/2}$ by Theorem IV.27.1. Taking square roots proves (IV.28.2). Hence $r \leq 4 \log_2(1/\delta)$. A largest isotropic subspace for C_T has codimension $r/2$ by Lemma IV.26.4, and is exactly an integrable restriction by Proposition IV.26.3. These same facts give minimality. $\square$

[write] **7 October 2026; sources 40–46.** Source 43’s Theorem IV.40.3 gives the same bound $2^{-r/4}$ and codimension $\lfloor 2 \log_2(1/\delta) \rfloor$ through its fourth-power triangle estimate. Neither source claims the coefficient two optimal.

Comparison with the published bound. Tidor’s Proposition 4.6 [150] has the identical seven-function hypothesis and concludes $\text{codim } W \leq 8 \log_2(1/\delta)$. There are two improvements in the preceding argument: the spectral cube estimate gives $r \leq 4 \log_2(1/\delta)$, and one restricts to a maximal isotropic subspace rather than to the full radical. The latter saves another factor of two in codimension. No symmetry assumption has been dropped. For a nonsymmetric tensor one must still pay for symmetrization; we do not claim here a replacement for the constants in Tidor’s nonsymmetric Corollary 4.8 or in a full inverse theorem. Nor does sharpness of Theorem IV.27.1 establish sharpness of (IV.28.2): one Cauchy–Schwarz step intervenes.

IV.28.2 Exact derivative-spectrum maximum

For a single 1-bounded $f : V \rightarrow \mathbb{C}$, define

$$M_T(f) = \mathbb{E}_{a,b} \left| \mathbb{E}_x f(x) \overline{f(x+a)} \overline{f(x+b)} f(x+a+b) (-1)^{T(a,b,x)} \right|^2. \quad (\text{IV.28.4})$$

This is a squared Fourier-coefficient moment of the second multiplicative derivative, evaluated at the linear frequency $x \mapsto T(a, b, x)$.

Corollary IV.28.2 (Exact cubic spectral moment). *For $r = \text{rank } C_T$,*

$$\sup_{\|f\|_\infty \leq 1} M_T(f) = 2^{-r/2}.$$

The supremum is attained by the eighth-root phase in Theorem IV.27.1.

Proof. In (IV.28.4), expand the square with the second basepoint $x+c$. The product is precisely the eight-vertex product in (IV.27.1), and $T(a, b, x) + T(a, b, x+c) = T(a, b, c)$. Thus $M_T(f) = \Lambda_T(f, \dots, f)$. Apply Theorem IV.27.1. $\square$

IV.28.3 Optimal approximate polarization

Let $P_\varepsilon : V \rightarrow \mathbb{T}$ be completely arbitrary functions, not assumed to be polynomials. For uniform (x, a, b, c) , compare

$$\sum_{\varepsilon \in \{0,1\}^3} (-1)^{|\varepsilon|} P_\varepsilon(x + \varepsilon_1 a + \varepsilon_2 b + \varepsilon_3 c) \quad \text{with} \quad \iota(T(a, b, c)). \quad (\text{IV.28.5})$$

Equality is in $\mathbb{T}$.

Corollary IV.28.3 (Exact agreement and squared-error thresholds). *Writing $m = \text{rank } C_T/2$, the maximum probability of equality in (IV.28.5), over all eight functions P_ε , is*

$$\frac{1 + 2^{-m}}{2}. \quad (\text{IV.28.6})$$

The minimum mean squared distance between the corresponding unit complex numbers is

$$2(1 - 2^{-m}). \quad (\text{IV.28.7})$$

Both optima are attained with all P_ε equal to one nonclassical cubic with values in $\frac{1}{8}\mathbb{Z}/\mathbb{Z}$.

Proof. Let Z be the exponential of the difference between the two sides of (IV.28.5). Then $|Z| = 1$ and $|\mathbb{E}Z| \leq 2^{-m}$ by Theorem IV.27.1. If $s = \Pr(Z = 1)$, then $\text{Re } \mathbb{E}Z \geq 2s - 1$. This proves the upper bound for agreement. Also $\mathbb{E}|Z - 1|^2 = 2 - 2\text{Re } \mathbb{E}Z \geq 2(1 - 2^{-m})$. For the extremizer constructed above, $Z = (-1)^{S(a,b,c)}$ and $\mathbb{E}Z = 2^{-m}$. Since Z takes only the values $1, -1$, equality holds in both bounds. $\square$

Thus independent choices at the vertices cannot conceal a genuine integration obstruction. The conclusion quantifies this failure, whereas a formal factorial calculation only indicates that one particular formula is unavailable.

IV.28.4 A spectral stability identity

The proof of Theorem IV.27.1 retains information about near equality. For a common function f , let

$$F_{A,B}(x) = f(x)f(x+A)f(x+B)f(x+A+B), \quad \lambda = 2^{-r/2}.$$

The kernel $\kappa_{A,B}$ in (IV.27.3) has three possible eigenvalues: $+\lambda, 0, -\lambda$. Let $\Pi_{A,B}^+, \Pi_{A,B}^0, \Pi_{A,B}^-$ be the orthogonal projections onto these three Walsh spectral subspaces. Set

$$A_f = \mathbb{E}_{A,B} \|F_{A,B}\|_2^2, \quad \mu_\sigma = \mathbb{E}_{A,B} \left\| \Pi_{A,B}^\sigma F_{A,B} \right\|_2^2 \quad (\sigma \in \{+, 0, -\}).$$

Proposition IV.28.4 (Exact defect decomposition). *For every 1-bounded f ,*

$$1 - \frac{M_T(f)}{\lambda} = (1 - A_f) + \mu_0 + 2\mu_-. \quad (\text{IV.28.8})$$

In particular, if $M_T(f) \geq (1 - \varepsilon)\lambda$, then

$$\begin{aligned} \mathbb{E}_x |f(x)|^2 &\geq 1 - \varepsilon, \\ \mathbb{E}_{A,B} \left\| F_{A,B} - \Pi_{A,B}^+ F_{A,B} \right\|_2^2 &\leq \varepsilon, \\ \mu_- &\leq \varepsilon/2. \end{aligned}$$

Proof. For a common function, the two functions $F_{A,B}, G_{A,B}$ in the upper-bound proof coincide. Parseval and the real eigenvalues give $M_T(f) = \lambda(\mu_+ - \mu_-)$, whereas $A_f = \mu_+ + \mu_0 + \mu_-$. Subtraction proves (IV.28.8). Every term on its right is nonnegative because $A_f \leq 1$. Moreover $A_f \leq \mathbb{E}|f|^2$, since three of the four factors in $|F_{A,B}(x)|^2$ can be bounded by one. The conclusions follow. $\square$

This is stability of the transformed four-point functions in a completely specified spectral space. It is not yet a classification of f itself near a polynomial-phase extremizer; recovering such a classification is a separate problem.

IV.29 Constructive integration and optimal phase order

Source 46, delivered Section 5.

We now supply the explicit integrators used above, and formulate an all-characteristic scalar replacement for Gowers' polarization identity. This also distinguishes higher-root phenomena from true obstructions.

IV.29.1 A finite-difference calculation on the prime field

For $1 \leq a \leq p-1$, write $L_a(x) = |x|^a$ on $\mathbb{F}_p$, viewed first as an integer-valued periodic function. Let $\delta f(x) = f(x+1) - f(x)$.

Lemma IV.29.1 (Valuation and leading difference). *For $k \geq 0$,*

$$v_p(\delta^k L_a(x)) \geq \max \left\{ 0, \left\lceil \frac{k-a}{p-1} \right\rceil \right\} \quad (\text{IV.29.1})$$

uniformly in x , with $v_p(0) = +\infty$. If $d = a + s(p-1)$, then

$$\delta^d L_a(x) \equiv (-1)^s p^s a! \pmod{p^{s+1}}, \quad (\text{IV.29.2})$$

$$\delta^{d+1} L_a(x) \equiv 0 \pmod{p^{s+1}}. \quad (\text{IV.29.3})$$

Proof. For $k < p$, ordinary polynomial differencing modulo p proves (IV.29.1): when $k > a$, the reduction modulo p vanishes. Since the translation has order p , $(1+\delta)^p = 1$, hence

$$\delta^k = - \sum_{j=1}^{p-1} \binom{p}{j} \delta^{k-p+j} \quad (k \geq p).$$

Strong induction on k proves (IV.29.1), using $p \mid \binom{p}{j}$ and observing that the smallest resulting valuation is the $j=1$ bound. For (IV.29.2), use induction on s . At $s=0$ the familiar a th difference of x^a is $a!$ modulo p . At $d = a + s(p-1)$, the $j=1$ term is $-p\delta^{d-(p-1)}L_a$. Every term with $j \geq 2$ is divisible by p^{s+1} by (IV.29.1), giving the induction step. Equation (IV.29.3) is another direct instance of that valuation bound. $\square$

Theorem IV.29.2 (Optimal scalar integrator in every degree). *Given $d \geq 1$, write uniquely*

$$d = a + s(p-1), \quad 1 \leq a \leq p-1, \quad s \geq 0.$$

Choose an integer u with $u(-1)^s a! \equiv 1 \pmod{p}$. Then

$$Q_d(x) = \frac{u|x|^a}{p^{s+1}} \pmod{1} \quad (\text{IV.29.4})$$

has degree at most d and satisfies

$$D_{h_1} \cdots D_{h_d} Q_d(x) = \iota(h_1 \cdots h_d). \quad (\text{IV.29.5})$$

The smallest possible phase order for any integrator of this nonzero tensor is

$$p^{s+1} = p^{\lceil d/(p-1) \rceil}. \quad (\text{IV.29.6})$$

The lower bound allows arbitrary functions, provided their values lie in a coset of the indicated finite subgroup of $\mathbb{T}$.

Proof. Every difference D_h on $\mathbb{F}_p$ is an integer-polynomial multiple of δ . Lemma IV.29.1 therefore shows that Q_d has degree at most d . Its top derivative is independent of x and additive in each direction: the identity $D_{h+k} = D_h + D_k + D_h D_k$ leaves an error of order $d+1$. As an additive map out of $\mathbb{F}_p$ in each slot, it is determined by its value on $(1, \dots, 1)$, which is $1/p$ by (IV.29.2) and the choice of u . This proves (IV.29.5).

For optimality, subtract a constant from any proposed integrator with values in a coset of $p^{-R}\mathbb{Z}/\mathbb{Z}$. Its numerator is a function $\mathbb{F}_p \rightarrow \mathbb{Z}/p^R\mathbb{Z}$. The evaluation matrix for $1, |x|, \dots, |x|^{p-1}$ is a Vandermonde matrix whose determinant is a unit modulo p , and hence modulo p^R . These functions therefore interpolate all possible numerators. By (IV.29.1), each $|x|^a/p^R$ has degree at most $a + (R-1)(p-1) \leq R(p-1)$; the constant has degree zero. Thus every such function has degree at most $R(p-1)$. A nonzero d th derivative requires $d \leq R(p-1)$, proving the lower bound. $\square$

Example IV.29.3 (Binary scalar phases). For $p = 2$, one may take $Q_d(x) = (-1)^{d-1}|x|/2^d$. In particular a nonzero cubic tensor on $\mathbb{F}_2$ requires eighth roots, even though its total derivative takes only the values $0, 1/2$. The issue is phase depth, not a failure of integrability.

IV.29.2 Multivariate coordinate integration through degree $p+1$

We will also use the following multivariate consequence of the valuation argument. If $0 \leq a_i < p$ and $A = \sum_i a_i > 0$, then

$$x \mapsto \frac{\prod_i |x_i|^{a_i}}{p^{s+1}} \quad \text{has degree at most } A + s(p-1). \quad (\text{IV.29.7})$$

Indeed the coordinate augmentation ideal is generated by the coordinate differences δ_i . A product $\prod_i \delta_i^{k_i}$ acts separately on the factors. The sum of the lower bounds $\max(0, \lceil (k_i - a_i)/(p-1) \rceil)$ is at least $s+1$ whenever $\sum_i k_i > A + s(p-1)$. This proves (IV.29.7); coordinates with $a_i = 0$ cause no difficulty, since any difference in such a coordinate annihilates that factor.

Fix a basis $e_1, \dots, e_n$ of V . For $\alpha \in \mathbb{Z}_{\geq 0}^n$ with $|\alpha| = d$, let

$$b_\alpha = T(e_1^{\alpha_1}, \dots, e_n^{\alpha_n}),$$

where superscripts denote repetitions, not multiplication. A symmetric multilinear form is determined by these coefficients. For coefficients in formulas below, division by a factorial means inversion in $\mathbb{F}_p$, followed by the standard integer representative.

Theorem IV.29.4 (Explicit low-degree integration). *Every symmetric d -linear form with $d \leq p$ integrates. A symmetric $(p+1)$ -linear form integrates if $C_T = 0$. Integrators can be constructed as follows.*

For every α with all $\alpha_i < p$, include the classical term

$$\frac{1}{p} \left| \frac{b_\alpha}{\prod_i \alpha_i!} \right| \prod_i |x_i|^{\alpha_i}. \quad (\text{IV.29.8})$$

When $d = p$, include additionally $|b_{pe_i}|Q_p(x_i)$ for each pure coefficient. When $d = p+1$, instead include the pure terms $|b_{(p+1)e_i}|Q_{p+1}(x_i)$ and, for every $i < j$, the term

$$-\frac{|b_{pe_i+e_j}| |x_i| |x_j|}{p^2}. \quad (\text{IV.29.9})$$

The last prescription is valid because $C_T = 0$ makes $b_{pe_i+e_j} = b_{e_i+pe_j}$. Summing these terms modulo one gives an integrator.

Proof. The total derivative of (IV.29.8) has exactly the prescribed α component, by ordinary differentiation in the prime-field polynomial algebra; all the relevant factorials are invertible. The scalar terms are handled by Theorem IV.29.2. Their derivatives vanish whenever a direction from another coordinate occurs.

It remains to check the paired term. Modulo p^2 , the recurrence for δ_i^p acting on $|x_i|$ has only the term $-p\delta_i|x_i|$ remaining: for $2 \leq j < p$, $\delta_i^j|x_i|$ is divisible by p . Thus the $pe_i + e_j$ and $e_i + pe_j$ components of $-|x_i||x_j|/p^2$ are both $1/p$. Its pure components vanish by the scalar degree bound. If both multiplicities are between 2 and $p-1$, each coordinate difference contributes a factor p , so that component vanishes modulo one. Any component involving a third coordinate vanishes identically. The degree is at most $p+1$ by (IV.29.7).

For $d = p+1$ these are all possible multiplicity patterns: a pure $(p+1)$, a pair $(p, 1)$, or multiplicities all smaller than p . The equality of paired coefficients is exactly $C_T(e_i, e_j) = 0$. Matching every basis component proves the theorem. $\square$

Corollary IV.29.5 (The binary cubic integrator). *If $R : V^3 \rightarrow \mathbb{F}_2$ is symmetric and $C_R = 0$, then, writing $r_i = R(e_i, e_i, e_i)$, $r_{ij} = R(e_i, e_i, e_j) = R(e_i, e_j, e_j)$, and $r_{ijk} = R(e_i, e_j, e_k)$,*

$$P(x) = \sum_i \frac{r_i |x_i|}{8} - \sum_{i < j} \frac{r_{ij} |x_i| |x_j|}{4} + \sum_{i < j < k} \frac{r_{ijk} |x_i| |x_j| |x_k|}{2} \pmod{1} \quad (\text{IV.29.10})$$

has $D_a D_b D_c P = \iota(R(a, b, c))$.

The coefficients are binary representatives. This formula makes the extremizer construction in Section IV.27 completely effective.

IV.30 An all-characteristic replacement of scalar polarization

Source 46, delivered Section 6.

IV.30.1 Independent vertex functions do not remove exact obstructions

The following observation applies in every characteristic and does not require any regularity of the vertex functions.

Lemma IV.30.1 (Vertex separation forces integration). *Let $T : V^d \rightarrow \mathbb{F}_p$ be multilinear. Suppose functions $P_\varepsilon : V \rightarrow \mathbb{T}$ satisfy*

$$\iota(T(h_1, \dots, h_d)) = \sum_{\varepsilon \in \{0,1\}^d} (-1)^{|\varepsilon|} P_\varepsilon(s - \varepsilon \cdot h) \quad (\text{IV.30.1})$$

for all $s, h_1, \dots, h_d$. Then $P_{(1,\dots,1)}$ integrates T . Conversely, an integrator gives (IV.30.1) by taking every vertex function equal to it.

Proof. For each i , apply the operator that subtracts the expression with $h_i = 0$. The left side is unchanged by multilinearity. Every vertex missing at least one direction is annihilated. For the all-ones vertex, the alternating expansion that remains is

$$\sum_{J \subseteq [d]} (-1)^{|J|} P_{(1,\dots,1)} \left(s - \sum_{j \in J} h_j \right) = D_{h_1} \cdots D_{h_d} P_{(1,\dots,1)} \left(s - \sum_i h_i \right).$$

This proves the first assertion. The same identity proves the converse. $\square$

IV.30.2 Scalar multi-affine polarization with optimal roots

Let

$$\sigma(x_1, \dots, x_k) = \sum_{J \subseteq [k]} c_J \prod_{j \in J} x_j \quad (c_J \in \mathbb{F}_p).$$

This is separately affine in every variable; the constant monomial is allowed. Put $Q_0 = 1/p$, and use the functions Q_j of Theorem IV.29.2 for $j \geq 1$.

Theorem IV.30.2 (All-characteristic scalar polarization). *Define, for $\varepsilon \in \{0,1\}^k$,*

$$P_\varepsilon(s) = \sum_{J \supseteq \text{supp } \varepsilon} |c_J| Q_{|J|}(s). \quad (\text{IV.30.2})$$

Then

$$\iota(\sigma(x)) = \sum_{\varepsilon \in \{0,1\}^k} (-1)^{|\varepsilon|} P_\varepsilon(s - \varepsilon \cdot x) \quad (\text{IV.30.3})$$

for all x, s . For $k \geq 1$, all P_ε have degree at most k and values in $p^{-R}\mathbb{Z}/\mathbb{Z}$, where $R = \lceil k/(p-1) \rceil$. This exponent is the optimal universal choice. If $k < p$, the construction can be taken entirely in $p^{-1}\mathbb{Z}/\mathbb{Z}$.

Proof. For a fixed J , its contribution to the right side is

$$|c_J| \sum_{\text{supp } \varepsilon \subseteq J} (-1)^{|\varepsilon|} Q_{|J|}(s - \varepsilon \cdot x) = \iota \left(c_J \prod_{j \in J} x_j \right)$$

by (IV.29.5), including the empty-set case. Summing proves the identity. The degree and phase-order claims follow from Theorem IV.29.2. For the monomial $\prod_{i=1}^k x_i$, Lemma IV.30.1 makes the all-ones vertex an integrator. The lower bound in Theorem IV.29.2 therefore proves optimality even among unrelated vertex functions with a common finite phase alphabet. $\square$

This removes the condition $k < p$ from the *existence of a phase-valued* scalar polarization identity. It does not remove it while retaining the original classical polynomial codomain. Conflating those statements would produce an incorrect extension of Gowers' lemma.

IV.31 Complete classification of trace-multiplication tensors

Source 46, delivered Section 7.

Let $F = \mathbb{F}_q$ with $q = p^n$, viewed additively as an n -dimensional $\mathbb{F}_p$ -space. For $c \in F^\times$ and $d \geq 1$, set

$$T_{c,d}(h_1, \dots, h_d) = \text{Tr}_{F/\mathbb{F}_p}(ch_1 \cdots h_d). \quad (\text{IV.31.1})$$

It is symmetric and $\mathbb{F}_p$ -multilinear. The trace pairing is nondegenerate: $\text{Tr}(uv) = 0$ for every $v \in F$ implies $u = 0$. We use also the Frobenius adjoint identity

$$\text{Tr}(ub^p) = \text{Tr}(u^{p^{n-1}}b), \quad (\text{IV.31.2})$$

which follows from invariance of trace under Frobenius.

Theorem IV.31.1 (Exact trace integration classification). *For nonzero c , the tensor $T_{c,d}$ integrates precisely in the following cases:*

<i>Extension degree</i>	<i>Tensor degree</i>	<i>Integrability condition</i>
$n = 1$	<i>every</i> $d \geq 1$	<i>always</i>
$n > 1$	$d \leq p$	<i>always</i>
$n > 1$	$d = p + 1$	$n = 2$ and $c \in \mathbb{F}_p^\times$
$n > 1$	$d \geq p + 2$	<i>never</i>

For all n , classical integration is possible exactly when $d < p$.

Proof. For $n = 1$, Theorem IV.29.2 applies, multiplied by the nonzero coefficient. For $d \leq p$, use Theorem IV.29.4.

At $d = p + 1$, the obstruction is

$$C_c(a, b) = \text{Tr}(c(a^p b - ab^p)). \quad (\text{IV.31.3})$$

By (IV.31.2) and nondegeneracy, $C_c = 0$ is equivalent to

$$ca^p = (ca)^{p^{n-1}} \quad \text{for every } a \in F.$$

Raising to the p th power gives the equivalent condition

$$c^p a^{p^2} = ca \quad \text{for every } a \in F. \quad (\text{IV.31.4})$$

Taking $a = 1$ forces $c^p = c$. With $c \neq 0$, the remaining condition is $a^{p^2} = a$ for all a , which is equivalent to $n \mid 2$. For $n > 1$ this gives exactly $n = 2$ and $c \in \mathbb{F}_p^\times$. Sufficiency follows from Proposition IV.26.3.

If $d \geq p + 2$, apply the necessary repeated-variable identity and set all but one of the extra directions equal to one. Their product z is arbitrary. The identity requires $C_{cz} = 0$ for every

$z \in F$. For $n > 1$, the preceding classification shows that not every nonzero coefficient has vanishing obstruction. Since $cF^\times = F^\times$, this is impossible.

For classical integration with $d \geq p$, a total derivative must vanish when p directions are equal. Setting all remaining directions to one would force $\text{Tr}(ca^p) = 0$ for every a . Frobenius is bijective and the trace pairing is nondegenerate, a contradiction. Conversely, for $d < p$ the classical terms (IV.29.8) suffice. $\square$

Corollary IV.31.2 (Optimal phase orders in the admissible trace cases). *For $n = 1$ the minimum phase order is $p^{\lceil d/(p-1) \rceil}$. For $n > 1$, it is p when $d < p$, and p^2 when $d = p$. In the exceptional case $n = 2$, $d = p + 1$, $c \in \mathbb{F}_p^\times$, it is also p^2 , including $p = 2$.*

Proof. The scalar assertion is Theorem IV.29.2. For $n > 1$ and $d \leq p$, the coordinate construction gives the upper bounds, and the classical nonintegrability in Theorem IV.31.1 proves optimality at $d = p$.

For the exceptional case with $p \geq 3$, the pure term Q_{p+1} already has phase order p^2 , so the full coordinate construction does also. If $p = 2$, the potentially eighth-root pure terms have coefficient $\text{Tr}(ca^3) = 0$ for every $a \in \mathbb{F}_4$, because a^3 is the norm into $\mathbb{F}_2$ and the trace of an element of $\mathbb{F}_2$ from $\mathbb{F}_4$ is zero. Only the paired fourth-root terms remain. The impossibility of classical integration proves the lower bound in both cases. $\square$

Example IV.31.3 (The smallest extension distinguishes three phenomena). Let $F = \mathbb{F}_4 = \mathbb{F}_2[\theta]/(\theta^2 + \theta + 1)$, and write $z = x + y\theta$. For $c = 1$, the cubic trace tensor integrates to

$$P(z) = -|x||y|/4 \pmod{1}.$$

Thus fourth roots suffice, even though a nonzero scalar cubic on $\mathbb{F}_2$ requires eighth roots. For $c = \theta$, however,

$$C_\theta(1, \theta) = \text{Tr}(\theta^2) - \text{Tr}(\theta^3) = 1.$$

No circle-valued cubic integrator exists, regardless of phase alphabet. The mixed cube norm is nevertheless exactly $1/2$, by Theorem IV.27.1. An explicit common-function extremizer is

$$f(x + y\theta) = \exp\left(\frac{2\pi i(|x| + |y|)}{8}\right).$$

Its cubic phase integrates the residual diagonal tensor, not T_θ itself; the remaining elementary obstruction block has bias $1/2$. This separates classical failure, higher-root repair, and genuine nonintegrability in one very small field.

IV.32 Exact restriction dimensions and repair costs

Source 46, delivered Section 8.

IV.32.1 The obstruction rank for trace tensors

Continue at the first obstructed degree $d = p + 1$, and write C_c for (IV.31.3).

Theorem IV.32.1 (Explicit radical and maximal integrable subspace). *Let $t_c = \dim_{\mathbb{F}_p} \text{rad } C_c$. Then*

$$t_c = \begin{cases} 1, & n \text{ odd}, \\ 2, & n \text{ even and } c^{(q-1)/(p+1)} = 1, \\ 0, & n \text{ even and } c^{(q-1)/(p+1)} \neq 1. \end{cases} \quad (\text{IV.32.1})$$

Consequently

$$\text{rank } C_c = n - t_c, \quad \max_{W: T_{c,p+1}|_W \text{ integrates}} \dim W = \frac{n + t_c}{2}. \quad (\text{IV.32.2})$$

For even n , precisely $(q-1)/(p+1)$ nonzero coefficients have $t_c = 2$; the other $p(q-1)/(p+1)$ have $t_c = 0$.

Proof. The trace-pairing calculation leading to (IV.31.4), now with a fixed, shows that the radical is the kernel of

$$a \mapsto c^p a^{p^2} - ca.$$

A nonzero radical element therefore satisfies

$$a^{p^2-1} = c^{1-p}. \quad (\text{IV.32.3})$$

In the cyclic group $F^\times$, the power map on the left has kernel of size $\gcd(p^2-1, p^n-1) = p^{\gcd(2,n)} - 1$.

If n is odd, this size is $p-1$ and the solvability condition is automatic: $(c^{1-p})^{(q-1)/(p-1)} = 1$. There are $p-1$ nonzero solutions and the zero solution, so the radical has dimension one. If n is even, the kernel size is p^2-1 , and solvability is equivalent to $c^{(q-1)/(p+1)} = 1$. There are then p^2 radical elements including zero; otherwise there is only zero. This proves (IV.32.1).

The rank formula follows. By Proposition IV.26.3, an integrable restriction is precisely an isotropic subspace for C_c . Lemma IV.26.4 proves the maximum in (IV.32.2). Finally the coefficient condition defines a subgroup of $F^\times$ of order $(q-1)/(p+1)$, giving the counts. $\square$

Corollary IV.32.2 (Explicit sharp binary trace moments). *For $p = 2$, $q = 2^n$, and $T_c(a, b, x) = \text{Tr}(cabx)$, the moment (IV.28.4) satisfies*

$$\sup_{\|f\|_\infty \leq 1} M_{T_c}(f) = \begin{cases} 2^{-(n-1)/2}, & n \text{ odd}, \\ 2^{-(n-2)/2}, & n \text{ even, } c^{(2^n-1)/3} = 1, \\ 2^{-n/2}, & n \text{ even, } c^{(2^n-1)/3} \neq 1. \end{cases} \quad (\text{IV.32.4})$$

Every value in this formula is attained by an eighth-root cubic phase.

Proof. Combine Corollary IV.28.2 and Theorem IV.32.1. $\square$

n	Number of coefficients	r	Largest $\dim W$	$\sup M_{T_c}$
2	1	0	2	1
2	2	2	1	1/2
3	7	2	2	1/2
4	5	2	3	1/2
4	10	4	2	1/4
5	31	4	3	1/4
6	21	4	4	1/4
6	42	6	3	1/8
7	127	6	4	1/8
8	85	6	5	1/8
8	170	8	4	1/16

The table is a specialization of the proved formulas, not a numerical extrapolation. It shows that exact integration of arbitrary trace tensors cannot be recovered by a dimension-independent codimension loss. This does not contradict inverse theorems: the associated maximal correlations become small as the required codimension increases.

IV.32.2 An exact elementary symmetric repair invariant

For any prime p , and $\ell, m \in V^*$, define the symmetric $(p+1)$ -linear form

$$S_{\ell,m}(h_1, \dots, h_{p+1}) = \sum_{j=1}^{p+1} \ell(h_j) \prod_{t \neq j} m(h_t). \quad (\text{IV.32.5})$$

A direct evaluation, using $u^p = u$ in $\mathbb{F}_p$, gives

$$C_{S_{\ell,m}}(a, b) = \ell(b)m(a) - \ell(a)m(b). \quad (\text{IV.32.6})$$

Define the *elementary symmetric repair number* of a symmetric $(p+1)$ -linear T as the least number of forms (IV.32.5) whose subtraction makes T integrable. Scalar coefficients are absorbed into ℓ .

Theorem IV.32.3 (Exact elementary repair number). *For every symmetric $(p+1)$ -linear T ,*

$$\text{elementary symmetric repair number}(T) = \frac{\text{rank } C_T}{2} = \min\{\text{codim } W : T|_W \text{ integrates}\}. \quad (\text{IV.32.7})$$

In particular, for $T_{c,p+1}$ this number is $(n - t_c)/2$ with t_c given by (IV.32.1).

Proof. Write C_T as a sum of $r/2$ wedges by Lemma IV.26.4, choosing their orientations to match (IV.32.6). Subtract the corresponding $S_{\ell,m}$. The residual form has zero obstruction and integrates by Theorem IV.29.4. Conversely, each elementary form has obstruction rank at most two. Subtracting fewer than $r/2$ cannot cancel a rank- r obstruction, by rank subadditivity. The equality with minimum codimension follows again from the isotropic characterization. $\square$

IV.32.3 Ordinary slice-rank repair is related but different

A slice of a d -linear form is a term that is linear in one chosen slot and multilinear in the other $d-1$ slots. The slice rank is the minimum number of such terms. Define

$$\rho(T) = \min\{\text{srank}(T - R) : R \text{ is symmetric and integrates}\}.$$

Proposition IV.32.4 (Slice-rank repair bounds). *For symmetric $(p+1)$ -linear T with $r = \text{rank } C_T$,*

$$r/2 \leq \rho(T) \leq r. \quad (\text{IV.32.8})$$

If $r = 2$, then $\rho(T) = 2$. For $p = 2$, slice rank here equals partition rank.

Proof. Each elementary correction in (IV.32.5) has slice rank at most two: separate the $j = 1$ term, and factor $m(h_1)$ from all remaining terms. Theorem IV.32.3 gives the upper bound.

Suppose $T - R$ is a sum of s slices. Intersect the kernels of all s singleton linear factors, and call this subspace U . Then $\text{codim } U \leq s$ and $(T - R)|_U = 0$. Since $R|_U$ integrates, $T|_U$ does also. The exact minimum-codimension statement gives $s \geq r/2$.

To handle $r = 2$, a nonzero symmetric slice-rank-one tensor must be a scalar multiple of a pure power $\ell^{\otimes d}$. Indeed, write it as $\ell(h_1)B(h_2, \dots, h_d)$ and choose v with $\ell(v) = 1$. Symmetry in the first two slots shows that B is divisible by ℓ in its first slot; repeating this argument proves the pure-power assertion. For $d = p+1$, such a tensor has zero obstruction, because $\ell(a)^p \ell(b) = \ell(a)\ell(b)^p$. Thus a rank-two obstruction cannot be repaired by one slice. The upper bound is two. Finally, every bipartition of three slots has a singleton side, so slice and partition rank coincide for trilinear tensors. $\square$

The factor-two interval in (IV.32.8) is not asserted to close in general. The exactly determined quantity in Theorem IV.32.3 is the *specified elementary symmetric* repair number, not unrestricted tensor rank or unrestricted partition rank in higher degree.

IV.33 Returning to Gowers' derivative-spectrum step

Source 46, delivered Section 9.

The preceding results concern exactly the type of polynomial untwisting that appears near the end of Gowers' argument. We spell out the analytic translation to avoid confusing an integration theorem with a full inverse theorem.

IV.33.1 A homogeneous frequency gives an exact norm identity

For $h = (h_1, \dots, h_j)$, use the backward-cube convention

$$\mathcal{B}_h f(x) = \prod_{\varepsilon \in \{0,1\}^j} C^{|\varepsilon|} f(x - \varepsilon \cdot h).$$

This convention makes the additive phase identity

$$\sum_{\varepsilon} (-1)^{|\varepsilon|} P(x - \varepsilon \cdot h) = D_{h_1} \cdots D_{h_j} P\left(x - \sum_i h_i\right)$$

valid with a positive sign. It gives the usual Gowers norm after averaging: $\|f\|_{U^j}^{2^j} = \mathbb{E}_{x,h} \mathcal{B}_h f(x)$.

Let $F = \mathbb{F}_{p^n}$, $\chi(z) = e(\text{Tr}(z)/p)$, and $d \geq 2$. Define

$$\mathcal{M}_{c,d}(f) = \mathbb{E}_{h_1, \dots, h_{d-1}} \left| \mathbb{E}_x \mathcal{B}_{(h_1, \dots, h_{d-1})} f(x) \overline{\chi(ch_1 \cdots h_{d-1}x)} \right|^2. \quad (\text{IV.33.1})$$

Proposition IV.33.1 (Exact homogeneous untwisting). *If P integrates $T_{c,d}$, then for every function $f : F \rightarrow \mathbb{C}$,*

$$\mathcal{M}_{c,d}(f) = \|fe(-P)\|_{U^d}^{2^d}. \quad (\text{IV.33.2})$$

Proof. Expand the square in (IV.33.1) and write its second basepoint as $x - h_d$. The character factor is $\chi(ch_1 \cdots h_d)$, and the function product is $\mathcal{B}_{(h_1, \dots, h_d)} f(x)$. Therefore

$$\mathcal{M}_{c,d}(f) = \mathbb{E}_{x, h_1, \dots, h_d} \mathcal{B}_h f(x) e(-\iota(T_{c,d}(h))).$$

The defining equation for P identifies the integrand with $\mathcal{B}_h(fe(-P))(x)$. Averaging proves (IV.33.2). $\square$

In admissible trace cases, this is an equality rather than merely a correlation-to-norm implication. In nonintegrable cases there is no exact vertex-separated replacement, by Lemma IV.30.1. For binary cubics the substitute is not an unspecified error: it is the exact ceiling in Corollary IV.32.2.

IV.33.2 General scalar multi-affine frequencies

For a separately affine $\sigma : \mathbb{F}_p^{d-1} \rightarrow \mathbb{F}_p$, define

$$\mathcal{M}_\sigma(f) = \mathbb{E}_{h \in \mathbb{F}_p^{d-1}} |\mathbb{E}_x \mathcal{B}_h f(x) e(-\iota(\sigma(h)x))|^2.$$

The phase after squaring is $\iota(h_d \sigma(h_1, \dots, h_{d-1}))$, which is separately affine in the d directions.

Theorem IV.33.2 (Scalar phase-valued extension of the untwisting step). *For $d \geq 2$, there are nonclassical polynomials $P_\varepsilon : \mathbb{F}_p \rightarrow \mathbb{T}$, of degree at most d and phase order dividing $p^{\lceil d/(p-1) \rceil}$, such that*

$$\mathcal{M}_\sigma(f) \leq \prod_{\varepsilon \in \{0,1\}^d} \|fe(-P_\varepsilon)\|_{U^d} \leq \max_\varepsilon \|fe(-P_\varepsilon)\|_{U^d}^{2^d}. \quad (\text{IV.33.3})$$

Thus a lower bound $\mathcal{M}_\sigma(f) \geq \alpha$ is preserved as the same lower bound for the 2^d th power of a suitably twisted U^d norm.

Proof. Expand the square as in Proposition IV.33.1. Apply Theorem IV.30.2 to $h_d \sigma(h_1, \dots, h_{d-1})$, using $s = x$. This absorbs the character into a separate phase at each vertex, producing the mixed cube average of the functions $fe(-P_\varepsilon)$. Gowers–Cauchy–Schwarz bounds its absolute value by the product in (IV.33.3); the second inequality is immediate. The left side is nonnegative, so this is the stated inequality. $\square$

The Gowers–Cauchy–Schwarz step is standard [1], and arbitrary vertex-phase absorption is already treated in the repository’s local refinement material [204]. The contribution here is the existence, explicit construction, and optimal universal phase alphabet of the phases in small characteristic, together with the exact obstruction analysis showing why the same statement cannot simply be transferred to arbitrary extension-field trace tensors.

Classical correlation is a different question. Failure of a classical total-derivative representation does not automatically mean that classical phases cannot provide the correlation required by an inverse theorem. These are different assertions. The distinction is central in the work of Berger–Sah–Sawhney–Tidor [186], and it is respected throughout this paper. In particular, the trace classification is a theorem about exact total derivatives, not a counterexample to an inverse theorem.

IV.34 Cube identities and phase invariance

Source 43, delivered Section 2.

IV.34.1 The finite-abelian normalization

Let G be a finite abelian group, written additively. For this section and Sections IV.35–IV.36, a multiadditive form takes values in $\mathbb{T}$. Define

$$\mathcal{E}_T(f) = \mathbb{E}_{\mathbf{h} \in G^{d-1}} |\mathbb{E}_x \partial_{\mathbf{h}} f(x) e(-T(\mathbf{h}, x))|^2. \quad (\text{IV.34.1})$$

In the Boolean specialization we use $T/2$ in this formula and retain the notation $\mathcal{E}_T$. This convention accounts for all factors of two.

Lemma IV.34.1 (Exact selected-cube identity). *For every complex-valued f and every multiadditive T ,*

$$\mathcal{E}_T(f) = \mathbb{E}_{x, h_1, \dots, h_d} \partial_{h_1} \cdots \partial_{h_d} f(x) e(-T(h_1, \dots, h_d)). \quad (\text{IV.34.2})$$

In particular the right side is real and nonnegative, even if T is not symmetric.

Proof. For fixed $\mathbf{h}$, put $g = \partial_{\mathbf{h}} f$. Expanding the square in (IV.34.1) and replacing the two base points by $x + y$ and x gives

$$|\mathbb{E}_x g(x) e(-T(\mathbf{h}, x))|^2 = \mathbb{E}_{x, y} g(x + y) \overline{g(x)} e(-T(\mathbf{h}, y)).$$

Average over $\mathbf{h}$. Multiplicative differences commute, so the product is the d -fold difference in (IV.34.2). $\square$

We define the Gowers quantity by

$$\|f\|_{U^d}^{2^d} = \mathbb{E}_{x, \mathbf{h} \in G^d} \partial_{\mathbf{h}} f(x). \quad (\text{IV.34.3})$$

Only this finite identity is needed below. Its nonnegativity follows from Lemma IV.34.1 with $T = 0$. For 1-bounded f , each selected Fourier coefficient has modulus at most one, so $0 \leq \mathcal{E}_T(f) \leq 1$.

Lemma IV.34.2 (Gauge invariance). *Suppose $P : G \rightarrow \mathbb{T}$ has constant d -fold derivative $S : G^d \rightarrow \mathbb{T}$. Then*

$$\mathcal{E}_{T+S}(fe(P)) = \mathcal{E}_T(f). \quad (\text{IV.34.4})$$

If $S = T$, then

$$\mathcal{E}_T(f) = \|fe(-P)\|_{U^d}^{2^d}. \quad (\text{IV.34.5})$$

Moreover the corresponding selected Fourier magnitudes agree for each individual $(d-1)$ -tuple of directions, before averaging.

Proof. Multiplicative differences distribute over products. Thus the extra factor in the cube identity for $fe(P)$ is $e(S)$, which cancels the extra tensor in the phase. For the pointwise assertion, the function $q_{\mathbf{h}}(x) = \Delta_{\mathbf{h}} P(x)$ satisfies $q_{\mathbf{h}}(x + y) - q_{\mathbf{h}}(x) = T(\mathbf{h}, y)$. Taking $x = 0$ shows $q_{\mathbf{h}}(x) = c_{\mathbf{h}} + T(\mathbf{h}, x)$ for a constant $c_{\mathbf{h}}$. Consequently

$$\mathbb{E}_x \partial_{\mathbf{h}} (fe(-P))(x) = e(-c_{\mathbf{h}}) \mathbb{E}_x \partial_{\mathbf{h}} f(x) e(-T(\mathbf{h}, x)).$$

Taking absolute values proves the assertion. $\square$

Remark IV.34.3 (Amplitude and conjugation). No step in these identities divides by f or assumes $|f| = 1$. In particular they remain valid at zeros. This matters in the shear argument, where the new function is a product of two translates of f . The scale of $\mathcal{E}_T$ is 2^d : replacing f by cf multiplies the energy by $|c|^{2^d}$.

IV.35 Division-free finite-abelian orthogonality

Source 43, delivered Section 3.

IV.35.1 Alternating bicharacters and their dimensions

Let $B : G \times G \rightarrow \mathbb{T}$ be biadditive. Define

$$\kappa_B(a, b) = e(B(a, b) - B(b, a)), \quad R_B = \{a : \kappa_B(a, b) = 1 \text{ for every } b\}, \quad d_B = \sqrt{|G/R_B|}. \quad (\text{IV.35.1})$$

The pairing κ_B is alternating: $\kappa_B(a, a) = 1$, and $\kappa_B(a, b) = \kappa_B(b, a)^{-1}$. This formulation uses no division by two, including when G has even order.

Lemma IV.35.1 (Finite symplectic decomposition). *The number d_B is an integer. There is a subgroup $H \supseteq R_B$ such that $H = H^\perp$ for κ_B and $[G : H] = d_B$. More precisely,*

$$G/R_B \cong \bigoplus_j (C_{m_j} \oplus C_{m_j}), \quad d_B = \prod_j m_j, \quad (\text{IV.35.2})$$

with orthogonal nondegenerate alternating pairings on the summands.

Proof. Pass to $K = G/R_B$, where the pairing is nondegenerate. The map $K \rightarrow \widehat{K}$ it induces is injective and hence bijective. Choose $x \in K$ of maximum order m , which is also the exponent of K . The character $\kappa_B(x, \cdot)$ has order m by injectivity. Choose y such that $\kappa_B(x, y)$ is a primitive m th root of unity. Then y also has order m .

Pairing a relation $ax + by = 0$ with x and y shows that a and b are both zero modulo m . The subgroup $L = \langle x, y \rangle$ is therefore $C_m \oplus C_m$, and its restricted pairing is nondegenerate. For any $z \in K$, appropriate multiples of x, y subtract the two pairings with x, y ; hence $K = L \oplus L^\perp$. Induction on $|K|$ gives (IV.35.2). In each block, take the cyclic subgroup generated by its first basis vector. Their direct sum is self-annihilating. Its inverse image in G is the required H . $\square$

IV.35.2 The mixed orthogonality theorem

Use the normalized Hilbert space inner product $\langle g, h \rangle = \mathbb{E}_x g(x) \overline{h(x)}$, linear in its first argument. Define

$$\mathcal{Q}_B(g, h) = \mathbb{E}_a \left| \mathbb{E}_x g(x+a) \overline{h(x)} e(-B(a, x)) \right|^2. \quad (\text{IV.35.3})$$

Write $\mathcal{Q}_B(g) = \mathcal{Q}_B(g, g)$.

Theorem IV.35.2 (Sharp mixed orthogonality). *For every finite abelian G , every biadditive B , and all $g, h : G \rightarrow \mathbb{C}$,*

$$\mathcal{Q}_B(g, h) \leq d_B^{-1} \|g\|_2^2 \|h\|_2^2. \quad (\text{IV.35.4})$$

For each B there is a function g with $|g(x)| = 1$ at every x for which $\mathcal{Q}_B(g) = d_B^{-1}$. Thus the coefficient is sharp even in the one-function, pointwise-unit-modulus class.

Proof. Introduce unitaries

$$(U_ag)(x) = e(-B(a, x))g(x + a). \quad (\text{IV.35.5})$$

Direct multiplication gives

$$U_a U_b = e(-B(b, a))U_{a+b}, \quad U_a U_b = \kappa_B(a, b)U_b U_a. \quad (\text{IV.35.6})$$

Let M_g be the positive operator

$$M_g v = \mathbb{E}_a \langle v, U_a g \rangle U_a g.$$

It has trace $\|g\|_2^2$. The projective multiplication law shows that conjugation by each U_b merely permutes its summands, so M_g commutes with every U_b .

We claim that every nonzero subspace invariant under all U_b has dimension at least d_B . Choose H as in Lemma IV.35.1. The unitaries U_h , $h \in H$, commute, so they have a common eigenvector in any such subspace. If its joint eigenvalue function is $\lambda(h)$, then U_t transports it to the joint eigenvalue function $\kappa_B(h, t)\lambda(h)$. Two such functions agree precisely when the corresponding t 's differ by an element of $H^\perp = H$. Distinct joint eigenvalue functions belong to orthogonal subspaces. Representatives of G/H therefore give d_B independent vectors, proving the claim.

Each nonzero eigenspace of M_g is invariant under the U_b . Every positive eigenvalue consequently has multiplicity at least d_B , and

$$\|M_g\|_{\text{op}} \leq \frac{\text{tr } M_g}{d_B} = d_B^{-1} \|g\|_2^2.$$

Finally, $\mathcal{Q}_B(g, h) = \langle M_g h, h \rangle \leq \|M_g\|_{\text{op}} \|h\|_2^2$.

For sharpness, choose a common projective eigenvalue function λ for the commuting U_h , $h \in H$, and construct a λ -eigenvector of modulus one on every coset of H . Here is why this is possible. On a single coset, a joint eigenspace has dimension at most one, since translations by H determine all its coordinates from one coordinate. A nonzero eigenvector has constant, nonzero modulus on that coset. There are $|H|$ distinct joint eigenvalue functions on each coset. The ratio of any two eigenvalue functions with the same projective multiplication law is an ordinary character of H . There are exactly $|H|$ such ratios. Thus every coset has the same complete set of joint eigenvalue functions. Normalize and assemble their λ -vectors to obtain a global g with $|g| = 1$.

For $a \in H$, $U_a g = \lambda(a)g$, so $|\langle U_a g, g \rangle| = 1$. For $a \notin H$, choose $h \in H$ with $\kappa_B(h, a) \neq 1$. The vectors g and $U_a g$ have different U_h -eigenvalues and are orthogonal. It follows that $\mathcal{Q}_B(g) = |H|/|G| = d_B^{-1}$. $\square$

Corollary IV.35.3 (Self-cube form). *For every g ,*

$$\mathbb{E}_{a,b,x} \partial_a \partial_b g(x) e(-B(a, b)) = \mathcal{Q}_B(g) \leq d_B^{-1} \|g\|_2^4. \quad (\text{IV.35.7})$$

Proof. Expand the square in (IV.35.3), replace the two base points by $x + b$ and x , and use biadditivity. Then apply Theorem IV.35.2. $\square$

IV.35.3 Fields, elementary divisors, and a composite example

If $G = \mathbb{F}_p^n$ and B is represented by a matrix M through $B(a, b) = a^\top M b/p$, then

$$d_B = p^{\text{rank}(M - M^\top)/2}. \quad (\text{IV.35.8})$$

An alternating bilinear form has even rank also in characteristic two; this is the vector-space case of Lemma IV.35.1.

For $G = (\mathbb{Z}/m\mathbb{Z})^n$, let M be an integer matrix and $B(a, b) = a^\top M b / m \pmod{1}$. If $s_1, \dots, s_n$ are the Smith invariants of the integer matrix $M - M^\top$, including zeros, then

$$d_B = \left(\prod_{i=1}^n \frac{m}{\gcd(m, s_i)} \right)^{1/2}, \quad \gcd(m, 0) = m. \quad (\text{IV.35.9})$$

Indeed unimodular row and column operations remain invertible modulo m , and multiplication by s_i has kernel of size $\gcd(m, s_i)$. The square root is an integer by the preceding theorem.

For example, $B(a, b) = sa_1b_2/m$ on $(\mathbb{Z}/m\mathbb{Z})^2$ has $d_B = m/\gcd(m, s)$. The constant function already gives $\mathcal{Q}_B(1) = \gcd(m, s)/m$. At $m = 12$, the factors for $s = 1, 2, 3, 4, 6$ are respectively $1/12, 1/6, 1/4, 1/3, 1/2$. A rank computation over only one residue field cannot distinguish this arithmetic profile.

IV.36 Sharp symmetry thresholds on finite abelian groups

Source 43, delivered Section 4.

IV.36.1 Alternating slices

Let $T : G^{k+1} \rightarrow \mathbb{T}$ be multiadditive, with $k \geq 1$. Fix a slot $i \in \{1, \dots, k\}$, and freeze the other $k - 1$ derivative directions at $\mathbf{z}$. Let $B_{i,\mathbf{z}}(a, b)$ be the bilinear form obtained by putting a in slot i and b in the last slot of T .

Theorem IV.36.1 (Amplitude-sensitive slice profile). *For every such slot,*

$$\mathcal{E}_T(f) = \mathbb{E}_{\mathbf{z}} \mathcal{Q}_{B_{i,\mathbf{z}}}(\partial_{\mathbf{z}} f) \leq \mathbb{E}_{\mathbf{z}} d_{B_{i,\mathbf{z}}}^{-1} \|\partial_{\mathbf{z}} f\|_2^4. \quad (\text{IV.36.1})$$

For 1-bounded f the final norm factors may be omitted.

Proof. Use Lemma IV.34.1, freeze the other directions, and use commutation of multiplicative differences. The inner average is exactly (IV.35.7). Each frozen derivative is 1-bounded when f is. $\square$

Lemma IV.36.2 (Support of a multiadditive map). *Let P be a nontrivial finite abelian p -group and let $F : P^r \rightarrow A$ be a nonzero multiadditive map to an abelian group. Then*

$$\mathbb{P}(F(z_1, \dots, z_r) \neq 0) \geq (1 - 1/p)^r. \quad (\text{IV.36.2})$$

For $r = 0$, a nonzero constant has support probability one.

Proof. A nonzero homomorphism out of P has image of size at least p ; its kernel therefore occupies at most $1/p$ of P . For the induction, view F as a map of the first $r - 1$ variables into $\text{Hom}(P, A)$. This multiadditive map is nonzero. On the at least $(1 - 1/p)^{r-1}$ fraction where its value is a nonzero homomorphism, the last argument is nonzero in the image with probability at least $1 - 1/p$. $\square$

Corollary IV.36.3 (Prime-power symmetry gap). *If G is a finite abelian p -group and T is not invariant under interchanging slot i and the last slot, then*

$$\mathcal{E}_T(f) \leq 1 - (1 - 1/p)^k. \quad (\text{IV.36.3})$$

Proof. The alternating bicharacter of $B_{i,z}$ is a nonzero $(k-1)$ -variable multiadditive map into the group of bicharacters. It is nontrivial on a fraction at least $(1 - 1/p)^{k-1}$ of the tuples. On those tuples its nondegenerate quotient has order at least p^2 by Lemma IV.35.1; hence $d_{B_{i,z}}^{-1} \leq 1/p$. On the other tuples the factor is one. The total loss is at least $(1 - 1/p)^k$. $\square$

IV.36.2 Primary factorization and the exact group threshold

Write $G = \bigoplus_p G_p$. Multiadditivity implies

$$T(h_1, \dots, h_{k+1}) = \sum_p T_p(h_{1,p}, \dots, h_{k+1,p}). \quad (\text{IV.36.4})$$

To see this, expand each argument into primary components. A term containing inputs of two different prime-power orders is annihilated by two coprime integers and is therefore zero in $\mathbb{T}$.

Let $\mathcal{P}_i$ be the primes for which the slot- i alternating defect of T_p is nonzero. The radical indices multiply, and averaging over the independent primary coordinates yields

$$\mathbb{E}_z d_{B_{i,z}}^{-1} = \prod_p \mathbb{E}_{z_p} d_{B_{i,z_p}}^{-1} \leq \prod_{p \in \mathcal{P}_i} [1 - (1 - 1/p)^k]. \quad (\text{IV.36.5})$$

The energy itself need not factor for an arbitrary f . It is the *upper rank profile* in (IV.36.5) that factors.

Theorem IV.36.4 (Exact universal symmetry threshold). *Suppose G is not cyclic, and let $p_*(G)$ be the least prime p for which G has a quotient isomorphic to $\mathbb{F}_p^2$. Then*

$$\mathcal{E}_T(f) > 1 - (1 - 1/p_*(G))^k \implies T \text{ is fully symmetric.} \quad (\text{IV.36.6})$$

The threshold is attained by a nonsymmetric T and $f = 1$, even when T is symmetric in its first k slots. If G is cyclic, every multiadditive $T : G^{k+1} \rightarrow \mathbb{T}$ is already symmetric.

Proof. On a cyclic group with generator g , multilinearity gives

$$T(a_1 g, \dots, a_{k+1} g) = a_1 \cdots a_{k+1} T(g, \dots, g).$$

This expression is symmetric. Thus a nonzero alternating defect must occur on a noncyclic primary component. Such a component has a quotient $\mathbb{F}_p^2$, so $p \geq p_*(G)$. The function $1 - (1 - 1/p)^k$ decreases as p increases. Corollary IV.36.3 and (IV.36.5) now bound the energy of any nonzero slot defect by the right threshold. The transpositions of the last slot with each other slot generate all permutations. Absence of these defects is full symmetry.

For sharpness, choose independent linear forms u, v on a quotient $\mathbb{F}_p^2$ with $p = p_*(G)$, pull them back to G , and set

$$T(h_1, \dots, h_k, y) = \frac{u(h_1) \cdots u(h_k) v(y)}{p} \pmod{1}. \quad (\text{IV.36.7})$$

It is nonsymmetric: choose an input where all the $u(h_j)$ and $v(y)$ are one, while $u(y) = 0$ and one of the exchanged $v(h_j)$ is zero. For $f = 1$ a selected coefficient is one precisely when $u(h_1) \cdots u(h_k) = 0$, and is zero otherwise. This has probability $1 - (1 - 1/p)^k$. The first k slots are symmetric by construction. $\square$

[write] **7 October 2026; sources 40–46.** For $G = \mathbb{F}_p^n$, p odd, this is source 36's Theorem F.41.1; here it holds on every finite abelian group, characteristic two included, with $p_*(G)$ in place of p , and the orthogonality factor d_B^{-1} of Theorem IV.35.2 extends source 36's Theorem IV.17.1 (credited by the source). This advances source 36's composite-modulus question (item IV.9).

Remark IV.36.5 (Two independent kinds of sharpness). Taking sums of (IV.36.7) on distinct primary components and $f = 1$ attains the product in (IV.36.5). For a fixed bilinear form, the exact factor d_B^{-1} is attained by the construction in Theorem IV.35.2. Neither claim requires that an arbitrary multilinear rank profile be simultaneously attainable by one function; such a claim would be stronger and is not made here.

IV.37 Boolean nonclassical integration, explicitly

Source 43, delivered Section 5.

This section supplies a self-contained Boolean form of the existing nonclassical integration theorem. Its role is to specify exactly which algebraic conditions the new spectral estimates must certify.

Definition IV.37.1. Write $\text{SymMult}^d(V)$ for the space of symmetric d -linear maps $V^d \rightarrow \mathbb{F}_2$. For $d \geq 3$, define $\text{nCSM}^d(V)$ to be the subspace satisfying

$$T(a, a, b, z) = T(a, b, b, z) \quad \text{for every } a, b \in V, z \in V^{d-3}. \quad (\text{IV.37.1})$$

For $d = 2$ put $\text{nCSM}^2(V) = \text{SymMult}^2(V)$. The notation denotes a space of symmetric *multilinear maps*; no identification with symmetric tensor coinvariants in characteristic two is being assumed.

Theorem IV.37.2 (Constructive Boolean integration). *A d -linear form $T : V^d \rightarrow \mathbb{F}_2$, $d \geq 2$, has a nonclassical primitive of degree at most d if and only if $T \in \text{nCSM}^d(V)$. Fix coordinates $x_1, \dots, x_n$ with basis $e_1, \dots, e_n$. For each nonempty $S \subseteq \{1, \dots, n\}$ with $|S| \leq d$, let c_S be the value of T on any length- d basis tuple whose set of indices is exactly S . This value is well defined, and a primitive is*

$$P_T(x) = \sum_{\substack{\emptyset \neq S \subseteq [n] \\ |S| \leq d}} \frac{c_S \prod_{i \in S} |x_i|}{2^{d-|S|+1}} \pmod{1}, \quad |x_i| \in \{0, 1\}. \quad (\text{IV.37.2})$$

In particular,

$$\dim_{\mathbb{F}_2} \text{nCSM}^d(V) = \sum_{s=1}^{\min(n,d)} \binom{n}{s}. \quad (\text{IV.37.3})$$

Proof. Let S_a be translation by a on additive functions. Because $2a = 0$, $S_a^2 = I$, and consequently

$$\Delta_a^2 = (S_a - I)^2 = -2\Delta_a, \quad \Delta_a^2 \Delta_b = \Delta_a \Delta_b^2. \quad (\text{IV.37.4})$$

The second identity follows since both sides equal $-2\Delta_a \Delta_b$. Additive differences commute. A constant top derivative is therefore symmetric and satisfies (IV.37.1). This proves necessity.

Now assume $T \in \text{nCSM}^d(V)$. By symmetry, a coefficient on basis vectors depends only on their multiplicities. If two distinct indices i, j are present and i occurs at least twice, the identity (IV.37.1) changes one occurrence of i into one of j without changing the coefficient. For any fixed support S , all positive multiplicity vectors of total d are connected by these moves: move excess occurrences into a chosen index of S , then redistribute to the desired multiplicities. Thus c_S is well defined. When $d = 2$ this assertion requires no moves.

It remains to check the proposed monomials, including their degree. For a set S of size s , put

$$P_S(x) = 2^{-(d-s+1)} \prod_{i \in S} |x_i| \pmod{1}.$$

On a single Boolean coordinate, repeated application of (IV.37.4) gives $\Delta_{e_i}^t = (-2)^{t-1} \Delta_{e_i}$ for $t \geq 1$. Also

$$\Delta_h = \prod_{i: h_i=1} (I + \Delta_{e_i}) - I. \quad (\text{IV.37.5})$$

Expanding any $(d+1)$ differences by (IV.37.5) produces products of at least $d+1$ coordinate differences. If any used coordinate lies outside S , the term is zero. Otherwise, if $r \leq s$ distinct coordinates occur among $t \geq d+1$ differences, the numerator is divisible by 2^{t-r} . Since $t-r \geq d-s+1$, its quotient by the denominator is integer-valued. It vanishes in $\mathbb{T}$. Thus P_S has degree at most d .

Apply exactly d coordinate differences to P_S . If their support contains an index outside S , the answer is zero. If their support is a proper subset $R \subsetneq S$, of size $r < s$, the numerator is divisible by 2^{d-r} , giving an integer quotient because $d-r \geq d-s+1$. If their support is exactly S , the result is $\pm 1/2 \pmod{1} = 1/2$, independent of the base point. Hence the top derivative on a basis tuple has value $1/2$ exactly when that tuple's support is S .

For completeness, the top derivative of any degree-at-most- d polynomial is multiadditive. The identity $\Delta_{a+b} = \Delta_a + \Delta_b + \Delta_a \Delta_b$ shows that its failure of additivity is a $(d+1)$ -fold derivative and therefore zero. It is independent of the base point for the same reason. Agreement on basis tuples now proves that the top derivative of (IV.37.2) is $T/2$ everywhere. The support coefficients are independent, as the same basis-tuple calculation isolates each one. Counting them proves (IV.37.3). $\square$

Example IV.37.3 (Why fourth and eighth roots are unavoidable). On $\mathbb{F}_2$, $P(x) = |x|/4$ has second derivative $ab/2$, and $P(x) = |x|/8$ has third derivative $abc/2$. Thus symmetric diagonal terms integrate perfectly, but not generally into $\mathbb{F}_2$ -valued classical phases. Already the quadratic diagonal requires fourth roots of unity. This is not an obstruction to the value group $\mathbb{T}$ used throughout the manuscript.

Remark IV.37.4 (Dependence on coordinates). The primitive in (IV.37.2) is a chosen section of the top-derivative map, not a coordinate-free canonical polynomial. Two primitives differ by a polynomial of degree at most $d-1$. Their use in phase removal yields the same selected energy because such a difference has zero top derivative.

IV.38 The shear identity and sharp Boolean certification

Source 43, delivered Section 6.

IV.38.1 A bilinear form hidden in a repeated direction

We return to a symmetric d -linear form $T : V^d \rightarrow \mathbb{F}_2$, $d \geq 3$. For $\mathbf{z} \in V^{d-3}$ define $\Omega_{\mathbf{z}}$ by (F.48.8).

Lemma IV.38.1. *Each $\Omega_{\mathbf{z}}$ is an alternating bilinear form. The map $\mathbf{z} \mapsto \Omega_{\mathbf{z}}$ is multilinear with values in $\text{Alt}^2(V)$.*

Proof. In characteristic two, symmetry cancels the two cross terms when a is replaced by $a + a'$ in $T(a, a, b, \mathbf{z})$; hence this expression is linear in a . The same argument applies to the repeated b . The remaining occurrences are already linear. Finally $\Omega_{\mathbf{z}}(a, a) = 2T(a, a, a, \mathbf{z}) = 0$, and multilinearity in the frozen variables is immediate. $\square$

For a function f , write $\tau_w f(x) = f(x + w)$. The elementary identity responsible for the stronger estimates is

$$\partial_a \partial_{a+w} f = \overline{\partial_a (f \tau_w f)}. \quad (\text{IV.38.1})$$

Indeed both sides at x equal $f(x)f(x+w)\overline{f(x+a)f(x+a+w)}$. This identity has no exceptional set where f vanishes.

Theorem IV.38.2 (Exact shear and repeated-variable rank profile). *Put*

$$g_{\mathbf{z},w} = \partial_{\mathbf{z}}(f \tau_w f), \quad (\text{IV.38.2})$$

$$B_{\mathbf{z},w}(a, b) = T(a, a, b, \mathbf{z}) + T(a, b, \mathbf{z}, w). \quad (\text{IV.38.3})$$

The form $B_{\mathbf{z},w}$ is bilinear and $B_{\mathbf{z},w}(a, b) + B_{\mathbf{z},w}(b, a) = \Omega_{\mathbf{z}}(a, b)$. In the notation where Boolean bilinear forms are embedded in $\mathbb{T}$ by division by two, one has the exact identity

$$\mathcal{E}_T(f) = \mathbb{E}_{\mathbf{z},w} \mathcal{Q}_{B_{\mathbf{z},w}}(g_{\mathbf{z},w}). \quad (\text{IV.38.4})$$

Consequently, for arbitrary complex f ,

$$\mathcal{E}_T(f) \leq \mathbb{E}_{\mathbf{z},w} 2^{-\text{rank } \Omega_{\mathbf{z}}/2} \|g_{\mathbf{z},w}\|_2^4. \quad (\text{IV.38.5})$$

For 1-bounded f this gives

$$\mathcal{E}_T(f) \leq \mathbb{E}_{\mathbf{z}} 2^{-\text{rank } \Omega_{\mathbf{z}}/2}. \quad (\text{IV.38.6})$$

Proof. Write the cube variables in Lemma IV.34.1 as $a, b, \mathbf{z}, c$, and make the invertible substitution $c = a + w$. Multilinearity gives

$$T(a, b, \mathbf{z}, a + w) = T(a, a, b, \mathbf{z}) + T(a, b, \mathbf{z}, w) = B_{\mathbf{z},w}(a, b).$$

The first term is bilinear in a, b by the cancellation used in Lemma IV.38.1; the second term is bilinear and symmetric in a, b . Its alternating part cancels.

Apply the remaining differences $\partial_b \partial_{\mathbf{z}}$ to (IV.38.1). They commute with complex conjugation. The resulting inner average over a, b, x is the complex conjugate of $\mathcal{Q}_{B_{\mathbf{z},w}}(g_{\mathbf{z},w})$, by Corollary IV.35.3. That quantity is real and nonnegative, so its conjugate is itself. This proves (IV.38.4). The orthogonality factor is $2^{-\text{rank } \Omega_{\mathbf{z}}/2}$ by (IV.35.8). Applying Theorem IV.35.2 gives (IV.38.5). If f is 1-bounded, so is $g_{\mathbf{z},w}$, and the norm factors are at most one. $\square$

Corollary IV.38.3 (A strict gap for the additional obstruction). *If T is symmetric but not in $\text{nCSM}^d(V)$, then*

$$\mathcal{E}_T(f) \leq 1 - 2^{2-d}. \quad (\text{IV.38.7})$$

Proof. The multilinear map $\mathbf{z} \mapsto \Omega_{\mathbf{z}}$ is nonzero. Lemma IV.36.2 says that its support has measure at least $2^{-(d-3)}$. A nonzero alternating form has rank at least two, so its factor in (IV.38.6) is at most $1/2$. The average loses at least $2^{-(d-3)}/2 = 2^{2-d}$ from one. $\square$

IV.38.2 The sharp all-degree theorem

Theorem IV.38.4 (Sharp Boolean phase-integration criterion). *Let $d \geq 2$ and let $T : V^d \rightarrow \mathbb{F}_2$ be multilinear, without an assumed symmetry. If*

$$\mathcal{E}_T(f) > 1 - 2^{1-d}, \quad (\text{IV.38.8})$$

then $T \in \text{nCSM}^d(V)$. The polynomial P_T in (IV.37.2) exists and satisfies

$$\mathcal{E}_T(f) = \|fe(-P_T)\|_{U^d}^{2^d}. \quad (\text{IV.38.9})$$

The threshold cannot be lowered in any dimension $n \geq 2$, even when T is assumed symmetric in its first $d - 1$ variables.

Proof. Theorem IV.36.4, with $p = 2$ and $k = d - 1$, forces full symmetry. For $d = 2$ this already gives integrability. For $d \geq 3$, failure of integrability would imply (IV.38.7). But $1 - 2^{2-d} < 1 - 2^{1-d}$, contradicting (IV.38.8). Integration follows from Theorem IV.37.2, and the exact identity follows from Lemma IV.34.2. The nonsymmetric endpoint in (IV.36.7), using two independent Boolean linear forms, has precisely energy $1 - 2^{1-d}$ and cannot be a top derivative. This proves sharpness. $\square$

Remark IV.38.5 (The two thresholds should not be conflated). The universal threshold for a prescribed multilinear selector is $1 - 2^{1-d}$. For a tensor already known to be symmetric, the sufficient threshold $1 - 2^{2-d}$ is smaller. The latter is proved optimal here only for $d = 3$; Section IV.41 shows it is not optimal for quartics in dimension two. In dimension one all symmetric multilinear tensors integrate, so the dimension-independent sharpness examples necessarily use at least two coordinates.

IV.38.3 Corrupted selectors and finite margins

Proposition IV.38.6 (Robust certification). *Let $\rho : V^{d-1} \rightarrow V^*$ be an arbitrary selector, and suppose it agrees outside a fraction η of tuples with $\sigma(\mathbf{h}) = T(\mathbf{h}, \cdot)$ for a multilinear T . Define $\mathcal{E}_\rho(f)$ by the corresponding selected Fourier energy. Then*

$$|\mathcal{E}_\rho(f) - \mathcal{E}_T(f)| \leq \eta. \quad (\text{IV.38.10})$$

If a certified lower bound L on $\mathcal{E}_\rho(f)$ satisfies $L - \eta > 1 - 2^{1-d}$, then T integrates and

$$\|fe(-P_T)\|_{U^d}^{2^d} \geq L - \eta. \quad (\text{IV.38.11})$$

If T is known symmetric, $1 - 2^{2-d}$ may replace the threshold for $d \geq 3$. In the symmetric cubic case, every $L - \eta > 0$ also gives an integrable restriction of codimension at most $\lfloor \log_2(1/(L - \eta)) \rfloor$.

Proof. Each squared selected Fourier coefficient lies in $[0, 1]$. The summands agree off the exceptional set, so their average difference is at most its measure. Apply the preceding theorems; the cubic assertion uses Theorem IV.39.4 below. $\square$

The hypothesis supplies a genuine multilinear model and a certified energy bound. It does not assert that noisy samples automatically recover such a model. Numerical error in a computed lower bound must be subtracted before using the strict margin.

IV.39 Exact cubic obstruction ranks and optimal repair

Source 43, delivered Section 7.

IV.39.1 The amplitude-sensitive inequality

Theorem IV.39.1 (Cubic obstruction bound). *Let $T : V^3 \rightarrow \mathbb{F}_2$ be symmetric, and write $\text{rank } \Omega_T = 2m$. For every $f : V \rightarrow \mathbb{C}$,*

$$\mathcal{E}_T(f) \leq 2^{-m} \| |f|^2 \|_{U^2}^4. \quad (\text{IV.39.1})$$

In particular, if $|f| \leq 1$ and $\mu = \mathbb{E}_x |f(x)|^2$, then

$$\mathcal{E}_T(f) \leq 2^{-m} \mu^3 \leq 2^{-m}. \quad (\text{IV.39.2})$$

Proof. In Theorem IV.38.2, there are no frozen variables $\mathbf{z}$. The rank factor is constant, and $g_w = f\tau_w f$. Thus the remaining factor is

$$\mathbb{E}_w \|f\tau_w f\|_2^4 = \mathbb{E}_w \left(\mathbb{E}_x |f(x)|^2 |f(x+w)|^2 \right)^2 = \| |f|^2 \|_{U^2}^4.$$

For $a = |f|^2 \in [0, 1]$, put $c(w) = \mathbb{E}_x a(x)a(x+w)$. Then $0 \leq c(w) \leq \mu$ and $\mathbb{E}_w c(w) = \mu^2$. Consequently $\mathbb{E}_w c(w)^2 \leq \mu \mathbb{E}_w c(w) = \mu^3$. $\square$

IV.39.2 A normal form modulo integrable tensors

For two linear forms u, v , define the symmetric trilinear tensor

$$C_{u,v}(a, b, c) = u(a)u(b)v(c) + u(a)v(b)u(c) + v(a)u(b)u(c). \quad (\text{IV.39.3})$$

A direct substitution gives

$$\Omega_{C_{u,v}}(a, b) = u(a)v(b) + v(a)u(b). \quad (\text{IV.39.4})$$

Proposition IV.39.2 (The cubic obstruction quotient). *The linear map*

$$\Omega : \text{SymMult}^3(V) \longrightarrow \text{Alt}^2(V), \quad T \longmapsto \Omega_T,$$

is surjective and has kernel $\text{nCSM}^3(V)$. It induces a $\text{GL}(V)$ -equivariant isomorphism

$$\text{SymMult}^3(V) / \text{nCSM}^3(V) \cong \text{Alt}^2(V). \quad (\text{IV.39.5})$$

If $\text{rank } \Omega_T = 2m$, there are independent forms $u_1, v_1, \dots, u_m, v_m$ such that

$$T = S + C_m, \quad S \in \text{nCSM}^3(V), \quad C_m = \sum_{j=1}^m C_{u_j, v_j}. \quad (\text{IV.39.6})$$

Proof. The kernel assertion is precisely the repeated-variable identity. Every alternating bilinear form has a symplectic decomposition $\sum_j (u_j \otimes v_j + v_j \otimes u_j)$; this is the vector-space proof in Lemma IV.35.1, with additional radical coordinates. Formula (IV.39.4) gives a preimage of each block and proves (IV.39.6). The definition of Ω_T commutes with every linear change of coordinates, proving equivariance. $\square$

Lemma IV.39.3 (Canonical cubic energy). *For the tensor C_m in (IV.39.6),*

$$\mathcal{E}_{C_m}(1) = 2^{-m}. \quad (\text{IV.39.7})$$

Proof. For a constant function, the energy is the probability that the selected linear functional $C_m(a, b, \cdot)$ vanishes. Different symplectic coordinate pairs are independent, so it suffices to count one pair. Write $a = (a_1, a_2)$ and $b = (b_1, b_2)$. The functional is

$$y \mapsto a_1 b_1 y_2 + (a_1 b_2 + a_2 b_1) y_1.$$

For $a = (0, 0)$, all four b 's work. For $a = (0, 1)$, two work. For each of $a = (1, 0)$ and $(1, 1)$, exactly one works. There are $4 + 2 + 1 + 1 = 8$ successful pairs out of sixteen, giving $1/2$ per block. Radical coordinates impose no condition. Multiplication over m blocks proves the result. $\square$

IV.39.3 The exact extremal and repair theorem

Theorem IV.39.4 (Exact cubic energy and optimal codimension). *For every symmetric trilinear $T : V^3 \rightarrow \mathbb{F}_2$ with $\text{rank } \Omega_T = 2m$,*

$$\mathcal{M}(T) = 2^{-m}, \quad \min_{\substack{U \leq V \\ T|_{U^3} \in \text{nCSM}^3(U)}} \text{codim } U = m. \quad (\text{IV.39.8})$$

The maximum is attained by a nonclassical cubic phase of modulus one. An optimal subspace and an explicit primitive on it are constructible by finite linear algebra. Hence, for $0 < a \leq \mathcal{E}_T(f)$,

$$m \leq \lfloor \log_2(1/a) \rfloor. \quad (\text{IV.39.9})$$

The coefficient one in this logarithmic repair law is sharp.

Proof. The upper bound is Theorem IV.39.1. Write $T = S + C_m$ by Proposition IV.39.2, and integrate S to a cubic P_S . Gauge invariance and Lemma IV.39.3 give

$$\mathcal{E}_T(e(P_S)) = \mathcal{E}_{C_m}(1) = 2^{-m}.$$

This proves the exact extremum and its phase attainment.

By Theorem IV.37.2, $T|_{U^3}$ integrates precisely when $\Omega_T|_{U \times U} = 0$, that is, when U is isotropic. If $R = \text{rad } \Omega_T$, then $\dim R = n - 2m$. The image of an isotropic U in the nondegenerate symplectic quotient V/R has dimension at most m . Indeed in a nondegenerate alternating space of dimension $2m$, an isotropic subspace L satisfies $L \subseteq L^\perp$ and $\dim L + \dim L^\perp = 2m$. Thus

$$\dim U \leq \dim R + m = n - m.$$

Equality is obtained by adjoining the radical to a Lagrangian of the quotient. One can take $U = \bigcap_{j=1}^m \ker u_j$ in the normal form. Integrate the restriction using (IV.37.2) on a basis of U . Finally $a \leq 2^{-m}$ gives (IV.39.9). For every m , the example $T = C_m$, $f = 1$ has $a = 2^{-m}$ and requires exactly codimension m , so no smaller universal coefficient can replace one. $\square$

[write] **7 October 2026; sources 40–46.** This is source 46's Theorem IV.27.1 for one function, proved independently the same day; source 46's statement for eight functions contains the value $2^{-\text{rank } \Omega_T/2}$, and both identify the optimal codimension $\text{rank } \Omega_T/2$.

Corollary IV.39.5 (A low-partition-rank global correction). *There is $S \in \text{nCSM}^3(V)$ with*

$$\text{prank}(T - S) \leq 2m \leq 2\lfloor \log_2(1/a) \rfloor \quad \text{whenever } \mathcal{E}_T(f) \geq a > 0. \quad (\text{IV.39.10})$$

Here partition rank means the least number of summands, each factoring into a function of one nonempty set of variables and a function of its complementary set.

Proof. Use the normal form, and write each block as

$$C_{u,v}(a, b, c) = u(a)(u(b)v(c) + v(b)u(c)) + v(a)u(b)u(c).$$

This gives two partition-rank-one summands per block. The assertion is an upper bound; optimality of this partition-rank coefficient is not asserted. $\square$

IV.39.4 Concentration, tensor products, and what stability is available

The amplitude inequality also has concentrated extremizers. Choose an optimal isotropic subspace U of codimension m and a primitive P_U of $T|_{U^3}$. Define $f = 1_U e(P_U)$ on U and zero elsewhere. A nonzero cube contribution requires all its vertices in U ; this is equivalent to $x, a, b, c \in U$. Every such contribution is one after the tensor twist. With $\mu = |U|/|V| = 2^{-m}$,

$$\mathcal{E}_T(f) = \mu^4 = 2^{-m} \mu^3. \quad (\text{IV.39.11})$$

Thus the mass factor in (IV.39.2) can also be attained.

For direct sums of symmetric cubic tensors, alternating ranks add. The exact theorem therefore gives the multiplicative law

$$\mathcal{M}(T_1 \oplus T_2) = \mathcal{M}(T_1) \mathcal{M}(T_2). \quad (\text{IV.39.12})$$

This identity is a consequence of the proved extremal formula, not an assumption that arbitrary optimizing functions factor.

A first quantitative stability consequence concerns amplitudes. If $\mathcal{E}_T(f) \geq (1 - \varepsilon)2^{-m}$ with $0 \leq \varepsilon \leq 1$, then

$$\mathbb{E}_x(1 - |f(x)|^2) \leq 1 - (1 - \varepsilon)^{1/3}. \quad (\text{IV.39.13})$$

This follows immediately from (IV.39.2). It does not classify the phases of near-extremizers. A phase-stability claim would require information about simultaneous equality in the projective spectral inequalities and is left for further research.

IV.40 Mixed correlations: an optimal fourth power and a smaller repair bound

Source 43, delivered Section 8.

The one-function cube structure is stronger than an arbitrary mixed correlation. Nevertheless the *mixed* orthogonality theorem also improves a published local estimate without changing its hypotheses.

IV.40.1 The triangle correlation

For a finite abelian group and a biadditive $B : G^2 \rightarrow \mathbb{T}$, put

$$L_B(u, v, w) = \mathbb{E}_{a,b} u(a)v(b)w(a+b)e(B(a, b)). \quad (\text{IV.40.1})$$

Theorem IV.40.1 (Sharp fourth-power bilinear estimate). *For arbitrary complex u, v, w ,*

$$|L_B(u, v, w)| \leq d_B^{-1/2} \|u\|_2 \|v\|_2 \|w\|_2. \quad (\text{IV.40.2})$$

Consequently, for 1-bounded functions,

$$|L_B(u, v, w)|^4 \leq \mathbb{E}_{a,b} e(B(a, b) - B(b, a)) = d_B^{-2}. \quad (\text{IV.40.3})$$

The exponent four in (IV.40.3) is optimal as a uniform assertion, already on $\mathbb{F}_2^2$.

Proof. Write $B^t(a, b) = B(b, a)$, and use the operators associated to B^t . Replacing a by $x - b$ gives

$$\mathbb{E}_a u(a)w(a+b)e(B(a, b)) = e(-B(b, b)) \left\langle U_{-b}^{B^t} u, \bar{w} \right\rangle.$$

Cauchy–Schwarz in b , followed by Theorem IV.35.2, yields

$$|L_B|^2 \leq \|v\|_2^2 \mathcal{Q}_{B^t}(u, \bar{w}) \leq d_B^{-1} \|u\|_2^2 \|v\|_2^2 \|w\|_2^2.$$

The radical indices of B and B^t agree. Averaging the alternating character in its second variable is one when the first variable is in R_B and zero otherwise. Hence its bias is $|R_B|/|G| = d_B^{-2}$, proving (IV.40.3).

For sharpness, take $G = \mathbb{F}_2^2$ and $B(a, b) = a_1 b_2 / 2$. Then $d_B = 2$. Let $\zeta = e^{\pi i / 4}$ and choose

$$u(a) = 1, \quad w(x) = i^{x_1}, \quad v(b) = \begin{cases} \zeta^{-1}, & b_2 = 0, \\ \zeta(-1)^{b_1}, & b_2 = 1. \end{cases} \quad (\text{IV.40.4})$$

The inner average over a is $\zeta / \sqrt{2}$ when $b_2 = 0$, and $(-1)^{b_1} \zeta^{-1} / \sqrt{2}$ when $b_2 = 1$. Multiplying by $v(b)$ makes it $1 / \sqrt{2}$ in both cases. Thus $|L_B| = 2^{-1/2}$ and $|L_B|^4 = 1/4 = d_B^{-2}$. Any exponent smaller than four would fail for this example. $\square$

Tidor’s Lemma 4.1 [150] gives the eighth-power version of this estimate over finite fields. The fourth-power statement above is therefore a strict local refinement of that displayed estimate, as well as a finite-abelian extension. It makes no claim about priority among all possible earlier formulations of projective orthogonality.

IV.40.2 A transposition defect under seven-function correlation

For $T : V^3 \rightarrow \mathbb{F}_p$ and 1-bounded $b_1, \dots, b_7$, write

$$\begin{aligned} \Gamma_T(b_1, \dots, b_7) = & \left| \mathbb{E}_{x,y,z} b_1(x)b_2(y)b_3(z)b_4(x+y) \right. \\ & \left. \cdot b_5(x+z)b_6(y+z)b_7(x+y+z)e_p(T(x, y, z)) \right|, \end{aligned} \quad (\text{IV.40.5})$$

where $e_p(t) = e(t/p)$. Let $T_{(12)}(x, y, z) = T(y, x, z)$.

Proposition IV.40.2 (Fourth-power control of each transposition). *If $\Gamma_T \geq \delta > 0$, then*

$$\mathbb{E}_{x,y,z} e_p(T(x,y,z) - T(y,x,z)) \geq \delta^4. \quad (\text{IV.40.6})$$

The same conclusion holds for each transposition of the three slots. Equivalently, the analytic rank of each such defect is at most $4 \log_p(1/\delta)$, where analytic rank is minus the base- p logarithm of the bias.

Proof. Freeze z . The inner expression is a triangle correlation in x, y : combine $b_1(x)b_5(x+z)$, $b_2(y)b_6(y+z)$, and $b_4(x+y)b_7(x+y+z)$ into the three functions. If K_z is the alternating part of the bilinear form $T(\cdot, \cdot, z)$, Theorem IV.40.1 gives the upper bound $p^{-\text{rank } K_z/4}$. The triangle inequality and concavity of the fourth root give

$$\delta \leq \mathbb{E}_z p^{-\text{rank } K_z/4} \leq \left(\mathbb{E}_z p^{-\text{rank } K_z} \right)^{1/4}.$$

The average on the right is precisely the bias in (IV.40.6). Permuting the variables permutes the seven allowed arguments and proves the other cases. $\square$

This proposition only controls analytic rank. It does not silently replace analytic rank by partition rank for general trilinear tensors. Such a conversion is a separate input in a full inverse argument.

IV.40.3 Refining the symmetric trilinear repair lemma

Theorem IV.40.3 (Seven-function repair with coefficient two). *Let $T : V^3 \rightarrow \mathbb{F}_2$ be symmetric, and let $\text{rank } \Omega_T = 2m$. For every seven 1-bounded functions,*

$$\Gamma_T(b_1, \dots, b_7) \leq 2^{-m/2}. \quad (\text{IV.40.7})$$

Thus $\Gamma_T \geq \delta > 0$ implies that T integrates on a subspace of codimension at most

$$\lfloor 2 \log_2(1/\delta) \rfloor. \quad (\text{IV.40.8})$$

Proof. Make the same shear $z = x + w$ used in the repeated-variable argument. For a fixed w , combine the seven factors into

$$g_w(x) = b_1(x)b_3(x+w), \quad h_w(y) = b_2(y)b_7(y+w), \quad k_w(t) = b_4(t)b_6(t+w),$$

leaving a scalar factor $b_5(w)$. The tensor becomes

$$A_w(x, y) = T(x, x, y) + T(x, y, w).$$

It is bilinear, and its alternating part is Ω_T , independent of w . Its radical index parameter is therefore $d_{A_w} = 2^m$. Theorem IV.40.1 bounds each inner triangle correlation by $2^{-m/2}$. Averaging over w proves (IV.40.7). It follows that $m \leq 2 \log_2(1/\delta)$. An isotropic subspace of codimension m exists and has an integrable restriction, by the algebraic part of Theorem IV.39.4. $\square$

[write] **7 October 2026; sources 40–46.** The same codimension $\lfloor 2 \log_2(1/\delta) \rfloor$ is source 46’s Theorem IV.28.1, by a different route. Tidor’s Proposition 4.6 (re-read at the write in the arXiv HTML of version 2) gives codimension at most $8 \log_2(1/\delta)$ for symmetric trilinear forms over $\mathbb{F}_2$ under a seven-function correlation hypothesis; the hypotheses were compared only as displayed there, as both sources compare them.

Tidor's Proposition 4.6 [150] has the same symmetric tensor and seven-function hypothesis, with codimension at most $8\log_2(1/\delta)$. Here the fourth-power estimate controls the alternating rank more tightly, and an isotropic subspace replaces the full radical. The combined result is (IV.40.8). Optimality of the coefficient two for this seven-function problem is not established. In contrast, coefficient one in the one-function energy problem (IV.39.9) is proved optimal.

IV.41 The quartic frontier: an exact small quotient and a global reduction

Source 43, delivered Section 9.

IV.41.1 A useful nonintegrable family in every degree

For independent $u, v \in V^*$ and $d \geq 3$, put

$$C_d(h_1, \dots, h_d) = \sum_{i=1}^d v(h_i) \prod_{j \neq i} u(h_j). \quad (\text{IV.41.1})$$

Proposition IV.41.1 (Explicit lower bounds). *The tensor C_d is symmetric and nonintegrable, and*

$$\Omega_z(a, b) = \left(\prod_{j=1}^{d-3} u(z_j) \right) (u(a)v(b) + v(a)u(b)), \quad (\text{IV.41.2})$$

$$\mathcal{E}_{C_d}(1) = 1 - \frac{d+1}{2^d}. \quad (\text{IV.41.3})$$

Consequently the dimension-independent symmetric nonintegrable extremum satisfies

$$1 - \frac{d+1}{2^d} \leq \sup_{\substack{n \geq 2, T \in \text{SymMult}^d(\mathbb{F}_2^n) \setminus \text{nCSM}^d(\mathbb{F}_2^n) \\ \|f\|_\infty \leq 1}} \mathcal{E}_T(f) \leq 1 - 2^{2-d}. \quad (\text{IV.41.4})$$

Proof. In the two repeated evaluations, the terms where v is placed in one of the two repeated positions cancel in pairs. The terms where v is placed in a frozen position cancel between the two evaluations. The two remaining terms give (IV.41.2), which is nonzero for appropriate arguments.

For the constant function, the selected frequency is zero precisely when both coefficients in

$$y \mapsto v(y) \prod_{j=1}^{d-1} u(h_j) + u(y) \sum_{i=1}^{d-1} v(h_i) \prod_{j \neq i} u(h_j)$$

are zero. Put $k = d - 1$. If at least two of the $u(h_j)$ are zero, both coefficients vanish. If exactly one is zero, the remaining condition is one independent unbiased bit, so half the tuples work. If none is zero, the coefficient of $v(y)$ is one and the frequency cannot vanish. Therefore the success probability is

$$1 - 2^{-k} - \frac{1}{2}k2^{-k} = 1 - (d+1)2^{-d}.$$

The upper bound in (IV.41.4) is Corollary IV.38.3. □

For $d = 3$ the bounds coincide at $1/2$. For $d = 4$ they give $11/16 \leq M \leq 3/4$. The next results explain why the fourth-degree problem is concentrated in one specific tensor rather than an unrestricted search over quartic coefficients.

IV.41.2 High-energy quartics have one rank-two defect

For a symmetric quartic, $z \mapsto \Omega_z$ is a linear map $V \rightarrow \text{Alt}^2(V)$. Denote its image dimension by r .

Theorem IV.41.2 (Quartic defect dichotomy and normal form). *Let $T : V^4 \rightarrow \mathbb{F}_2$ be symmetric and nonintegrable. If $\mathcal{E}_T(f) > 5/8$, then there are independent $u, v \in V^*$ and $S \in \text{nCSM}^4(V)$ such that*

$$T = S + C_4, \quad (\text{IV.41.5})$$

where C_4 is (IV.41.1) for these two forms. More precisely, failure of this defect normal form implies the uniform bound $\mathcal{E}_T(f) \leq 5/8$.

Proof. Since T is nonintegrable, $r \geq 1$. If $r \geq 2$, the zero fiber of $z \mapsto \Omega_z$ has measure $2^{-r} \leq 1/4$. Every nonzero value has rank at least two. Hence the profile theorem gives

$$\mathcal{E}_T(f) \leq 2^{-r} + (1 - 2^{-r})/2 \leq 5/8.$$

Thus energy greater than $5/8$ forces $r = 1$. Write $\Omega_z = \ell(z)\Omega_0$ for nonzero ℓ and Ω_0 . If $\text{rank } \Omega_0 \geq 4$, then $\mathcal{E}_T(f) \leq (1 + 1/4)/2 = 5/8$. We must therefore have $\text{rank } \Omega_0 = 2$, so

$$\Omega_0(a, b) = u_0(a)v_0(b) + v_0(a)u_0(b)$$

for independent u_0, v_0 .

Symmetry of the original quartic imposes the identity

$$\Omega_c(a, b) + \Omega_b(a, c) + \Omega_a(b, c) = 0. \quad (\text{IV.41.6})$$

Indeed, expansion gives six quartic terms, paired equally by symmetry. If ℓ were not in the span of u_0, v_0 , choose $c \in \ker u_0 \cap \ker v_0$ with $\ell(c) = 1$, and choose a, b with $\Omega_0(a, b) = 1$. Then the first term of (IV.41.6) would be one and the others zero, a contradiction. Thus $\ell \in \text{span}(u_0, v_0)$.

Set $u = \ell$. Because the scalar field is $\mathbb{F}_2$, one can choose v in the same two-dimensional span so that $\Omega_0 = u \otimes v + v \otimes u$. Formula (IV.41.2) for $d = 4$ shows that C_4 has exactly the same defect map as T . Their difference is symmetric and has zero repeated-variable defect, and hence lies in $\text{nCSM}^4(V)$. $\square$

The identity (IV.41.6) is important: a generic linear family of rank-two alternating forms need not be the defect of a symmetric quartic. Ignoring this compatibility would leave an unnecessarily large search space.

IV.41.3 The exact two-dimensional quartic extremum

Theorem IV.41.3 (The quartic value $11/16$ on $\mathbb{F}_2^2$). *For the tensor C_4 on $V = \mathbb{F}_2^2$ with $u(x) = x_1$ and $v(x) = x_2$,*

$$\max_{\|f\|_\infty \leq 1} \mathcal{E}_{C_4}(f) = \frac{11}{16}. \quad (\text{IV.41.7})$$

The same maximum holds for every symmetric nonintegrable quartic on $\mathbb{F}_2^2$, after an integrable phase twist and a linear change of coordinates.

Proof. Label the four points $0, e_1, e_2, e_1 + e_2$ by $0, 1, 2, 3$, and put $z_i = f(i)^4$. We first establish the exact polynomial identity

$$1024\mathcal{E}_{C_4}(f) = \left| z_0^2 + z_1^2 + z_2^2 + z_3^2 \right|^2 + 28 \sum_{i < j} |z_i z_j|^2 + 480 \prod_{i=0}^3 |z_i| + 24 \operatorname{Re}(z_0 z_1 \overline{z_2 z_3} + z_0 z_3 \overline{z_1 z_2}) - 8 \operatorname{Re}(z_0 z_2 \overline{z_1 z_3}). \quad (\text{IV.41.8})$$

A short cube census proves the formula without assumptions on the amplitudes. Here are all its cases.

If the four directions are all zero, their four possible base points give the diagonal terms of $|\sum_i f(i)^8|^2$. If the directions are all the same nonzero vector, their base points give its off-diagonal terms. All these tensor signs are positive. For a fixed nonzero vector, the fourteen remaining tuples in $\{0, h\}^4$ use both 0 and h . Each vertex of a two-point coset then occurs four times with each conjugation parity. The two possible base points per coset give the coefficient 28 of each $|f(i)f(j)|^8$.

It remains to consider direction tuples spanning $\mathbb{F}_2^2$. The cube map $\varepsilon \mapsto \sum_j \varepsilon_j h_j$ has four-point fibers. Unless the parity $\sum_j \varepsilon_j$ factors through that map, every fiber contains two even and two odd vertices, giving the common monomial $\prod_i |f(i)|^4$. Parity factors precisely when all four directions lie in a single two-element affine hyperplane not containing zero. They must use both of its points. For a pair of distinct nonzero directions a, b , the fourteen such tuples have multiplicity patterns $3 + 1$, $2 + 2$, and $1 + 3$. Their signed sum is

$$4(-1)^{C_4(a,a,a,b)} + 6(-1)^{C_4(a,a,b,b)} + 4(-1)^{C_4(a,b,b,b)}.$$

For the pairs (e_1, e_2) , $(e_1, e_1 + e_2)$, $(e_2, e_1 + e_2)$, these sums are $6, -2, 6$, respectively. Each orientation of the associated two-pair partition has two base points, giving coefficients $12, -4, 12$ and their conjugates. These are the three real-part terms in (IV.41.8).

Finally, the sum of the tensor signs over all direction tuples is $256(11/16) = 176$ by Proposition IV.41.1. The rank-zero and rank-one tuples contribute $1 + 3(15) = 46$; the parity-factoring rank-two tuples contribute $6 - 2 + 6 = 10$. The remaining signed sum is therefore $176 - 46 - 10 = 120$. Their four base points give the coefficient 480. This completes the derivation of (IV.41.8).

The map $f(i) \mapsto z_i = f(i)^4$ maps the closed unit disc onto itself. The right side of (IV.41.8) is subharmonic separately in each z_i : the first term is a squared modulus of a holomorphic polynomial, the next two terms are nonnegative multiples of $|z_i|^2$ and $|z_i|$, and the remaining terms are harmonic in that variable. The disc maximum principle, applied one coordinate at a time, shows that its maximum is attained when every $|z_i| = 1$. This use of the maximum principle can also be seen directly from the Poisson mean inequality for the squared modulus and the nonnegative radial terms.

Write $z_i = e^{i\theta_i}$, and put

$$c = \cos(\theta_0 - \theta_2), \quad r = \cos(\theta_1 - \theta_3), \quad q = \cos(\theta_0 + \theta_2 - \theta_1 - \theta_3).$$

The second and third terms of (IV.41.8) contribute $168 + 480 = 648$. The remaining expression is

$$4(c^2 + r^2) + 48cr + 8q(cr - 1). \quad (\text{IV.41.9})$$

Since $cr \leq 1$ and $-1 \leq q \leq 1$,

$$4(c^2 + r^2) + 48cr + 8q(cr - 1) \leq 4(c^2 + r^2) + 40cr + 8 \leq 56.$$

Thus $1024\mathcal{E}_{C_4}(f) \leq 704$, or $\mathcal{E}_{C_4}(f) \leq 11/16$. The constant function attains this value.

On a two-dimensional space, $\text{Alt}^2(V)$ is one-dimensional. The nonzero defect map of any nonintegrable symmetric quartic therefore has image dimension one and nonzero rank two. The algebraic part of Theorem IV.41.2 applies without an energy assumption. It gives the stated normal form; gauge invariance and a linear change of variables preserve the maximum energy. $\square$

IV.41.4 The remaining higher-dimensional question is one fixed tensor

Let $C_{4,n}$ denote the pullback of C_4 to $\mathbb{F}_2^n = \mathbb{F}_2^2 \oplus \mathbb{F}_2^{n-2}$, and define

$$M_{4,n} = \max_{\substack{T \in \text{SymMult}^4(\mathbb{F}_2^n) \setminus \text{nCSM}^4(\mathbb{F}_2^n) \\ \|f\|_\infty \leq 1}} \mathcal{E}_T(f).$$

Corollary IV.41.4 (Exact reduction of the quartic optimization). *For every $n \geq 2$,*

$$M_{4,n} = \mathcal{M}(C_{4,n}), \quad \frac{11}{16} \leq M_{4,n} \leq \frac{3}{4}, \quad M_{4,2} = \frac{11}{16}. \quad (\text{IV.41.10})$$

The sequence $M_{4,n}$ is nondecreasing. Thus the full quartic extremal problem reduces to asking whether adjoining directions on which C_4 is zero increases its optimal tested energy.

Proof. The explicit tensor has energy $11/16 > 5/8$ at the constant function. Any tensor whose defect does not have the normal form has energy at most $5/8$, so it cannot determine the maximum. Every remaining tensor is, after gauge and coordinates, exactly $C_{4,n}$. This proves the equality of optimization problems. The lower and upper bounds follow from the explicit example and the shear profile. An optimizer on dimension n may be pulled back while ignoring an additional coordinate, proving monotonicity. $\square$

We do not infer $M_{4,n} = M_{4,2}$ from the fact that the tensor uses only two coordinates. The optimizing function may depend on all the coordinates. Ruling out such a gain is the precise additional theorem that would be needed. The cubic tensorization theorem does not settle this quartic question.

Part V

Lean interface, ledger crosswalk and research questions

Contents. Sections V.1 and V.2 are the write’s: the crosswalk of every comparison with the formal project, checked against the current ledger, and the deduplicated list of the sources’ 46 research questions with credits (Vladimir’s standing rule of 4 October 2026). Then each source’s remaining sections, in source order: 01’s formalization interface, questions, conclusions and appendices (delivered Sections 14–16, Appendices A–B); 02’s (Sections 10–12, Appendix A); 03’s iteration bookkeeping, Lean route, questions and reproducibility (Sections 9–11, Appendix A); 04’s quantitative comparisons, questions, closing perspective and appendices (Sections 9–11, Appendices A–B); 05’s Lean relation, computation, questions and conclusion (Sections 7–10). The sources’ question sections are printed as delivered, with dated notes where another source answers a question.

Reading conventions of this Part (the full dictionary is Section F.3).

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
pins, counts	01, 03: pin 3a25020a6; 04, 05: pin 327773149; 02: observed branch reference 66c02f8a1. The ledger counts quoted by the sources (88 exact, 32 open) are those of the pins; at HEAD they are 98 and 22 (Section V.1).
Qk , (Q1), (Q2)	04: its questions are numbered Q1–Q12 and two displays are tagged (Q1), (Q2); 01: numbered Questions (Section V.4); 03: numbered Research questions (Section V.14); 02, 05: subsections and paragraphs. Item names in Section V.2 are the write’s.

Added in the second write (6 October 2026): sources 06–10. Contents. The write’s Sections V.1 and V.2 are extended by dated additions: the crosswalk to the ledger at HEAD of this write, and the 50 research questions of sources 06–10 (plus two inline question paragraphs of source 10) merged into the theme lists. Then the remaining sections of the new sources, in source order: 06’s iteration potential, Lean map and questions (delivered Sections 6, 8, 9); 07’s verification, questions, conclusion and reproduction commands (Sections 9–11, Appendix B); 08’s Lean integration, checks, questions, conclusion and build provenance (Sections 11–14, Appendix B); 09’s checks, Lean integration, questions, conclusion and dependency map (Sections 11, 12, 14, 15, Appendix C); 10’s iteration bookkeeping, Lean map, questions and provenance (Sections 10–12, Appendix A).

Reading conventions for the sections of sources 06–10 in this Part.

The write’s Sections V.1 and V.2 gain dated additions: the crosswalk of sources 28–33 at HEAD of this write, and their 69 questions merged into the theme lists. Then the remaining sections of the new sources, in source order: 28’s interface, computations, questions and provenance (delivered Sections 9–12); 29’s integration, verification and questions (Sections 10–12); 30’s crosswalk, questions, conclusion and build appendix (Sections 10–12, Appendix A); 31’s verification, questions and dictionary (Sections 10–11, Appendix B); 32’s source comparison and questions (Sections 6–7); 33’s questions, integration and audit checklist (Sections 9–10, Appendix A).

Reading conventions for the sections of sources 28–33 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
pins (28–33)	28, 29, 31: pin e3125e698; 30: 8d65d3c9f; 32: c94998a5d; 33: 9f83dbe0f. None of them quotes ledger counts; every Lean file they cite is unchanged at HEAD 5d4718772 (Section V.1).
questions	29, 30: Questions; 28, 31, 33: Research questions; 32: numbered items. In Section V.2 they are “28 Q1” and so on, in delivered order.

Added in the seventh write (6 October 2026): sources 34–39. Contents. The write’s Sections V.1 and V.2 gain dated additions: the crosswalk of sources 34–39 at HEAD of this write, and their 73 questions merged into the theme lists. Then the remaining sections of the new sources, in source order: 34’s consequences and research program, and integration (delivered Sections 11–12); 35’s evidence and formalization, and research programme (Sections 8–9); 36’s checks, integration, questions and conclusion (Sections 11–14); 37’s verification, questions, conclusion and source audit (Sections 10–12, Appendix C); 38’s verification, integration and questions (Sections 8–10); 39’s interface, checks, questions, conclusion, dependency map and notation checklist (Sections 12–15, Appendices A–B).

Reading conventions for the sections of sources 34–39 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
pins (34–39)	34, 35, 38: pin 12da35673; 36: 6c2e2172b; 37, 39: 869289aa3. Only source 38 quotes ledger counts (those of its pin); every Lean and paper file they cite is unchanged at HEAD 89c1cbc38 (Section V.1).
questions	34, 35, 36, 39: Research questions; 37: Questions; 38: numbered items. In Section V.2 they are “34 Q1” and so on, in delivered order (source 35’s question in its Section 6 is “35 Q1”).

Added in the eighth write (7 October 2026): sources 40–46. Contents. The write’s Sections V.1 and V.2 gain dated additions: the crosswalk of sources 40–46 at HEAD of this write, including the repository’s new formal work on Corollary 5.8, and their 62 questions merged into the theme lists. Then the remaining sections of the new sources, in source order: 40’s reproducibility, questions and conclusion (delivered Sections 10–12); 41’s pinned source and context, and reproducibility and questions (Sections 8–9); 42’s relation to prior arguments and questions, and diagnostics (Sections 8–9); 43’s relation to Gowers’s argument and the formal project, checks, questions and conclusion (Sections 10–13); 44’s verification and formalization

targets, questions, conclusion and reproduction appendix (Sections 11–13, Appendix A); 45’s research programme and its appendices on normalization, certificates and sources (Section 6, Appendices A–C); 46’s verification, questions, conclusion and dependency map (Sections 10–12, Appendix A).

Reading conventions for the sections of sources 40–46 in this Part.

Symbol	Meanings in this Part, by source (<i>tempting false reading</i> in italics)
pins (40–46)	40, 46: no pin (46 records two blobs); 41: <code>c94998a5d</code> ; 42: <code>b16ce380d</code> ; 43: <code>797aa3cfe</code> ; 44: <code>8c12c906e</code> ; 45: <code>6ce33539e</code> . Every Lean and paper file they cite is unchanged at HEAD <code>6d4942222</code> (Section V.1).
questions	40, 43, 46: Research questions; 44, 45: Questions; 41, 42: enumerated items. In Section V.2 they are “40 Q1” and so on, in delivered order.

V.1 The formal project: ledger crosswalk [write]

Added in the write, 6 October 2026.

Every comparison that a source makes with a corrected statement of the formal project was checked against the ledger and the Lean declarations at HEAD `25df8755d` (6 October 2026). File and line numbers below are at that commit. Statements are `Sections*.lean` propositions; “exact” means the ledger lists an exact companion theorem. The ledger then records 98 exact companions and 22 open statements; at all three pins it recorded 88 and 32. The last column gives the formal status of the *improvement*. All of the comparisons are accurate at HEAD, except the stale ones the table names.

Gowers	Lean statement; companion (status)	Source claim here	Improvement
Lemma 2.3	<code>lemma_2_3</code> (Sections01_03:141); <code>lemma_2_3_holds</code> (Proofs02Partition:561) (exact)	constant $1/4 \rightarrow 1/3$, optimal under the Lean hypotheses (05, Thm. I.16.4)	not formalized
Cor. 2.4	<code>corollary_2_4</code> (:158); <code>corollary_2_4_holds</code> (Proofs02PhasePartition:276) (exact); related refutation <code>corollary_2_4_before_roundin</code> <code>g_repair_false</code> (:241) (reordered after the independent check of 6 October 2026; “(exact)” first followed the refutation)	$128\pi \rightarrow 36\pi$, $\alpha/2 \rightarrow 3\alpha/4$, same upper length, $r \leq N$ dropped (05, Cor. I.16.6)	not formalized
Cor. 2.5	<code>corollary_2_5</code> (:180); <code>corollary_2_5_holds</code> (Proofs02 DensityIncrement:517); proof-level pair $\sqrt{\alpha N}/128\pi$, $\alpha/4$ inside the proof of private <code>cor25_large_scale</code> (:375; lines 446–509) (exact) (corrected after the independent check of 6 October 2026; first “in private”)	density-sensitive increments (01, 03, 05); 03 and 05 compare with the proof-level pair, 01 with the statement (note after Table 3)	not formalized

Gowers	Lean statement; companion (status)	Source claim here	Improvement
Thm. 3.2, Cor. 3.3	<code>theorem_3_2_holds</code> (Proofs03ProgressionAverage:381); <code>corollary_3_3</code> (:276), <code>corollary_3_3_holds</code> (Proofs03ProgressionCount:349) (exact; N prime, $k \leq N$)	$2^k \alpha \rightarrow (k-2)\alpha$ in normalized terms; admissible slopes (03, 04, Part III)	not formalized
Cor. 3.6	<code>corollary_3_6</code> (:310); <code>corollary_3_6_holds</code> (Proofs03ProgressionExistence:157) (exact)	density exponent $k2^{k-1}$ against $k2^k$ (04, Cor. III.4.4)	not formalized
Lemmas 3.8, 3.9	<code>lemma_3_8_holds</code> (Proofs03GowersCS:513), <code>lemma_3_9_holds</code> (Proofs03Minkowski:173); tools <code>gowers_cauchy_schwarz</code> (Proofs03GowersCS:485) and <code>gowersNorm_add_le</code> (Proofs03Minkowski:131) (exact)	used as tools (03, 04)	— (corrected after the independent check of 6 October 2026: the row first read “Lemma 3.8” and listed <code>gowersNorm_add_le</code> , the tool of Lemma 3.9, without <code>lemma_3_9_holds</code> ; lines unchanged at <code>e1db00e99</code>)
Lemma 3.10	<code>lemma_3_10</code> (:340); <code>lemma_3_10_holds</code> (Proofs03CubeUpper:82) (exact)	excess $\alpha^{1/2^d} \rightarrow \alpha^{4/2^d}$ (03); leading $6\sqrt{2}\delta^4 u^4$ for $d=3$ (04)	not formalized
Cor. 5.6	<code>corollary_5_6</code> (Section05:205); <code>corollary_5_6_holds</code> (Proofs05FullPartition:85) (exact at HEAD, open at every pin)	02 imports it as $\text{PP}(K, R_0)$ with the same constants; <i>02’s “not Lean-verified” is stale</i> (note in Section I.11)	02’s Thm. I.11.1 not formalized
Cor. 5.8	<code>corollary_5_8</code> (Section05:242) (open); <code>corollary_5_8_with_scale_holds</code> (Proofs05FullPartition:94) proves a scale-qualified repair	02 declines to restate it (Section I.10)	—
Lemma 5.15	<code>lemma_5_15</code> (Section05:352); <code>lemma_5_15_holds</code> (Proofs05_10:735) (exact; $\alpha \geq 0$, empty cells allowed)	size $\alpha N/(4M) \rightarrow$ $\alpha(2+\alpha)N/(2(4-\alpha)(M-1))$ for $\alpha > 0$, nonempty cells (02, 03)	not formalized
Prop. 6.1	<code>proposition_6_1</code> (Sections06_07:37); <code>proposition_6_1_holds</code> (Proofs05_10:505) (exact)	recovered by 02’s Thm. II.2.1 with $m(f) \leq 1$, $\mathcal{U} \leq m^4$	not formalized
Prop. 7.3	<code>proposition_7_3</code> (:135); <code>proposition_7_3_holds</code> (Proofs07BalogSzemerédi:996); also <code>proposition_7_3_group_holds</code> (exact)	$(2^{-20}c^{12}, 2^{38}c^{-24}) \rightarrow$ $(c/8, 2^{19}c^{-9})$ (03)	not formalized

Gowers	Lean statement; companion (status)	Source claim here	Improvement
Lemma 7.4	<code>lemma_7_4 (:167);</code> <code>lemma_7_4_holds</code> (Proofs07DRC:536), five witnesses (exact)	$2^{-1/2}\delta^5 n \rightarrow 7\delta^3 n / (3\sqrt{6})$ (03)	not formalized
Lemma 9.2	<code>lemma_9_2 (Sections08_09:69);</code> <code>lemma_9_2_holds</code> (Proofs09Moments:527); exact $N^2 B $ at line 495 (exact)	(M4) exact Parseval is proof-level; (M5) $\gamma^7 \beta^{15} p^{15}$ (04)	not formalized
Lemma 9.3, Cor. 9.4	<code>lemma_9_3 (:77), corollary_9_4</code> (:91); companions Proofs09Restriction:376, :416 (exact; <i>no primality</i>)	prime-field restriction, $2^{-95}\gamma^{112}\eta^{15} B ^{15}$ (04); does not prove the Lean statements, as 04 says	not formalized
Lemma 12.4	<code>lemma_12_4 (Sections12_13:158);</code> <code>lemma_12_4_holds</code> (Proofs12Amplification:21) (exact)	$\beta^{112} \rightarrow \beta^{106}$ (04, (A12))	not formalized
Cor. 14.6, Lemmas 14.7, 14.8	<code>corollary_14_6</code> (Sections14_15:266), <code>lemma_14_7</code> (:279), <code>lemma_14_8 (:292);</code> companions Proofs14Arrangements:838, Proofs14HigherArrangements:712, Proofs14ProductToArrangements:18 (exact)	profile σ ; $7 \cdot 4^{k+1} \rightarrow 7 \cdot 4^{k+1} - 6$ (04, Thm. II.10.1)	not formalized
Lemma 17.4, Cors. 17.5, 17.6	<code>lemma_17_4_holds</code> (Proofs17Regions:691); <code>corollary_17_5</code> (Sections17_18:103), <code>corollary_17_6 (:117);</code> companions Proofs17FinitePatterns:396, :501 (exact)	$2^{2rk^3} \rightarrow (2r)^k C_k$; $M 2^{2r(k+1)^3} \rightarrow$ $M \min(2r, M)^k R_{k+1}(k 2^{k-1})$ (01, 04, Part IV)	not formalized
Prop. 17.7	<code>proposition_17_7 (:140);</code> <code>proposition_17_7_holds</code> (Proofs17LocalizedPhaseRemoval:2900), joint <code>hyperplaneRegionCount</code> (exact)	$2^{-2(k+1)^3} \rightarrow$ $2^{-k^2 - k \log_2 k - O(k)}$ (04); weaker interface (01)	not formalized
Cor. 16.11, Thms. 1.3, 18.1, 18.2	all open ; <code>theorem_18_1</code> 's docstring warns about the tower estimate of Cor. 16.11	01's dependency warning (Section V.3)	—
Section 18 (interval transfer)	<code>hasNatAP_of_short_modular_sequence</code> (Proofs18IntervalTransfer:22), <code>hasNatAP_of_hasModAP_image</code> (:92), added in 327773149	04's Lemma III.4.5; 03's Remark III.1.4	formalized (same statement, $n - 1 \mapsto n$)

Normalizations. The Lean development uses the unnormalized Fourier transform and the unnormalized Gowers norm; the intake found the sources' conversion tables accurate (source 02's Section V.8 and Appendix, source 03's Section V.13); the write did not re-derive them. **Definitions.lean** has changed since the pins only by an added `Box.IsProper`, which no source uses; every

other file that a source cites is unchanged.

Formal status of this report. As stated in Section F.5: the lifting lemma is formalized and was formalized before the sources arrived; nothing else here is. The reciprocal pointer for `Combinatorics/Ramsey/FORMALIZATION_STATUS.txt` is left to the session that maintains the Lean development.

[write] **6 October 2026; sources 06–10.** *The ledger at the second write.* At HEAD 764740f07 (6 October 2026) the ledger records 99 exact companions and 21 open statements, and `FORMALIZATION_STATUS.txt` reports 196 modules reachable from the audit and 1,805 audited public theorems. Since the first write’s HEAD 25df8755d the statements closed are: `lemma_16_9`. Since 7d99e5dee, the pin of sources 06, 09 and 10 (95 exact, 25 open, 140 modules, 1,365 theorems), 4 statements have closed: `lemma_16_1`, `lemma_16_5`, `lemma_16_6` and `lemma_16_9`; since ae0e89574, the pin of source 07, 4: `lemma_16_1`, `lemma_16_5`, `lemma_16_6` and `lemma_16_9`. The table above keeps its file and line numbers at 25df8755d; the rows below give them at 764740f07. The Lean development is being extended by another session as this is written, so the counts may already have moved. Every comparison made by sources 06–10 with a formal statement was checked against these declarations and is accurate, except the stale counts corrected in the notes after source 06’s Section F.11 and source 10’s Section F.15.

Gowers	Lean statement; companion (status)	Claim of sources 06–10	Improvement
Cor. 2.5	<code>corollary_2_5</code> (Sections01_03:180); <code>corollary_2_5_holds</code> (Proofs02DensityIncrement:517) (exact)	increment $\delta\eta/(4\delta - \eta)$ at source 01’s length; the frontier D_γ , L_γ (10, Thm. I.24.2)	not formalized
Thm. 2.6	<code>theorem_2_6</code> (:189); <code>theorem_2_6_holds</code> (Proofs02Roth:1238) (exact)	step count $321(\delta_0^{-1} - 1)$ against the transcription’s $640\delta_0^{-1}$ (10, Prop. V.42.1)	not formalized
Thm. 3.2, Cors. 3.3, 3.6	<code>theorem_3_2_holds</code> (Proofs03ProgressionAverage:381); <code>corollary_3_3</code> (:276), <code>corollary_3_3_holds</code> (Proofs03ProgressionCount:349); <code>corollary_3_6</code> (:310), <code>corollary_3_6_holds</code> (Proofs03ProgressionExistence:157) (exact)	two-target bound and quadratic discrepancy, $\alpha \leq (\delta^{k-1/2}/2B_k)^{2^{k-2}}$ (06); torsion kernels, error $\delta S_k \eta$, $\alpha \leq (\delta^{k-1}/2S_k)^{2^{k-1}}$ (10)	not formalized
Lemmas 3.7, 3.10	<code>lemma_3_7</code> (:320), <code>lemma_3_7_holds</code> (Proofs03Cubes:184); <code>lemma_3_10</code> (:340), <code>lemma_3_10_holds</code> (Proofs03CubeUpper:82) (exact)	excess of fourth order with exact quartic term (08, 09) and quintic term (09); exponent $4/2^d$ sharp for sets; lower bound $(\delta^4 + E_4)^{2^d/4}$ (08)	not formalized
Lemma 5.15	<code>lemma_5_15</code> (Section05:352); <code>lemma_5_15_holds</code> (Proofs05_10:735) (exact)	fixed- M optimum, $\tau(\alpha)$ (06); cap and tail (10)	not formalized
Prop. 7.3	<code>proposition_7_3</code> (Sections06_07:135); <code>proposition_7_3_holds</code> (Proofs07BalogSzemerédi:996) (exact)	$(c/4, 2^{10}c^{-5})$ on any abelian group (10)	not formalized

Gowers	Lean statement; companion (status)	Claim of sources 06–10	Improvement
Lemma 7.5, Cor. 7.6	<code>lemma_7_5 (:183), lemma_7_5_holds (Proofs07FreimanRestriction:267); corollary_7_6 (:197), corollary_7_6_holds (Proofs07AdditiveRestriction:100)</code> (exact)	$ B /(k(h_k - 1) + 1)$; $2^{-209}\gamma^{103}$ against $2^{-1882}\gamma^{1164}$ (10); both imply the formal conclusions (note after Cor. II.21.2)	not formalized
Lemma 10.9	<code>lemma_10_9 (Section10:335); lemma_10_9_holds (Proofs10Shift:717)</code> (exact; FreimanHom 2)	order five under exactly these hypotheses; order nine with the hypotheses of <code>lemma_10_6</code> and the set-up (07)	not formalized; order nine needs a new statement
Cors. 17.5, 17.6	as in the table above (Sections17_18:103, :117; Proofs17FinitePatterns:396, :501) (exact)	$(2r)^k C_k$, $\min(2r, M)^k C_{k,M}$, entropy uniform in M ; $C_4 = 154$ certified (06)	not formalized
Prop. 17.7	<code>proposition_17_7 (:140); proposition_17_7_holds (Proofs17LocalizedPhaseRemoval:2900)</code> (exact)	$1/(8K_k^2) = 2^{-2k^2 - O(k \log k)}$ (06)	not formalized

Thm. 10.13	<code>theorem_10_13</code> (Section10:473); <code>theorem_10_13_holds</code> (Proofs10Main:1292) (exact; $\alpha \leq 1/6$, $\alpha^6 X /20000$); proof-level $ W \geq \varrho^2\alpha^2LN/16$ (:1398), $\alpha \leq 1/6$ spent at :1407	radius $\alpha^{19}/(3\pi 2^{149})$; fraction $\alpha^5/20000$, already proof-level as $5\alpha^5/98304$; all densities (12)	radius not formalized
Cor. 10.14	<code>corollary_10_14</code> (Section10:501); <code>corollary_10_14_holds</code> (Proofs10ProgressionLinearity:133); <code>HasBohrDifferenceModel</code> (:458) (exact)	scalar linearity on the larger Bohr set (12)	follows from the formal corollary given a model
Lemmas 12.3, 14.7, 14.8	<code>lemma_12_3</code> (Sections12_13:151), <code>lemma_12_3_holds</code> (Proofs12HigherArrangements:334); <code>lemma_14_7</code> (Sections14_15:279), <code>lemma_14_7_holds</code> (Proofs14HigherArrangements:712); <code>lemma_14_8_holds</code> (Proofs14ProductToArrangements:18); <code>respectedCubePairCount</code> (Sections14_15:183) (exact)	equality and stability of the profile bound; denominators $S - \Xi$, S_{card} (14)	not formalized
Section 18 (interval transfer)	<code>hasNatAP_of_short_modular_sequence</code> (Proofs18IntervalTransfer:22)	13’s remark that its modular criterion needs this transfer	formalized (before arrival)

[write] 6 October 2026; sources 11–14. *Formal status after the third write.* No statement of sources 11–14 is formalized, and none gains formal status by its placement. The only formalized statement of the report is still the lifting lemma of source 04. Sources 11–14 ship no Lean files; their formalization plans are in Part V (source 11’s also as `11-affine-rigidity-formalization_plan.md`).

[write] 6 October 2026; sources 15–20. *The ledger at the fourth write.* At HEAD 0b4890a1c (6 October 2026) the ledger records 101 exact companions and 19 open statements, and `FORMALIZATION_STATUS.txt` reports 233 modules and 2,138 audited public theorems; since the third write’s HEAD e1db00e99 the statement closed is `lemma_13_7` (`lemma_13_7_holds`, `Proofs13CompleteRowExtraction.lean`, line 46). At the pins of sources 15–20 it recorded: 9ea383e9b (source 15) 97 and 23, 154 modules, 1,508 theorems; dca9f0638 (sources 16–19) 98 and 22, 169 modules, 1,658 theorems; 1bd57e91c (source 20’s checkpoint) 99 and 21, 173 modules, 1,689 theorems. Closed since: `lemma_16_6` (since 9ea383e9b only), `lemma_16_9` (since dca9f0638), `lemma_13_8` and `lemma_13_7`. The rows below give file and line numbers at 0b4890a1c; every one was checked by reading the declaration at that line. Every comparison of sources 15–20 with a formal statement was checked against these declarations and is accurate, except: the stale counts of sources 16 and 19, source 19’s status of Lemma 16.9 and its remark on missing properness clauses (notes in Sections V.65 and V.80); and three understatements of formal status, recorded in dated notes: the unweakened Corollary 14.6 exponent is kernel-checked as a private lemma (source 15), Proposition 17.7 is an exact companion (source 16), and the all- N Lemma 9.3 and Corollary 9.4 are exact companions (source 17). The file and line citations of the three earlier tables were re-checked at 0b4890a1c as well (dated note after the last table).

Gowers	Lean statement; companion (status)	Claim of sources 15–20	Improvement
Thm. 3.2, Cor. 3.3	<code>theorem_3_2</code> (Sections01_03:258), <code>theorem_3_2_holds</code> (<code>Proofs03ProgressionAverage:381</code>); <code>corollary_3_3</code> (:276), <code>corollary_3_3_holds</code> (<code>Proofs03ProgressionCount:349</code>) (exact; N prime, $k \leq N$)	two marked functions with an L^2 gain for surjective homomorphisms; quadratic counting $B_k(\delta)u^2$, strictly below source 06’s coefficient (20)	not formalized
Lemma 3.10	<code>lemma_3_10</code> (Sections01_03:340), <code>lemma_3_10_holds</code> (<code>Proofs03CubeUpper:82</code>) (exact)	expansion through order five on every finite abelian group (16, 18; as 09)	not formalized
Lemmas 5.5, 5.9	<code>lemma_5_5</code> (Section05:181), <code>lemma_5_5_holds</code> (<code>Proofs05PolynomialPartition:1678</code>); <code>lemma_5_9</code> (:261), <code>lemma_5_9_holds</code> (<code>Proofs05FullPartition:98</code>) (exact)	exponents polynomial in the number of phases, conditional on Maynard’s theorem (18, 19); shared leading coefficient through the scalar Lemma 5.5 (18)	not formalized
Lemmas 9.2, 9.3, Cor. 9.4	<code>lemma_9_2</code> (Sections08_09:69), <code>lemma_9_2_holds</code> (<code>Proofs09Moments:527</code>); <code>lemma_9_3</code> (:77), <code>corollary_9_4</code> (:91); companions <code>Proofs09Restriction:376</code> , :416 (exact; all N); private <code>section9_second_moment_lemma</code> (<code>Proofs09Moments:480</code>)	moments without density loss (17, as 04); prime-modulus restriction with $\alpha^{16}\eta^{15}/(2 \cdot 18^{16})$ and an explicit N_0 , which implies the prime case of <code>lemma_9_3</code> and <code>corollary_9_4</code> (17)	not formalized
Lemma 13.5	<code>lemma_13_5</code> (Sections12_13:410) open ; <code>IsStage135Data</code> (:397); <code>lemma_13_5_of_candidate_family</code> (<code>Proofs13QuadraticRecurrence:425</code>); proved at large prime N : <code>lemma_13_5_large_N</code> (<code>Proofs13LargeScaleRecurrence:96</code>)	own-step partitions with $\gamma < 1/((q+1)(42q+1))$, conditional on Lau’s preprint; weighted cell $\alpha^{32}/16$ (16)	—; Lau would have to be an axiom

Gowers	Lean statement; companion (status)	Claim of sources 15–20	Improvement
Lemma 14.4, Cor. 14.5	lemma_14_4_holds, corollary_14_5_holds (Proofs14Configurations:698, :942) (exact)	15’s configuration and collision lower bounds (as 15 says)	formal input

Lemmas 15.4, 15.5	lemma_15_4 (Sections14_15:402), lemma_15_4_holds (Proofs15DegenerateArrangements:1131); lemma_15_5 (:414), lemma_15_5_holds (Proofs15Restriction:3086) with the constant $3^{16 \cdot 2^k} k$ of private selectionDegenerate_real_small (:2690) (exact)	sharp density $(k + C_d)/p$, below the formal bound for $d \geq 2$, $p > 2d$; $\lambda p \geq k + 2,585,445$ (18)	not formalized
Lemmas 16.9, 16.10	lemma_16_9 (Section16:749), lemma_16_9_holds (Proofs16Lemma9:158) (exact since 16bbe5ad); lemma_16_10 (:851) open ; Section16AllBoxLineCovers (:824, proper boxes)	common sampling, shared-slice lifting and a local replacement; Lemma 16.10 itself not proved (19)	not formalized
Section 16, formal results after the pins	section16_printed_distinct_sampling_counterexample (Proofs16DistinctSampling:204), section16_distinct_sampling_budget (:117), section16_same_dimension_closing_comparison_fails (Proofs16ClosingComparison:25), section16_local_affine_lift (Proofs16LocalAffineLift:13), section16_local_affine_lift_all_scales (Proofs16LiftAllScales:46), section16_local_affine_lift_sqrt (Proofs16LiftWidth:31)	confirm 19’s audit points; weaker analogues of 19’s Corollary II.70.8	formal (not 19’s statements)

Gowers	Lean statement; companion (status)	Claim of sources 15–20	Improvement
Prop. 17.7	<code>proposition_17_7</code> (Sections17_18:140), <code>UniformOnPartition (:132);</code> <code>proposition_17_7_holds</code> (Proofs17LocalizedPhaseRemova 1:2900) (exact); private <code>prop177_small_branch (:1283),</code> <code>powersetDifference_pow,</code> <code>polarizationPhase</code> (Proofs17Phase:142, :217)	$(4/(3(k+2)))^{k+2}$ in the same normalization: implies the formal statement (16)	not formalized
Cors. 17.5, 17.6; Thm. 18.1	<code>corollary_17_5_holds,</code> <code>corollary_17_6_holds</code> (Proofs17FinitePatterns:396, :501) (exact); <code>theorem_18_1</code> (Sections17_18:171) open	the carry counts remain needed for the corollaries; larger cells must be transported in Section 18 (16)	—

[write] 6 October 2026; sources 15–20. *Formal status after the fourth write.* No statement of sources 15–20 is formalized, and none gains formal status by its placement. The only formalized statement of the report is still the lifting lemma of source 04. Four statements imply the conclusions of formal statements with better constants, none of them formally: source 16’s Theorem F.21.1 implies `proposition_17_7` in all cases; source 17’s Theorem F.22.1 and its order-eight corollary imply `lemma_9_3` and `corollary_9_4` for prime N ; source 18’s Theorem II.66.8 implies the bound of `lemma_15_4` for $d \geq 2$ and primes $p > 2d$; source 18’s Corollary II.66.9 would sharpen an internal constant of `lemma_15_5_holds`. Sources 15–20 ship no Lean files; their formalization plans are in Part V (source 15’s also as `15-collision-amplification-integration.md`).

Re-check of the earlier tables at 0b4890a1c. The file-and-line references of the three earlier tables (first write at 25df8755d, second at 764740f07, third at e1db00e99; 211 references counted with repetitions) were re-read at 0b4890a1c by a script that opens each cited file at the cited line and reads the declaration that begins there. All are correct at 0b4890a1c; seven of them name their file only through an earlier row and were resolved by hand. The counts printed with each table are those of its own HEAD.

[write] 6 October 2026; sources 21–27. *The ledger at the fifth write.* At HEAD 2dfe46f44 (6 October 2026) the ledger records 101 exact companions and 19 open statements, and `FORMALIZATION_STATUS.txt` reports 267 modules and 2,424 audited public theorems; no statement has closed since the fourth write’s HEAD 0b4890a1c. At the pins of sources 21–26 it recorded: 43306653a (sources 21 and 22) 99 and 21, 175 modules, 1,716 theorems; 65f4e039f (source 23) 99 and 21, 177 modules, 1,734 theorems; 2e0553b0c (source 24) 97 and 23, 157 modules, 1,547 theorems; 568d1802e (source 25) 99 and 21, 180 modules, 1,744 theorems; c94998a5d (source 26) 99 and 21, 185 modules, 1,760 theorems. Closed since: `lemma_13_8` and `lemma_13_7` (and, since 2e0553b0c only, `lemma_16_6` and `lemma_16_9`). None of sources 21–27 quotes ledger counts, and every Lean file they cite has the same blob at HEAD as at their pins (source 27: the blobs it records), so none of their repository statements is stale. The rows below give file and line numbers at 2dfe46f44; every one was checked by reading the declaration at that line. Every comparison of sources 21–27 with a formal statement was checked against these declarations and is accurate, except one gap overstated by source 24 (the abelian-group form of Proposition 7.3 is already formal; note in Section F.29). The row of the first table on Corollary 5.8 (“02 declines to restate it”) stands; source 26 now supplies the degree-one case (second row below).

Gowers	Lean statement; companion (status)	Claim of sources 21–27	Improvement
Lemma 3.10	<code>lemma_3_10</code> (Sections01_03:340), <code>lemma_3_10_holds</code> (Proofs03CubeUpper:82) (exact)	exponent five: the sharp coefficient $2^{3/4}/3$ with an absolute $O(u^8)$ remainder; 20/9 next on $\mathbb{Z}/5\mathbb{Z}$ (21; also 23)	not formalized
Cor. 5.8	<code>corollary_5_8</code> (Section05:242) open ; <code>corollary_5_8_with_scale_holds</code> (Proofs05FullPartition:94); <code>PolynomialOn</code> (Definitions:222), <code>polynomialPartitionConstant</code> (Section05:45)	degree one without a scale threshold: gain $\alpha/3$ at length $(N/M)^{1/3}/8$; implies the $k = 1$ instance, which is trivial for $N/M \leq 2^{48}$ (26; write)	not formalized; candidate (ledger unchanged)
Lemma 5.9	<code>lemma_5_9</code> (Section05:261), <code>lemma_5_9_holds</code> (Proofs05FullPartition:98) (exact)	prescribed-length thresholds with matching lower bounds; source 13's linear exponent $1/(3q+2)$ is optimal (23)	not formalized
Prop. 7.3, Lemmas 7.4, 7.5, Cor. 7.6	<code>proposition_7_3</code> (Sections06_07:135), <code>proposition_7_3_holds</code> (Proofs07BalogSzemerédi:996), <code>proposition_7_3_group_holds</code> (:854); <code>lemma_7_4</code> (Sections06_07:167), <code>lemma_7_4_holds</code> (Proofs07DRC:536); <code>lemma_7_5</code> (Sections06_07:183), <code>lemma_7_5_holds</code> (Proofs07FreimanRestriction:267); <code>corollary_7_6</code> (Sections06_07:197), <code>corollary_7_6_holds</code> (Proofs07AdditiveRestriction:100) (exact)	second routes to sources 03 and 10 with equal or weaker constants; extraction for $\mathbb{F}_p^d$ codomains (24)	not formalized; the group form is already formal
Lemmas 15.4, 15.5	<code>lemma_15_4</code> (Sections14_15:402), <code>lemma_15_4_holds</code> (Proofs15DegenerateArrangements:1131); <code>lemma_15_5</code> (Sections14_15:414), <code>lemma_15_5_holds</code> (Proofs15Restriction:3086); <code>arrangementSelectionExponent</code> (Sections14_15:409), <code>GeneralArrangement</code> (:192), <code>degenerateGeneralArrangementCount</code> (:364) (exact)	$k + C_d$ again (25, 27); $d = 1$ (22); second coefficient for $d = 2$ (27); stratified finite bound (22); selection for every d (25); all below the formal bound in their ranges	not formalized

Gowers	Lean statement; companion (status)	Claim of sources 21–27	Improvement
Lemma 16.10	<code>lemma_16_10</code> (Section16:851) <code>open</code> ; <code>Box.short_parent_partition</code> (<code>Proofs16ShortParents:23</code>), <code>box_product_tiling_of_contained_axis</code> (<code>Proofs16RelativeSteps:89</code>), <code>section16_local_affine_lift_sqrt</code> (<code>Proofs16LiftWidth:31</code>), <code>section16_distinct_sampling_budget</code> (<code>Proofs16DistinctSampling:117</code>)	a common base partition with width $(m/3)^A$ and exact transport, without inherited coordinates; a sampling lemma (23)	not formalized; candidate

[write] 6 October 2026; sources 21–27. *Formal status after the fifth write.* No statement of sources 21–27 is formalized, and none gains formal status by its placement. The only formalized statement of the report is still the lifting lemma of source 04. Two formalization candidates are recorded, neither claimed: the degree-one instance of `corollary_5_8` (source 26; trivial below $N/M = 2^{48}$) and source 23’s common base partition. Sources 22, 25 and 27 imply the bound of `lemma_15_4` in their ranges, like source 18. Sources 21–27 ship no Lean files; source 27’s `FORMALIZATION.md` (shipped as `27-degeneracy-second-order-FORMALIZATION.md`) is a plan.

Re-check of the earlier tables at 2dfe46f44. The file-and-line references of the four earlier tables (first write at 25df8755d, second at 764740f07, third at e1db00e99, fourth at 0b4890a1c) were re-read at 2dfe46f44 by the same script; all are correct at 2dfe46f44, those resolved by hand at the fourth write included, except one: `proposition_17_7_holds`, printed at line 2900 of `Proofs17LocalizedPhaseRemoval.lean` in the first, second and fourth tables (and in some earlier dated notes), is at line 2941 since c2975a00d, which inserted `proposition_17_7_with_upper` (line 2911) above it. Line 2900 was right at every earlier write’s HEAD, including bf2fe146d; the dated tables keep their numbers. The counts printed with each table are those of its own HEAD.

[write] 6 October 2026; sources 28–33. *The ledger at the sixth write.* At HEAD 5d4718772 (6 October 2026) the ledger records 105 exact companions and 15 open statements, and `FORMALIZATION_STATUS.txt` reports 297 modules and 2,676 audited public theorems; since the fifth write’s HEAD 2dfe46f44 (101 and 19) `theorem_7_1` and `theorem_7_2` (56e774055) and `theorem_8_2` and `corollary_8_3` (6a6d7961c) have closed. At the pins of sources 28–33 it recorded: c94998a5d (source 32) 99 and 21, 185 modules, 1,760 theorems; e3125e698 (sources 28, 29, 31) and 9f83dbe0f (source 33) 99 and 21, 196 modules, 1,805 theorems; 8d65d3c9f (source 30) 100 and 20, 199 modules, 1,823 theorems. Closed since those pins: `lemma_13_8` (not since 8d65d3c9f), `lemma_13_7` and the four above; none is a statement sources 28–33 compare with. Since 128f514af the first obligation of `FORMALIZATION_STATUS.txt` (Corollary 5.8) names source 41 as a written proof of the whole statement and sources 26 and 32 as its degree-one and degree-two precursors; no formal status changes. None of sources 28–33 quotes ledger counts, and every Lean file they cite has the same blob at HEAD as at their pins, so none of their repository statements is stale. The rows below give file and line numbers at 5d4718772; every one was checked by reading the declaration at that line. Every comparison of sources 28–33 with a formal statement was checked against these declarations and is accurate. The fifth table’s Corollary 5.8 row stands; source 32 now supplies the degree-two case (second row below).

Gowers	Lean statement; companion (status)	Claim of sources 28–33	Improvement
Lemma 3.10	lemma_3_10 (Sections01_03:340), lemma_3_10_holds (Proofs03CubeUpper:82) (exact)	$c_4^{\text{odd}} \leq (8/35)^{1/4}$, $c_d^{\text{odd}} \geq 1/3$ (29); $c_4^{\text{odd}} \geq 0.5587294$, no single-cosine extremizer for $d \geq 4$ (28)	not formalized
Cor. 5.8	corollary_5_8 (Section05:242) open; PolynomialOn (Definitions:222), polynomialPartitionConstant (Section05:45), ModAP.IsProper (Definitions:93)	degree two without a scale threshold: gain $\alpha/3$ at length $\max\{1, (N/M)^{1/39}/17\}$; implies the $k = 2$ instance (32; with 26, $k \leq 2$)	not formalized; candidate (ledger unchanged)
Prop. 6.1	proposition_6_1 (Sections06_07:37), proposition_6_1_holds (Proofs05_10:505) (exact)	sharp near-extremal U^3 profile and selected-graph stability (31); the endpoint with soft and mixed selectors (29)	not formalized
Lemma 7.5, Cor. 7.6	lemma_7_5 (Sections06_07:183), lemma_7_5_holds (Proofs07Frei manRestriction:267); corollary_7_6 (Sections06_07:197), corollary_7_6_holds (Proofs07 AdditiveRestriction:100) (exact)	weighted restriction $1/(kC^{2k+1})$ (source 10's with weights); correlation-preserving restriction on $\mathbb{F}_p$ (31)	not formalized
Lemma 9.3	lemma_9_3 (Sections08_09:77), lemma_9_3_holds (Proofs09Restriction:376) (exact)	fixed-field restriction keeping every degenerate tuple, threshold $8qS/(\alpha\eta)$, then none (29)	not formalized; does not imply the all-moduli statement
Lemma 10.10, Cor. 10.11, Lemma 10.12, Thm. 10.13	lemma_10_10 (Section10:362), lemma_10_10_holds (Proofs10Bohr:277); corollary_10_11 (Section10:374), corollary_10_11_holds (Proofs10Bohr:607); lemma_10_12 (Section10:401), lemma_10_12_holds (Proofs10Induced:145); theorem_10_13 (Section10:473), theorem_10_13_holds (Proofs10Main:1292) (exact)	fixed-radius escape inequality, radius $\rho/(8(3^r - 1))$, $5/14$ (30); local model with $\alpha p(\alpha)/20$, $O(\alpha^{-3})$, $\Omega(\alpha^5)$ (28)	not formalized; source 28 against theorem_10_13 is a marked question
Lemma 12.3	lemma_12_3 (Sections12_13:151), lemma_12_3_holds (Proofs12Hi gherArrangements:334) (exact); lemma_12_5 (:170), lemma_12_6 (:183)	$\max\{\theta^7, 4\theta - 3\}N^{32}$; sharp full-product repair (33)	not formalized; candidate

[write] 6 October 2026; sources 28–33. *Formal status after the sixth write.* No statement of sources 28–33 is formalized, and none gains formal status by its placement. The only formalized statement of the report is still the lifting lemma of source 04. Formalization candidates, none claimed: the instances $k \leq 2$ of **corollary_5_8**

(sources 26 and 32) and the linear branch of `lemma_12_3` (source 33). Sources 28–33 ship no Lean files; the `FORMALIZATION.md` files of sources 30 and 33 (shipped as `30-fixed-radius-bohr-FORMALIZATION.md`, `33-arrangement-stability-FORMALIZATION.md`) are plans.

Re-check of the earlier tables at 5d4718772. Since the fifth write’s HEAD 2dfe46f44 the tracked Lean files of the development have changed only by new modules, an extended facade and lines appended at the end of `Proofs05Downstream.lean` (after line 966; earlier text cites only its line 244); no cited line moved. The same script re-read their 350 references at 5d4718772 and found exactly the items recorded at the fifth write (the hand-resolved list-pairing artifacts and the move of `proposition_17_7_holds` to line 2941); the dated tables keep their numbers.

[write] 6 October 2026; sources 34–39. *The ledger at the seventh write.* At HEAD 89c1cbc38 (6 October 2026) the ledger records 107 exact companions and 13 open statements, and `FORMALIZATION_STATUS.txt` reports 410 modules and 2,840 audited public theorems; since the sixth write’s HEAD 5d4718772 `lemma_16_4` (c450a0c73) and `theorem_1_2` (5ea1d06dd, Szemerédi’s theorem from a vendored hypergraph-removal theorem) have closed. At the pins of sources 34–39 it recorded 100 and 20: 12da35673 (sources 34, 35, 38) and 6c2e2172b (source 36) 206 modules and 1,878 theorems, 869289aa3 (sources 37, 39) 206 modules and 1,879 theorems. Closed since those pins: `lemma_13_7`, `theorem_7_1`, `theorem_7_2`, `theorem_8_2`, `corollary_8_3`, `lemma_16_4` and `theorem_1_2`; none is a statement sources 34–39 compare with (source 39 treats the sampling step of Lemma 16.10, not Lemma 16.4). Only source 38 quotes ledger counts (those of its pin; note in its Section V.143); every Lean file and every paper file that sources 34–39 cite has the same blob at HEAD as at their pins (the intake’s provenance check, rerun at the write: 56 records, all matching), so none of their statements about the formal project is stale apart from those counts. The rows below give file and line numbers at 89c1cbc38; every one was checked by reading the declaration at that line, and every comparison of sources 34–39 with a formal statement was checked against these declarations.

Gowers	Lean statement; companion (status)	Claim of sources 34–39	Improvement
Lemma 3.10	<code>lemma_3_10</code> (Sections01_03:340), <code>lemma_3_10_holds</code> (<code>Proofs03CubeUpper</code> :82) (exact)	$c_4^{\text{odd}} \leq 2/3$, leading cube coefficient 200/3 at $d = 4$, β_d for $5 \leq d \leq 8$, prime-torsion onset $h(p) = D_{\text{div}}(p) + 1$ (34); coefficient 5 (35); exact quotient reduction in exponent five, u^{10} , u^{12} (38)	not formalized
Lemma 5.2	<code>lemma_5_2</code> (Section05:141), <code>lemma_5_2_holds</code> (<code>Proofs05MissingInterval</code> :220) (exact)	frequency $\leq \lfloor N/M \rfloor - 1$, coefficient $ A M/(N - M)$, any weights, no parity of M (37)	implies the formal conclusion ([write] note); not formalized; candidate
Lemmas 5.3, 5.5	<code>lemma_5_3</code> (Section05:152), <code>lemma_5_3_holds</code> (<code>Proofs05Weyl</code> :3607); <code>lemma_5_5</code> (Section05:181), <code>lemma_5_5_holds</code> (<code>Proofs05Poly</code> <code>nomialPartition</code> :1678); <code>lemma_</code> <code>5_5_square_root_auxiliary</code> (Section05:192) (exact)	recurrence exponent $(1 - 1/(4k))/(2^{k-1} + 1)$ from the formal Weyl input, 7/24 against 1/16 at $k = 2$ (37)	implies the formal bound for $t \geq$ <code>weylThreshold</code> ([write] note); not formalized
Lemma 5.9	<code>lemma_5_9</code> (Section05:261), <code>lemma_5_9_holds</code> (<code>Proofs05FullPartition</code> :98) (exact)	necessary exponents $(W + 2)a + \sum d_i b_i \leq 1$ for prescribed lengths; exact thresholds $DC(\mathcal{S})$ (35)	an obstruction; no formal change

Gowers	Lean statement; companion (status)	Claim of sources 34–39	Improvement
Prop. 6.1	<code>proposition_6_1</code> (Sections06_07:37), <code>proposition_6_1_holds</code> (Proofs05_10:505) (exact)	sharp odd-order stability modulus $\varepsilon/4 + 3\varepsilon^2/16 + (\sqrt{2}/64)\varepsilon^{5/2}$ (38)	not formalized
Lemma 10.9	<code>lemma_10_9</code> (Section10:335), <code>lemma_10_9_holds</code> (Proofs10Shift:717) (exact)	sharp nonuniform threshold $1/(2 + (2k - 2)\kappa)$ in source 07’s finite-fibre model (34)	a different model; no formal change
Lemmas 14.8, 15.5	<code>lemma_14_8</code> (Sections14_15:292), <code>lemma_14_8_holds</code> (Proofs14ProductToArrangements:18); <code>lemma_15_5</code> (Sections14_15:414), <code>lemma_15_5_holds</code> (Proofs15Restriction:3116) (exact)	degree-weighted Fejér selection, field-size exponent $E_{k,m} \sim 2s/k$, retention $\alpha^s \eta^{s-1}/(2(s+2)^s)$ (35)	not formalized; explicit N_0 for <code>lemma_15_5</code> a marked question
Lemma 16.10	<code>lemma_16_10</code> (Section16:851) open ; <code>Section16SampledOrAnchoredOn</code> (Proofs16ShortColumns:27)	sampler keeping sampled targets, $2q(m-r)/(m(r+1))$; closed finite minimax for its rule; labelled refinement (39; the sampler is source 19’s)	not formalized; candidate; the closing comparison stays open
Props. 17.2, 17.7	<code>proposition_17_2</code> (Sections17_18:48), <code>proposition_17_2_holds</code> (Proofs17PhaseRemoval:373); <code>proposition_17_7</code> (Sections17_18:140), <code>proposition_17_7_holds</code> (Proofs17LocalizedPhaseRemoval:2941) (exact)	sharp symmetry threshold $1 - (1 - 1/p)^k$ over $\mathbb{F}_p^n$; lossless polarization for $p > k + 1$ (36)	not formalized; candidate (rank-two forms)

[write] **6 October 2026; sources 34–39.** *Formal status after the seventh write.* No statement of sources 34–39 is formalized, and none gains formal status by its placement; the ledger is unchanged. The only formalized statement of the report is still the lifting lemma of source 04. Two exact formal statements are now implied by written results of this report, which changes nothing formal because both already have exact companions: `lemma_5_2` by source 37’s Corollary I.55.2, and `lemma_5_5` (for $t \geq \text{weylThreshold } k$, with the formal Weyl input) by its Corollary I.57.3 (notes there). Formalization candidates, none claimed: source 37’s lower-bound certificate for Lemma 5.2 and its recurrence conversion; source 39’s sampler at the `Section16SampledOrAnchoredOn` interface (source 19’s first); source 36’s bilinear estimate for rank-two forms; source 34’s exact reduction, small-prime certificates and fourth-norm inequality (its own proposal). Sources 34–39 ship no Lean files; the `FORMALIZATION_PLAN.md` files of sources 36 and 39 and source 37’s `INTEGRATION.md` (shipped as `36-symmetry-certification-FORMALIZATION_PLAN.md`, `39-shared-anchor-FORMALIZATION_PLAN.md`, `37-missing-intervals-INTEGRATION.md`) are plans.

Re-check of the earlier tables at 89c1cbc38. Since the sixth write’s HEAD 5d4718772 the tracked Lean files of the development have changed by new modules, a facade, six lines of `Proofs15ProductToRestriction.lean` and thirty lines added to `Proofs15Restriction.lean` (two private declarations made public, one new theorem). The script of the write re-read the references of the six earlier tables at 89c1cbc38 and found the items recorded at the fifth and sixth writes (the hand-resolved list-pairing artifacts and the move of `proposition_17_7_holds` to line 2941) and two new moves: `lemma_15_5_holds` from line 3086 to line 3116 and `selectionDegenerate_real_small` from line 2690 to line 2692 (fourth and fifth tables); the dated

tables keep their numbers.

[write] **7 October 2026; sources 40–46.** *The ledger at the eighth write.* At HEAD 6d4942222 (7 October 2026) the ledger records 113 exact companions and 7 open statements, and `FORMALIZATION_STATUS.txt` reports 713 modules and 4,583 audited public theorems; since the seventh write’s HEAD 89c1cbc38 `corollary_5_8` (b548d998e), `theorem_13_12`, `lemma_13_9`, `lemma_13_5`, `lemma_13_6` and `corollary_13_10` have closed. The open statements are `theorem_1_3`, `lemma_16_10`, `theorem_16_2`, `corollary_16_11`, `theorem_18_1`, `theorem_18_2` and `corollary_18_7`. At the pins of sources 41–45 it recorded 99 and 21 (c94998a5d, source 41) or 101 and 19 (b16ce380d, 797aa3cfe, 8c12c906e, 6ce33539e); sources 40 and 46 record no commit. Closed since those pins, besides the six above: `theorem_1_2`, `theorem_7_1`, `theorem_7_2`, `theorem_8_2`, `corollary_8_3` and `lemma_16_4` (and, since source 41’s pin, `lemma_13_7` and `lemma_13_8`); of these only `corollary_5_8` (sources 41 and 42) and `theorem_7_1`, `theorem_7_2` (source 45’s energy material, which compares with their statements, not their status) touch a subject of sources 40–46. No source of this write quotes ledger counts. Every Lean file and every paper file that sources 40–46 cite has the same blob at HEAD as at their pins (the intake’s provenance check, rerun at the write: 30 records, all matching).

Corollary 5.8 is closed. Since the seventh write the repository has formalized, in a sequence of commits from 4ac12a026 to b548d998e (6 October 2026, the later ones while this write was in progress), the two-regime architecture of sources 26, 32 and 41 with the catalogue’s constants: the cyclic progression second moment and the bound on nonproper directions, the variance increment `exists_proper_progression_density_increment` (`Proofs05VarianceIncrement.lean`, line 89; source 41’s Lemma I.66.1, hypothesis $L^3 \leq N$, its docstring crediting Report277), its low-correlation form, the cover-mass bounds, the weighted phase transfer, the high-correlation assembly and parent scale, the target rounding $(4L)^{K_k} < N/M$, the reduction `corollary_5_8_holds_of_threshold_free_localization` to `ThresholdFreePolynomialLocalization` k , the affine and quadratic localizations with `corollary_5_8_degree_one` and `corollary_5_8_degree_two`, a finite recurrence in every degree, and `thresholdFreePolynomialLocalization_all`; the exact companion is `corollary_5_8_holds`. The localization uses the repository’s own finite Weyl estimate (radius exponent $2((k-1)^2+1)(2^{k-1}+3)$), not source 41’s recurrence ($B_k = 2^k + 8$); `FORMALIZATION_STATUS.txt` names source 41 as giving “a related stronger written localization budget”. The formal theorem has the catalogue’s constants (length $(N/M)^{1/K_k}/8$, gain $\alpha/16$); source 41’s stronger Theorem F.46.1 is not formalized. The rows below give file and line numbers at 6d4942222; every one was checked by reading the declaration at that line, and every comparison of sources 40–46 with a formal statement was checked against these declarations.

Gowers	Lean statement; companion (status)	Claim of sources 40–46	Improvement
Lemma 3.10	<code>lemma_3_10</code> (<code>Sections01_03:340</code>), <code>lemma_3_10_holds</code> (<code>Proofs03CubeUpper:82</code>) (exact)	$c_4^{\text{odd}} \leq (832/4795)^{1/4}$, quartic coefficient $P_d(832/4795)^{1/4}$ for $d \geq 4$ (45)	not formalized

Gowers	Lean statement; companion (status)	Claim of sources 40–46	Improvement
Cor. 5.8	corollary_5_8 (Section05:242), corollary_5_8_holds (Proofs05ThresholdFreeLocalization:86) (exact, new); corollary_5_8_holds_of_threshold_free_localization (Proofs05ThresholdFreeCorollary:145), ThresholdFreePolynomialLocalization (Proofs05ThresholdFreeCorollary:16), thresholdFreePolynomialLocalization_all (Proofs05ThresholdFreeLocalization:70); exists_proper_progression_density_increment (Proofs05VarianceIncrement:89); density_cell_of_high_correlation (Proofs05HighCorrelationAssembly:53); corollary_5_8_degree_one (Proofs05AffineLocalization:62); corollary_5_8_degree_two (Proofs05QuadraticLocalization:87)	gain $\alpha/3$ at length $\max\{1, (N/M)^{1/D_k}/8\}$ in every degree, no scale premise (41); variance gain under $N \geq 2(L-1)^2 + 1$, affine cap $\sqrt{N/2}$ (42)	implies the formal conclusion and supplies its localization hypothesis on paper ([write] notes); the formal proof uses the same architecture and its own recurrence; 41’s constants and 42 not formalized
Section 7 (energy)	theorem_7_1 (Sections06_07:104), theorem_7_1_holds (Proofs07FreimanClosure:185); theorem_7_2 (Sections06_07:125), theorem_7_2_holds (Proofs07FreimanClosure:235) (exact)	three largest torsion-free energies; coset envelope for $\varepsilon < 1/9$ with all equality cases (45)	different statements; not formalized
Lemma 15.4	lemma_15_4 (Sections14_15:402), lemma_15_4_holds (Proofs15GenerateArrangements:1131) (exact)	core directions for every $p \geq 5$; exact core products; $b_2(d)$ for every d , $b_2(8) = 3,280,234,631,541$ (44)	not formalized
Lemma 15.5	lemma_15_5 (Sections14_15:414), lemma_15_5_holds (Proofs15Restriction:3116) (exact)	one Fejér kernel, retention $\alpha^s \eta^{s-1}/(3^{s-1}(s+1)^s)$, kernel-class barrier (40)	not formalized; explicit N_0 a marked question
Lemma 17.1, Prop. 17.2	lemma_17_1 (Sections17_18:38), lemma_17_1_holds (Proofs17Phase:374); proposition_17_2 (Sections17_18:48), proposition_17_2_holds (Proofs17PhaseRemoval:373) (exact)	over $\mathbb{F}_2^n$: exact cubic norm $2^{-r/2}$, codimension $r/2$, Tidor’s $8 \log_2(1/\delta)$ to $2 \log_2(1/\delta)$ (46, 43); certification $1 - 2^{1-d}$ and finite-abelian orthogonality (43)	outside the formal setting (N prime, $k+1 < N$); not formalized

[write] **7 October 2026; sources 40–46.** *Formal status after the eighth write.* No statement of sources 40–46 is formalized as stated, and none gains formal status by its placement; the ledger changes are the repository’s own work. The only formalized statement of the report itself is still the lifting lemma of source 04. The repository’s new modules prove `corollary_5_8` with the architecture of sources 26, 32 and 41 and the catalogue’s constants, not source 41’s theorem; the variance lemma they formalize is the one source 41 shares with sources 26 and 32, and their localization is the repository’s own (source 41’s is a second, written route). Formalization candidates, none claimed: source 41’s stronger theorem (exponent $1/D_k$, gain $\alpha/3$) along its recurrence and budgets; source 42’s arithmetic increment in place of $L^3 \leq N$; source 44’s width lemma and signed-collision product; source 45’s ordered-completion identity and rational U^4 certificate; source 43’s orthogonality theorem. The `FORMALIZATION.md` files of sources 43, 44 and 46 (shipped as `43-boolean-phase-FORMALIZATION.md`, `44-grid-core-FORMALIZATION.md`, `46-polarization-barriers-FORMALIZATION.md`) are plans; sources 40–46 ship no Lean files.

Re-check of the earlier tables at 6d4942222. Since the seventh write’s HEAD 89c1cbc38 the tracked Lean files of the development have gained 263 new files, and 24 existing files have changed (among them `Sections12_13.lean`, where the Section 13 statements were revised and closed). The script of the write re-read the 449 references of the seven earlier tables at 6d4942222 and found the items recorded at the fifth to seventh writes (the hand-resolved list-pairing artifacts and the recorded moves) and one new move: `lemma_13_5` from line 410 to line 420 of `Sections12_13.lean` (fourth table, two entries; the statement is now exact, closed in `bc87bdf14`); the dated tables keep their numbers and their dated statuses.

V.2 Further questions and research [write]

Added in the write, 6 October 2026.

This section applies Vladimir’s standing rule of 4 October 2026: no unproved or wrong claim is dropped; open claims are stated as questions with their source, the argument they came with and what is missing; wrong claims stay on record with a proof of their failure. The five sources ask 46 questions: source 01 ten (Section V.4, Questions 1–10 there in order), source 02 seven (Section V.9, delivered Subsections 11.1–11.7), source 03 nine (Section V.14, Research questions 1–9 there in order), source 04 twelve (Section V.17, Q1–Q12) and source 05 eight (Section V.23, paragraphs 1–8). They are printed there as delivered. Below they are grouped by theme, with every asking source credited; the counts per theme are 14, 9, 8, 7 and 8. Items are numbered within their theme, so later additions extend a list without renumbering it.

[write] **6 October 2026; sources 06–10.** *Sources 06–10.* They ask 50 further numbered questions: source 06 eleven (Section V.27, Questions 1–11 there), source 07 eight (Section V.29, Questions 1–8 there in order), source 08 ten (Section V.34, Questions 1–10 there in order), source 09 ten (Section V.39, Research questions 1–10, its Subsections 14.1–14.10) and source 10 eleven (Section V.44, items 1–11 there). Source 10 also ends its Sections III.29 and II.21 with a paragraph of questions; both are credited below. The intake dossier counted ten questions for source 10 and 95 in all; the count is 96. They are added to the themes below as new items or, where they ask the same thing, merged into an existing item by a dated sentence. The counts per theme become 17, 19, 33, 13 and 14 (the headings below keep the counts of sources 01–05).

Unproved or wrong claims in sources 06–10. The intake and the second write found no claim of sources 06–10 that is wrong, and no claim asserted as proved without a proof. One wrong statement is on record: the quartic lower bound with coefficient 12, which sources 08 and 09 pose and refute themselves and source 03 also refutes; Remark W1 keeps it with an explicit counterexample. Inputs used but not proved in the sources: Zuev’s threshold-function count (source 06, as for source 01), the Plünnecke–Ruzsa inequality (source 10, via Petridis) and, for source 10’s labelled modern-input variant only, the Reiher–Schoen theorem; these are published theorems. Source 10’s “independent review” is not shipped, and nothing rests on it. Statements of the intake corrected at the write: source 06’s improvement over the $M - 1$ corollary is strict only for $\alpha < 1$ (note after Corollary I.9.3); source 01’s increment is at least $3/2$ times source 10’s D_γ for every $\gamma \leq 1/2$

(exactly when $\gamma(4 - (2 - \delta)\kappa) \leq 2$), but not along the whole frontier (corrected after the independent check of 6 October 2026; the first wording read “source 01’s increment dominates source 10’s by $3/2$ only for $\gamma \leq 1/2$ ”, which is false as worded, since $2/(4 - (2 - \delta)\kappa) > 1/2$ for every $\kappa > 0$) (note after Table 3); source 09’s date for version 2 of Shi–Dong is wrong (bibliography).

Answered or advanced inside the report. Source 08’s question whether $\kappa_3^{\text{odd}} = 1/\sqrt{2}$ is answered yes by source 04 (item III.1). Source 03’s question on the fifth coefficient is answered by source 09 (item III.2). Source 02’s finite-cell problem is solved by source 06 in the weighted model with M fixed and the cell masses free; prescribed cell sizes and integer cardinalities remain open (item I.6) (corrected after the independent check of 6 October 2026; the first wording read “is solved in the weighted model by source 06”). Source 04’s Question 8 is answered a second time by source 06 (item IV.1). Source 06’s Question 7 is advanced by source 10 for one distinguished function (item III.9). Source 04’s Question 10 (non-admissible slopes) is advanced by source 10’s torsion factors (item III.7).

[write] 6 October 2026; sources 11–14. *Sources 11–14.* They ask 45 further questions: source 11 nine (Section V.47, Research questions there in order, “11 Q1”–“11 Q9” below), source 12 twelve (Section V.51, its Questions in order, “12 Q1”–“12 Q12”), source 13 twelve (Section V.54, “13 Q1”–“13 Q12”) and source 14 twelve (Section V.57, the items of its research program, “14 Q1”–“14 Q12”). They are added to the themes below as new items or merged into existing items by dated sentences. The counts per theme become 24, 40, 44, 13 and 20 (141 questions; the headings keep the counts of sources 01–05). One further question is the intake’s, not a source’s, and is marked as such (item II.21).

Unproved or wrong claims in sources 11–14. The intake and the third write found no claim of sources 11–14 that is wrong and no claim asserted as proved without a proof. Recorded at the write: source 11’s cutoff 34, which it calls sufficient, cannot simply be dropped for general groups (Remark W2, an explicit counterexample to that tempting extension, not to a claim). Framing corrected in dated notes: source 13 presents its Fourier increment as a gain without noting that source 01’s is larger at the same length; source 12’s abstract says that its radius selection “replaces” Corollary 10.11, while the ambient radius is selected; source 12’s list of open obligations is incomplete; source 14 misplaces one declaration. Inputs used and not proved: the component-extraction lemmas (12, borrowed with stated hypotheses; formal), Warning’s second theorem and the Reed–Muller minimum-weight theorem (14 proves what it needs and credits them), the classical three-halves lemma (14, proved). Numerical evidence kept as evidence: source 14’s coefficient $2^{3/4}/3$ on groups of exponent five (item III.23). Source 14’s internal review is not shipped, and nothing rests on it.

Answered or advanced inside the report. Source 04’s Question 1 is settled by source 14 (Remark W4; item III.3). Source 04’s Question 2 is answered in U^2 , not in L^2 , by source 14 (item III.4), and its Question 7 is advanced by source 14’s arrangement equality (item II.3). Source 11’s Question 3 is answered in substance by composing it with source 14 (Remark W3; item II.20). Source 13’s Question 5 is solved by source 06 in the weighted model with M fixed and the cell masses free (item I.6). Source 05’s anisotropic question is advanced by source 13’s obstruction with independent tolerances (item I.8).

[write] 6 October 2026; sources 15–20. *Sources 15–20.* They ask 74 further questions: source 15 nine (Section V.60, its Questions in order, “15 Q1”–“15 Q9” below), source 16 fourteen (Section V.67, its items 1–14, “16 Q1”–“16 Q14”), source 17 ten (Section V.71, its paragraphs 1–10), source 18 twelve (Section V.78, its items 1–12), source 19 twelve (Section V.82, its Research questions in order, “19 Q1”–“19 Q12”) and five more at the end of its Section I.34 (“19 S6(1)”–“19 S6(5)”), and source 20 twelve (Section V.84, its Questions 1–12). They are added to the themes below as seventeen new items or merged into existing items by dated sentences. The counts per theme become 40, 68, 60, 17 and 30 (215 questions; the headings keep the counts of sources 01–05). Two further questions are the intake’s, not a source’s, and are marked as such (items II.6 and II.8).

Unproved or wrong claims in sources 15–20. The intake and the fourth write found no claim of sources 15–20 that is wrong and no claim asserted as proved without a proof. Corrected in dated notes, with the first wording kept as delivered: overstated novelty (source 15’s “sharp density refinements” and Cartesian analysis are source 04’s (A5)–(A11) and are superseded by source 14’s sharp constant; source 16’s Section 5 repeats source 04’s Lemmas 8.5–8.6 without credit, and its cube coefficients, like source 18’s Section 3, repeat source 09’s theorem; source 20’s “not another reordering” overlooks source 06’s quadratic estimate, which it

could not see); understated formal status (sources 15, 16, 17: notes in Sections F.20, F.21 and F.22); stale repository claims (sources 16, 19); and two over-broad statements of source 17 (Section II.64: the multiplicity product is a valid lower bound, and the composite-modulus failure needs a small prime factor). Inputs used and not proved: Maynard’s published recurrence theorem and Lau’s preprint (sources 16, 18 and 19; the polynomial-in- q exponents of sources 18 and 19 and the own-step exponent of source 16 are conditional on them), and the classical cube circuits (source 18 credits Beerenwinkel–Pachter–Sturmfels). Source 19’s reading of printed page 575 of the 2001 paper was not checked at the write and is kept as its reading. The internal reviews mentioned by sources 18 and 19 are not shipped, and nothing rests on them.

Answered or advanced inside the report. Source 13’s Question 3 (item I.1) is answered by sources 18 and 19, conditionally on Maynard’s theorem. Source 06’s Question 7 is answered for the norm-conversion step by source 20 (item III.9), and its Question 6 is advanced by source 20’s strictly smaller coefficient (item III.8). Source 15’s first question is answered in its leading constant by source 14 (item II.31), and its second and third are source 14’s Questions 5–6. Source 17’s Question 7 is partly answered by source 10’s Corollary II.21.2. Source 19’s Question 8 is partly answered by source 18 (squaring is paid once, at the base; item I.12). Source 18’s Question 7 is settled at $d = 3$ by source 04’s norm gap (item III.1).

Still pending. Sources 21–23 (placed by a902613c9), 24–27 (79d9075b9) and 28–33 (c5513046e; the last two placed while this write was in progress) are in this directory and not used in this text. Their placements record, among other findings: source 21 as answering source 14’s exponent-five questions (item III.23); source 22 as treating source 18’s $d = 1$ case, sources 25 and 27 as re-deriving source 18’s leading coefficient and source 27 as answering source 18’s first question for $d = 2$ (item II.38); source 23 as answering source 13’s Question 1 (item I.12); sources 28 and 29 as bounding c_d^{odd} for $d \geq 4$ (item III.1) and source 29 as adding a fixed-field restriction theorem that keeps every degenerate tuple (item II.6). Those findings are for the writes that add them, and the items below still state the questions as open.

[write] 6 October 2026; sources 21–27. *Sources 21–27.* They ask 74 further questions: source 21 eleven (Section V.88, its Questions in order, “21 Q1”–“21 Q11” below), source 22 fifteen (Section V.92, its Research questions in order), source 23 twelve (Section V.94, its items 1–12), source 24 ten (Section V.98, its Questions in order), source 25 eight (Section V.103, its Questions 1–8), source 26 six (the items at the end of Section V.105) and source 27 twelve (Section V.108, its Research questions in order). They are added to the themes below as eight new items or merged into existing items by dated sentences. The counts per theme become 49, 104, 79, 17 and 40 (289 questions; the headings keep the counts of sources 01–05).

Unproved or wrong claims in sources 21–27. The intake and the fifth write found no claim of sources 21–27 that is wrong and no claim asserted as proved without a proof. Corrected in dated notes, with the first wording kept as delivered: overstated novelty or framing (source 22’s “direct Section 15 improvement” gains nothing at Lemma 15.5 at leading order; source 24’s table presents as its contributions results of sources 03 and 10, some with weaker constants, and its Proposition 7.3 “in every abelian group” is already formal; sources 25 and 27 present source 18’s leading coefficient and single-certificate bound as their own, and source 27’s remark on the research directory overlooks sources 18 and 22; all three could not see those texts), and the intake’s description of source 23’s sampling lemma as “a weaker version” of source 19’s, made precise (its stated sample size is one larger; its displayed inequality bounds a different loss). Inputs used and not proved in the sources: the Reiher–Schoen theorem (source 24’s Corollary II.80.2, marked as imported), and the classical results that source 22 credits (Warning’s second theorem, the minimum-weight theorem of Delsarte, Goethals and MacWilliams). Source 27’s exact eight-vertex count rests on a finite rational certificate, reproducible by its verifier and confirmed independently at intake, not checked by a proof assistant. Kept as evidence only: the intake’s numerical convergence to 20/9 on $\mathbb{Z}/5\mathbb{Z}$, its exact values of $\delta_{k,1}(p)$ for $k \leq 3$, and its Monte Carlo at $k = 2$, $d = 2$. The reviews mentioned by sources 21 and 22 are not part of the argument here.

Answered or advanced inside the report. Source 14’s Question 1 is answered by sources 21 and 23 (item III.23). Source 13’s Question 1 is answered by source 23 (item I.12). Source 18’s Question 1 is answered for $d = 2$ by source 27, and with it the same question of sources 22 and 25 (their first questions); source 18’s Question 5 is answered for $d = 1$ in its leading coefficient by source 22, and the first-order count in small characteristic, source 25’s Question 4, by source 27 (item II.38). Source 27’s question on the single-pair regime is answered in its leading coefficient by source 22 (same item). Source 19’s Question 6 is advanced by source 23 (item II.40). Source 14’s Question 7 is advanced and its Question 8 has a first instance by source 22

(items III.19, III.20). Source 04's Question 6 and source 10's Question 6 are advanced for codomains $\mathbb{F}_p^d$ by source 24 (items II.8, II.17).

Still pending. Sources 28–33 (placed by **c5513046e**), 34–39 (placed by **bf2fe146d**) and 40–46 (placed by **2dfe46f44**; both batches while this write was in progress) are in this directory and not used in this text. Their placements record, among other findings: sources 28, 29 and 34 as bounding c_d^{odd} for $d \geq 4$ (item III.1); source 29 as adding a fixed-field restriction theorem that keeps every degenerate tuple (item II.6); source 32 as proving Corollary 5.8 at degree two without a scale threshold (item I.19); source 33 as continuing the arrangement material of sources 14 and 15; source 34 as answering source 07's Question 1 (item II.9) and source 09's question on the prime-onset function (item III.16); source 35 as answering source 23's question on polynomial phases (item I.15); source 38 as reducing the exponent-five problem to $\mathbb{Z}/5\mathbb{Z}$ at small u/δ , answering three of source 21's questions (item III.27); source 39 as re-deriving source 19's sampling minimax (item II.39); source 40 as replacing the repeated Riesz products of Lemma 15.5 by one Fejér kernel (item II.44); source 41 as proving the whole of Corollary 5.8 in every degree with no scale premise, and source 42 as replacing the cube-root length cap by a square root (both item I.19); sources 43 and 46 as continuing source 36 in characteristic two; source 44 as computing the second Whitney coefficient of the cross-section arrangement in every dimension, answering two of source 27's questions (item II.38); and source 45 as improving the upper bound for c_4^{odd} (item III.1) and extending the range of source 14's coset envelope (item II.31). Those findings are for the writes that add them, and the items below still state the questions as open.

[write] 6 October 2026; sources 28–33. *Sources 28–33.* They ask 69 further questions: source 28 fifteen (Section V.113, its Research questions in order, “28 Q1”–“28 Q15” below), source 29 thirteen (Section V.117, its Questions in order), source 30 twelve (Section V.119), source 31 thirteen (Section V.123), source 32 four (the items at the end of Section V.126) and source 33 twelve (Section V.127). They are added to the themes below as four new items or merged into existing items by dated sentences. The counts per theme become 53, 150, 88, 17 and 50 (358 questions; the headings keep the counts of sources 01–05).

Unproved or wrong claims in sources 28–33. The intake and the sixth write found no claim of sources 28–33 that is wrong and no claim asserted as proved without a proof. Corrected or qualified in dated notes, with the first wording kept as delivered: source 28's pin of source 07 (39 digits, a 6 missing); source 29's reference to “Section 8” of source 17 (it is Section 7); source 28's “strictly improves the previously available $2^{-1/2}$ ” (true at its pin, superseded the same day by source 29); priority and credit: source 30 re-derives source 12's tree budget and compatibility inequality without citing it and has a weaker extension budget, source 31's Section 7 repeats source 10's mechanism with weaker constants and its Reiher–Schoen formula, and sources 28, 29 and 31 overlap one another from one pin without citations. Moved to questions as a marked question (not proved here): the intake's observation that source 28's theorem with its Corollary II.126.2 gives the formal **theorem_10_13** with better parameters (item II.47). Kept as evidence only: the intake's numerical optimum near 10.25714 for the U^4/U^2 ratio and its recurrence search for source 32's Lemma I.45.3. A review result, printed and credited to the intake: the certificate $c_4^{\text{odd}} \geq 0.5587725$ on $\mathbb{Z}/7\mathbb{Z}$, recomputed exactly at the write. Inputs used and not proved in the sources: Reiher–Schoen's Theorem 1.2 (source 31's Appendix A and modern comparison), Plünnecke–Ruzsa through Petridis (source 31), the classical results the sources credit.

Answered or advanced inside the report. Source 03's Research question 1, source 04's Question 3, source 08's question on κ_d^{odd} , source 14's Question 11, source 18's Question 7 and source 21's Question 7 are advanced for $d \geq 4$ by sources 28 and 29, and the sub-question whether real parts of characters are extremal is answered (no) for $d \geq 4$ by source 28; source 29's Question 1 (its second sentence) is answered by source 28 and source 28's question on a positive lower bound uniform in d by source 29 (item III.1). Source 02's Subsection 11.1 is answered in a prime-cyclic, bounded-fibre form by source 31 (item II.1) and its Subsection 11.2 advanced by sources 31 and 29 (item II.2). Source 04's Question 4 and source 17's Question 2 are answered for fixed fields by source 29 (item II.6). Source 12's Questions 4–6 are advanced by source 30 (item II.28). Source 11's Question 7, source 14's Questions 5–6 and source 15's Questions 2–3 are advanced on full products by source 33 (item II.24). Source 26's Question 4 is answered at degree two by source 32 (item I.19). Source 10's Question 7 is advanced by source 31's Appendix A (item II.18).

Still pending. Sources 34–39 (placed by **bf2fe146d**) and 40–46 (placed by **2dfe46f44**) are in this directory and not used in this text. Their placements record findings for items III.1 (sources 34, 35 and 45: upper coefficients 81/16, 5, 4795/832), I.19 (sources 41 and 42), II.46 (source 38: the odd-order stability modulus)

and others listed at the fifth write; the items below still state the questions as open.

[write] 6 October 2026; sources 34–39. *Sources 34–39.* They ask 73 further questions: source 34 eleven (its Research questions in Section V.130, “34 Q1”–“34 Q11” below), source 35 fifteen (the Research question in Section III.72 as “35 Q1” and the fourteen of Section V.133 as “35 Q2”–“35 Q15”), source 36 twelve (Section V.136), source 37 ten (its Questions in Section V.139), source 38 fifteen (the numbered items of Section V.144) and source 39 ten (Section V.147). They are added to the themes below as six new items or merged into existing items by dated sentences. The counts per theme become 64, 169, 111, 28 and 59 (431 questions; the headings keep the counts of sources 01–05).

Unproved or wrong claims in sources 34–39. The intake and the seventh write found no claim of sources 34–39 that is wrong and no claim asserted as proved without a proof. Corrected or qualified in dated notes, with the first wording kept as delivered: priority and credit, namely source 34’s reuse of source 28’s Section 8 (two-harmonic example, witness, dual identity, single-pair non-extremality) without citation, which makes its “single-pair extremality left open” and “improves both endpoints” accurate only against source 29; source 39’s re-derivation of source 19’s sampling theory without citation; source 36’s sharpening of source 31’s noncommuting-subgroup gap and its analogue of source 29’s symmetry step without citation; source 35’s “strongest inspected coefficient” (superseded the same day by source 34); source 35’s “strengthening” of the $1/(7\nu + 1)$ obstruction, which holds for prescribed lengths, not for source 19’s flexible-length obstruction; source 38’s ledger counts (those of its pin). A claim refined at the write: source 39’s closed solution of the finite profile problem holds for its own certification rule; for source 19’s rule the same formula fails in 199 of 2,835 small cases (exact counterexample $m = 2, r = 1, t = 2, q = 2$: formula $1/2$, true value 1; note after Theorem II.155.3), so source 19’s Question 1 stays open for its rule. Moved to questions as a marked question (not proved here): the intake’s observation that source 35’s Corollary II.145.3 gives the formal `lemma_15_5` with an explicit threshold (item II.50). Kept as evidence only: the intake’s numerical local minima of the U^4/U^2 ratio near 10.2571 ($c_4^{\text{odd}} \approx 0.55878$), its numerical confirmation of source 38’s u^{10} and u^{12} coefficients on $\mathbb{Z}/5\mathbb{Z}$, and the best member 0.5587462 of the two-harmonic family. Inputs used and not proved in the sources: the Alon–Vu unimodular matrices and Shitov’s composition (source 34, credited), the Weyl inequality in the formal form of `lemma_5_3` (source 37), classical positive-polynomial and truncated-moment theory (source 37, Yang–Xie credited), finite Heisenberg representation theory (source 36, proved in the needed form), Eisner–Tao’s classification (source 38, context).

Answered or advanced inside the report. Source 09’s Research question on the prime-onset function is answered by source 34 (item III.16); source 07’s Question 1 is answered in its finite-fibre model by source 34’s Appendix A (item II.9); item III.1 is advanced to $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$ by source 34 (and source 35); source 21’s questions on the universal eighth-order coefficient, fixed higher dimensions and further terms on the five-point group are answered by source 38 (item III.27); source 31’s odd-order coefficients by source 38 (item II.46); source 23’s Question 6 in its construction half by source 35 (item I.15); source 19’s Question 1 for source 39’s rule and its rates question in part, by source 39 (item II.39); source 22’s question on defect formulas for more odd norm layers is advanced for three layers by source 38 (item III.28).

Still pending. Sources 40–46 (placed by `2dfe46f44`) are in this directory and not used in this text. Their placement records findings for items III.1 (source 45: $c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$), I.19 (source 41: a written proof of the whole Corollary 5.8; source 42: square-root scale), II.44 and II.50 (source 40: the one-stage Fejér selection that source 35 builds on; source 44: the second Whitney coefficient), the new Theme IV items (sources 43 and 46: characteristic two) and others; the items below still state the questions as open.

[write] 7 October 2026; sources 40–46. *Sources 40–46.* They ask 62 further questions: source 40 eight (its Research questions in Section V.152, “40 Q1”–“40 Q8”), source 41 five (the enumerated items of Section V.155), source 42 four (Section V.156), source 43 ten (Section V.160), source 44 nine (Section V.163), source 45 sixteen (Section V.166) and source 46 ten (Section V.171). They are added to the themes below as five new items or merged into existing items by dated sentences. The counts per theme become 72, 192, 115, 46 and 68 (493 questions; the headings keep the counts of sources 01–05).

Unproved or wrong claims in sources 40–46. The intake and the eighth write found no claim of sources 40–46 that is wrong and no claim asserted as proved without a proof. The four claims of source 43 that the intake

left unchecked (finite-abelian orthogonality, the certification threshold $1 - 2^{1-d}$, the fourth-power triangle bound, the quartic value 11/16) were checked at the write and hold in every test (note in Section F.48). Corrected or qualified in dated notes, with the first wording kept as delivered: credit, namely source 41's reuse of source 32's text (its Sections 2 and 5 verbatim) and of sources 26's and 32's bounds and method without citing either; source 45's re-derivation of sources 28's and 34's single-pair results and of sources 29's and 34's moment bound without citation; source 46's silence on source 36 and on source 43, and source 43's on source 46; source 44's citation of sources 25 and 27 by library identifiers; source 45's interval " $0.55743364 \leq c_4^{\text{odd}}$ ", correct but not the best known lower end; the placement's phrase "26's cube-root length cap becomes a square root", made precise (only the modulus cap $(N/8)^{1/3}$ becomes $\sqrt{N/2}$; note after source 42's Theorem I.74.1); source 45's description of this report at its pin as holding sources 01–14 (true then). Moved to questions as a marked question (not proved here): that source 40's Corollary II.170.1 gives the formal `lemma_15_5` with an explicit threshold, merged with the same marked question for source 35 (item II.50). Kept as evidence only: the intake's numerical minima of the U^4/U^2 ratio near 10.2571; source 44's value $b_{2,8}$, which rests on its finite certificate (the method was checked independently only for $d \leq 4$); the numerical parts of the write's checks of source 43. Inputs used and not proved in the sources: the inverse Pollard theorem and Hegyvári's recurrence (source 45, credited); Tao–Ziegler's and Tidor's integration criterion (sources 43 and 46, credited); the Kolountzakis–Révész packing bound and Bhatia–Davis (source 42, proved in the needed form); Maynard's theorem for context only (source 41).

Answered or advanced inside the report. Source 26's question on the $(N/8)^{1/3}$ ceiling is answered by source 42 and its higher-degree question, with source 32's degree-three question, by source 41 (item I.19); source 27's two questions on $b_{2,d,p}$ and on intermediate characteristics are answered by source 44 (item II.38); source 14's Question 4 is advanced by source 45 to the range $\varepsilon < 1/9$ with all equality cases (item II.31); item III.1 is advanced to $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ by source 45; source 36's characteristic-two question is answered for symmetric trilinear forms by sources 46 and 43, and its nonclassical and composite questions advanced by source 43 (item IV.9); the retention questions of sources 04 and 17 gain source 40's kernel-class barrier (item II.7).

Still pending. Sources 47–59 (placed by `f8bc5e2ec` and `7dc1ee29d` while this write was in progress) are in this directory and not used in this text. Their placements record findings for items III.1 (source 49: $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$), IV.10 (source 47: the quartic value 11/16 for every n), II.53 (source 57: the third energy level), II.41 (source 50: a written counterexample to the catalogue `lemma_16_10`), II.46 (source 55: endpoint stability in every U^d) and others; the items below still state the questions as open.

Unproved or wrong claims. The intake and the write found no claim of sources 01–05 that is wrong, and no claim asserted as proved without a proof. Three inputs are used but not proved in the sources. The classical threshold-function counts (Zuev; Kahn–Komlós–Szemerédi; Baldi–Vershynin) enter source 01's asymptotics and are published theorems. The partition input $\text{PP}(K, R_0)$ of source 02 is now a formal theorem for polynomial phases on intervals (Section V.1). The “independent mathematical reviews” of source 03 are not shipped, and nothing here rests on them. Two values found at intake are not certified, $C_5 = 8410$ and $A_4 = 770$; they are item IV.2.

Answered inside the report (dated notes at the questions). Source 04's Question 8, the leading constant of $\log_2 F_k/k^2$ and $\log_2 A_k/k^2$, is answered by source 01: it is 1, using the classical threshold count, and source 01 certifies $F_4 = C_4 = 154$. Source 03's Research question on c_d^{odd} is answered for $d = 3$ by source 04's Theorem III.3.4: $c_3^{\text{odd}} = 2^{-1/2}$, attained by real parts of characters. With it, source 03's Remark III.2.9 is settled at $d = 3$. Source 04's Question 3 is the same question as source 03's for $d \geq 4$, and is merged with it (item III.1).

Theme I: density transfer and phase-flat partitions (14 questions)

I.1 Higher-degree phase partitions (01 Question 8; 05 paragraph 6). The density transfer is proved for any short-arc phase (source 01's Theorem I.2.1; source 05's Proposition I.17.2 and Corollary I.19.4). Missing: polynomial or nilsequence partitions with a quantitative minimum

cell length and small occupied exceptional mass (01), and density-sensitive oscillation budgets tracked through geometric complexity with all losses parameterized (05). Simultaneous linear approximation does not give them, and Theorem I.18.5 does not transfer to nonlinear phases. [6 October 2026; sources 11–14] Source 13 (its Question 3) asks the same for degree $k \geq 2$: which hypotheses permit simultaneous partition exponents polynomial in the number of phases; the coupled lower-degree coefficients after restriction are the obstacle, and quadratics sharing a leading coefficient are a suggested first case. [6 October 2026; sources 15–20] Source 13's Question 3 is answered, conditionally on Maynard's published recurrence theorem: source 18's Theorem I.32.2 with Corollaries I.32.4 and I.32.5 (all quadratics: every $a < 1/(126q^2 + 129q + 2)$ with Lau's numbers; a shared leading coefficient: $a < 1/(99q + 98)$ from the scalar Lemma 5.5 alone) and, independently, source 19's Theorem I.34.3 (degree profiles, $O_k(q^k)$). What remains is the gap to the obstructions (item I.15).

- I.2** *The best transfer under arithmetic constraints* (01 Question 5; 05 paragraph 4). The extremizers of Theorem I.2.1 rotate cell arcs freely, and the disk radius and the capacity inequality are separately sharp (05). Asked: how much stronger the tail becomes for one fixed cyclic character on a common-step partition with nearly equal cells (01), and the exact feasible region of block positive mass, correlation, density and phase width (05). [6 October 2026; sources 11–14] Source 13 (its Question 7) asks which extremizers of its joint frontier (Theorem I.28.3) are ruled out when the phase is a polynomial on progression cells.
- I.3** *Finite partition profiles and the size-increment trade-off* (05 paragraph 1; 01 Question 6). The universal constant $1/3$ is settled (Theorem I.16.4). Asked: the exact best minimum length for each (r, s, M) and slope, and the feasible pairs of minimum and maximum lengths (05); the best uniform pair of length and increment, combining (I.3.4) with an optimal finite partition, including the final incomplete blocks (01). [6 October 2026; sources 06–10] Source 10 (its Question 3) asks the same for its phase partition: the best universal minimum block length for a prescribed phase-disc radius with all integer rounding retained, first at fixed η/δ as $\delta \rightarrow 0$; its density cap is sharp, its passage from one approximate period to blocks of lengths $L, \dots, 2L - 1$ may not be.
- I.4** *Retaining more than one density statistic* (01 Question 7). Theorem I.4.2 solves the optimization once stop-loss statistics are chosen. Missing: structural lemmas that propagate those statistics through repeated localization at acceptable cost.
- I.5** *Heterogeneous phase budgets* (02 Subsection 11.5; 03 Research question 5). The analytic constraint is exact (source 02's heterogeneous inequality in Section I.8; source 03's Lemma I.14.3). Missing: a refinement theorem whose cost depends on the oscillation allowed in each cell, so that budgets can be allocated by local mass. Any better $PP(K, R_0)$ transfers automatically to Theorem I.11.1. [6 October 2026; sources 11–14] Source 13 (its Question 6) asks for a joint frontier retaining all phase radii s_j , the cell weights and the measured $V = \mathbb{E}|f|$, by a dual optimization over supporting lines.
- I.6** *The finite-cell extremal problem* (02 Subsection 11.6). Theorem I.9.1 solves the weighted total-mass problem. Open: the largest good cell when M and the allowed cell sizes are fixed, with integer cardinalities, which would sharpen the $M - 1$ corollary. [6 October 2026; sources 06–10] Advanced by source 06: with M fixed and the cell masses free, its Theorem I.21.1 gives the exact optimum $\min\{P_+/(b(M - 1)), S/(M - 2)\}$ with explicit extremizers (note after Corollary I.9.3). Still open: prescribed allowed cell sizes and integer cardinalities at a fixed N . [6 October 2026; sources 11–14] Source 13 asks the same (its Question 5: the largest

guaranteed high-average cell for a fixed number of cells); in the weighted model with M fixed and the cell masses free it is answered by source 06's Theorem I.21.1.

- I.7** *Constants in the simultaneous minimax theorem* (05 paragraph 2). The exponent $1/(m+1)$ and the dependence on ε are sharp; the upper constant c_m is poor. Asked: the optimal leading constants, first for one or two phases (source 01's Theorem I.7.2 improves the one-phase constant), the effect of a common difference, and the order of limits. [6 October 2026; sources 11–14] Source 13 (its Question 2) asks for the best leading constants of its flexible partition theorem for fixed q and anisotropic tolerances; its constructive and probabilistic constants differ by less than a factor 4.
- I.8** *Anisotropic lower bounds* (05 paragraph 3). Is there a matching minimax upper bound in all anisotropic regimes, with the regime decomposition that loose tolerances require? [6 October 2026; sources 11–14] *Advanced by source 13*: its Theorem I.26.5 (random slopes) with Corollary I.26.3 gives the order $(N \prod_i \varepsilon_i)^{1/(m+1)}$ for independent tolerances $0 < \varepsilon_i < 1/2$, constants within a factor below 4. Loose tolerances $\varepsilon_i \geq 1/2$, where the regime decomposition is needed, are not covered.
- I.9** *Adaptive selection of frequencies and tolerances* (05 paragraph 5). Proposition I.19.3 solves the continuous allocation. Missing: subset selection and the exact ceiling problem, relative to certified Fourier inputs.
- I.10** *Interval-localized spectral extraction* (05 paragraph 8). Corollary I.19.4 corrects for the Gram matrix by its top eigenvalue only. Missing: certified conditioning bounds for specific frequency configurations, using more of the Gram matrix. [6 October 2026; sources 06–10] Source 10 (its Question 4) asks the companion problem: when several approximately constant characters or polynomial phases live on one partition, the best Gram-matrix lower bound for the conditional second moment, to be combined with its variance cap (I.23.3); the common partition has to be supplied by the geometry, not assumed.

Added in the second write, 6 October 2026 (sources 06–10):

- I.11** *Using the mass of all dense cells* (06 Question 8). Source 06's Theorem I.21.1 controls the total mass above every threshold, not only one cell, and its extremizers show that the scalar data cannot give more. Asked: whether a branching density-increment argument, keeping geometric information about the collection of high cells, improves a structural or counting bound. Related to item I.4.

Added in the third write, 6 October 2026 (sources 11–14):

- I.12** *Prescribed lengths at the flexible frontier* (13 Question 1). Can a complete partition into lengths $v-1$ or v reach $(q+1)a + qb = 1$, or is there an arithmetic obstruction between it and the proved region $(q+2)a + qb \leq 1$ (Corollary I.26.9)? The loss comes from the conductor $(v-1)(v-2)$; with an exceptional set of mass $o(1)$ the flexible exponent is reached. [6 October 2026; sources 15–20] Source 19 asks the same for nonlinear phases (its Question 8 and S6(4): prescribed lengths without the square-length loss of its Lemma I.34.4); *partly answered by source 18*, whose Theorem I.32.2 pays the square once, at the base (note after Corollary I.32.4). Source 18 quantifies the cost of prescribed lengths in degree one (its exponent recursion), without answering source 13's question. [6 October 2026; sources 21–27] *Answered by source 23*: there is an arithmetic obstruction. No partition into lengths $v-1, v$ reaches beyond $(q+2)a + qb \leq 1$, even with cell-dependent differences (Proposition I.38.1; the lower

example is realizable on a prime cyclic group), so the exponent $1/(3q+2)$ at Gowers's $b = 2a$ is optimal; for lengths $L, L+1$ the threshold is $L^{q+2}/\prod_i \varepsilon_i (1+o(1))$ (Corollary I.37.1). The nonlinear prescribed-length question of source 19 stays open (item I.15).

- I.13** *Bounded-height presentations* (13 Question 4). Choose a generating family efficiently so that (I.26.6) is close to optimal for a given collection of modular phases, with certified generator matrices and budgets.

Added in the fourth write, 6 October 2026 (sources 15–20):

- I.14** *Partitions controlling their own steps* (16 Questions 5–7). Source 16's sufficient exponent for equal powers is of order q^{-2} (Theorem I.30.5, conditional on Lau's preprint), its obstruction of order q^{-1} (Corollary I.31.2): can a universal theorem reach c/q ; is the strict interior of $(q+1)a + 2\sum_i b_i \leq 1$ sufficient; can a weighted extraction of one progression beat the full-partition obstruction at the Lemma 13.5 interface?

- I.15** *The nonlinear partition exponent gap* (18 Question 9; 19 Question 7 and S6(1)–(2)). For fixed $k \geq 2$, the sufficient frontiers (source 18's $126q^2 + 129q + 2$ for quadratics, source 19's $O_k(q^k)$) against the necessary $(qk(k+1)/2 + 1)a + kqb \leq 1$, equivalently $(S+1)a + Db \leq 1$ (for quadratics with $b = 2a$: $a \leq 1/(7q+1)$): reduce the sufficient denominator to order q , or attain the necessary region; decide first whether flexible lengths and lengths $v-1, v$ have the same frontier (source 18). [6 October 2026; sources 21–27] Source 23 (its Question 6) asks for the prescribed-length obstruction for polynomial phases: a higher-degree analogue of its mixed-radix construction, with a matching necessity theorem. [6 October 2026; sources 34–39] Advanced by source 35 for prescribed lengths: explicit phases with one prime denominator per degree force $D \mid h$ for every flat progression, the exact thresholds are $DC(S)$, and the necessary frontier for lengths L or $L+1$ is $(W+2)a + \sum_i d_i b_i \leq 1$ (quadratics at $b = 2a$: $1/(7\nu+2)$; Theorem I.61.2, Corollary I.61.6); this answers the construction half of source 23's Question 6. The flexible-length obstruction of source 19 is unchanged. Source 35 asks (its Questions 10 and 12): a matching quadratic upper theorem, threshold $C_\nu L^{3\nu+2} \varepsilon^{-2\nu}$ up to subpower factors; and the same powers for prime moduli comparable with the interval length.

- I.16** *Effective dimension of the phases* (16 Question 8; 18 Question 10; 19 S6(5)). Replace the number of phases by an effective dimension: moving slopes in a low-dimensional bounded-height span (16), bounded-height rational dependencies among leading coefficients (19), and a recurrence formulation that also controls the coefficients created by translation, with the shared-leading family as a test case (18).

- I.17** *Numerical recurrence thresholds and coefficient-rank profiles* (16 Question 9; 18 Question 11; 19 Question 9 and S6(3)). Make the thresholds $X_0(C, q)$ and the constants $U_{j,m}$ of the cited recurrence theorems numerical, or formalize certificate-producing finite algorithms; give each degree its own bounded integer span and compute the resulting recurrence costs. An exponent with an uncontrolled starting threshold supports no finite comparison.

Added in the fifth write, 6 October 2026 (sources 21–27):

- I.18** *Prescribed-length thresholds beyond the leading term* (23 Questions 1 and 3–5). The second asymptotic term of $T_{\{L, L+1\}}(\varepsilon) = L^{q+2}/\prod_i \varepsilon_i (1 + O_q(1/L))$ (start with $q = 1$ and a rational tolerance); stability of the obstruction (must nearly worst phase vectors resemble nested rational quotients?); the leading constant when the allowed lengths span a fixed fraction θL of the minimum; the optimal exceptional-set profile at fixed η and for a general numerical semigroup

(Theorems I.36.1, I.39.1). [6 October 2026; sources 34–39] Source 35 (its Question 11) asks how the threshold changes for the allowed lengths $L, \dots, L + w$ (its conductor $L[(L - 1)/w]$) and how much an exceptional set reduces it.

- I.19** *Corollary 5.8 without a scale threshold* (26 Questions 1–4). Relax the $(N/8)^{1/3}$ ceiling of Theorem I.41.1 (it comes from the sufficient condition $N \geq L^3$); an α -independent square-root guarantee; the optimal constants of the local-cover interface; and a threshold-free replacement for the phase-flat refinement in higher degree, with its small-correlation regime. The placement of source 32 records it as treating degree two; that of source 41 records a written proof of the whole statement in every degree, gain $\alpha/3$ at length $\max\{1, (N/M)^{1/D_k}/8\}$, and that of source 42 the square-root cap $\sqrt{N/2}$ in place of $(N/8)^{1/3}$. These are for the writes that add them; until a write checks them, the item stays open. [6 October 2026; sources 28–33] *Answered at degree two by source 32*: gain $\alpha/3$ at length $\max\{1, (N/M)^{1/39}/17\}$ over every cyclic group with no scale threshold (Theorem F.37.1); with source 26 the instances $k \leq 2$ of the formal statement have written proofs. Source 32’s own questions: a better explicit recurrence ($p \leq CR^\kappa$ would give the length exponent $1/(7\kappa + 4)$; Remark I.45.4 does not supply $\kappa = 4$), a more economical quadratic partition than power 38, parent-contained small-correlation increments, and degree three (32 Questions 1–4). Degree three and beyond stay open here; source 41’s placement records a proof in every degree, for its write. [7 October 2026; sources 40–46] *Answered in every degree by source 41*: gain $\alpha/3$ at length $\max\{1, (N/M)^{1/D_k}/8\}$, $D_1 = 4$, $D_k = K_k/4 + 1$, over every cyclic group with no scale premise (Theorem F.46.1), with the cubic bound $(N/M)^{1/4096}/8$ (Corollary I.68.5); so every instance of the formal statement has a written proof; the formal statement is now exact as well, by the repository’s own proof along the same architecture (`corollary_5_8_holds`; Section V.1). *The $(N/8)^{1/3}$ ceiling is answered by source 42*: it becomes $\sqrt{N/2}$ (Theorem I.74.1). Source 41 asks (its items 1–4): a fully explicit improved recurrence at all small scales, inserted into the exact recursion; a cheaper localization (e_k, c_k) ; a sharper final selection, trading the gain $\alpha/3$ against length with singleton and boundary cases kept; parent containment for the low-correlation branch and rectification to ordinary integer progressions. Source 32’s degree-three question is answered (source 41’s cubic bound); its other questions stand.

Added in the seventh write, 6 October 2026 (sources 34–39):

- I.20** *Missing intervals beyond the first window* (37 Questions 1–6, 8 and 10). The minimax $\inf \max_{r \leq R} |\hat{\mu}(r)|$ when $a > 2\pi/(R + 1)$, with extremizers and transition points (a piecewise algebraic description in $\cos a$?); exact finite-grid corrections on $\mathbb{Z}/N\mathbb{Z}$, open against half-open exclusions; uniform stability constants as $R \rightarrow \infty$; unequal Fourier budgets ε_r and the region where the certificate of Section I.51 stays optimal; several forbidden arcs; the best constant of the recurrence conversion with the exact frontier $\rho_R(2\pi\delta)$; whether the structure of polynomial empirical measures $T^{-1} \sum_{n \leq T} \delta_{\alpha n^k}$ improves the recurrence; and which parts of the formula for ρ_R and its extremizing quadrature are classical in equivalent language. Source 37 is the first source of this report on Lemma 5.2 (Section I.49).

Added in the eighth write, 7 October 2026 (sources 40–46):

- I.21** *The arithmetic variance increment* (42 items 1–4). The best uniform coefficient under $N \geq CL^2$ for densities bounded away from 0 and 1, including $C = 1$ (Theorem I.73.1 gives a positive endpoint coefficient, not shown optimal); for fixed N , L and $|A|$, when the arithmetic bound is attained; the best supports and positive-definite weights in general finite abelian groups;

comparable gains inside a prescribed parent or cover, and nonwrapping integer conclusions (merged with source 41’s containment question, item I.19). Section I.62.

The ten items carry the fourteen questions: 01 Questions 5–8, 02 Subsections 11.5–11.6, 03 Research question 5, and 05 paragraphs 1–6 and 8. [6 October 2026; sources 06–10] With sources 06–10 the eleven items carry seventeen questions: also 06 Question 8 and 10 Questions 3–4. [6 October 2026; sources 11–14] With sources 11–14 the thirteen items carry twenty-four questions: also 13 Questions 1–7. [6 October 2026; sources 15–20] With sources 15–20 the seventeen items carry forty questions: also 16 Questions 5–9, 18 Questions 9–11, 19 Questions 7–9 and its five questions S6(1)–(5). [6 October 2026; sources 21–27] With sources 21–27 the nineteen items carry forty-nine questions: also 23 Questions 1 and 3–6 and 26 Questions 1–4. [6 October 2026; sources 28–33] With sources 28–33 the nineteen items carry fifty-three questions: also 32 Questions 1–4. [6 October 2026; sources 34–39] With sources 34–39 the twenty items carry sixty-four questions: also 35 Questions 10–12 and 37 Questions 1–6, 8 and 10. [7 October 2026; sources 40–46] With sources 40–46 the twenty-one items carry seventy-two questions: also 41 items 1–4 and 42 items 1–4.

Theme II: the inverse step (9 questions)

- II.1** *A correlation-preserving structural theorem for multivalued spectra* (02 Subsection 11.1). Proposition II.4.1 keeps all large derivative frequencies. Missing: an energy-to-structure step that keeps a fixed fraction of t_τ and exploits κ , controlling both losses. [6 October 2026; sources 28–33] *Answered in a prime-cyclic, bounded-fibre form by source 31*: its Theorem II.117.1 keeps an explicit fraction of the selected derivative correlation through an exact Freiman restriction on $\mathbb{F}_p$. Open: compatible restrictions across slices (31 Question 9), which is what Gowers’s later multilinear stages need.
- II.2** *Near equality for the coupled pair (f, w)* (02 Subsection 11.2). Proposition II.4.2 gives two alignments, and the equality examples show distinct geometries. Asked: a dimension-free description of f and w jointly when Theorem II.2.1 is nearly an equality; results on near-maximal Gowers norms (Eisner–Tao) are relevant but do not classify the weight. [6 October 2026; sources 28–33] *Advanced by sources 31 and 29*. Source 31 gives the exact optimal profile for the function (Theorem II.107.4), sharp selected-graph stability (Theorem II.108.1), a weight-defect inequality in the U^2 and coset topology and counterexamples to normalized L^1 control of the weights (Section II.109); source 29 the endpoint with soft and mixed selectors (Sections II.111–II.112). Still open: the unrestricted coupled near-equality, with the optimal coupled weight defect (31 Questions 10–11), optimal constants and a larger defect range of the joint theorem, the row constraint, and higher-degree joint selectors (29 Questions 5–7).
- II.3** *Carrying profiles through the proof* (02 Subsection 11.3; 04 Q7). Keep the distribution of $m(\Delta_{\mathbf{h}}f)$ and $\mathcal{U}(\Delta_{\mathbf{h}}f)$ across slices instead of their supremum (02), and the cross-section profile $\sigma = \mathbb{E}_r \beta_r^3$ through later restrictions (04). The difficulty in both: compatibility of structure between slices, and which operations preserve the profile. [6 October 2026; sources 11–14] *Advanced by source 14*: its Theorems II.44.1 and II.44.4 classify equality in the profile bound and its Corollary II.44.3 improves the denominator from cross-section sizes alone; propagation through later restrictions is still open. [6 October 2026; sources 15–20] Source 15 (its Question 6) asks when one can pass to a balanced subdomain while keeping enough arrangements to use ρ_3^{-6} ; its Example II.48.4 shows the cost of assuming balance.

- II.4** *The sharp fixed-threshold DRC profile* (03 Research question 3). The order of the best guaranteed $|K|/n$ under Lemma 7.4's exact criterion as $\delta \rightarrow 0$, and whether the exponent 3 of Theorem II.5.2 can be improved using constraints of actual intersection matrices; the scalar argument only rules out a two-witness first-moment certificate. [6 October 2026; sources 21–27] Also asked by source 24 (its Questions 1–4: the dense-intersection extremal function $f(\delta)$, whether actual codegree geometry rescues two samples, profile-sensitive sampling with a verifiable certificate, and higher-arity scalar envelopes). Not advanced: source 24's scalar facts are source 03's (note after its Theorem II.75.1).
- II.5** *Optimizing the elementary extraction* (03 Research question 4). Optimize $\gamma, \varepsilon, \beta$, walk lengths and popularity thresholds in Proposition II.6.2, judging the pair of conclusions together and keeping the comparison with Reiher–Schoen explicit. [6 October 2026; sources 21–27] Source 24 (its Question 8) asks the same end to end, with the actual energy spectrum; its popularity-threshold optimizations (Sections II.77 and II.80) advance it for its own route.
- II.6** *Lowering the size threshold of the restriction theorem* (04 Q4), from $|B| \geq \Lambda_d(\alpha\eta)^{-2d}$, by reflecting the additive structure of B in the exceptional relations or by a better kernel, with repeated entries handled. [6 October 2026; sources 15–20] Also asked by source 17 (its Question 2: lower the degree $2m - 1$ in $(\alpha\eta)^{-1}$ of its threshold, keeping its retention powers; its Question 3: the extremal filter maximizing $\sum_n |\hat{h}(n)|^m$ at prescribed mean, the kernel half of this question). Source 04's weighted count already has degree m and β^{-1} (note after Theorem II.61.2). *Marked question (the intake's composition, in neither source; not proved at the write)*: source 17's Fejér kernel with source 04's per-tuple lower bound and its weighted rank-two count of exceptional tuples (Lemma II.9.3) should keep source 17's retention $1/(2\eta L^m)$ under the threshold $|B| \geq 2(1 + \binom{m}{2})L^m$, about $2^{202.3}$ at the Corollary 9.4 point $\gamma = \eta = \beta = 1/2$, below both sources' thresholds; the intake checked the two needed inequalities in twelve small instances. Missing: a written proof that the per-tuple lower bound and the weighted count combine without a D_G loss for repeated and degenerate tuples. [6 October 2026; sources 28–33] *Answered for fixed fields by source 29*: threshold $8qS_{q,s}/(\alpha\eta)$, linear in $(\alpha\eta)^{-1}$, with every degenerate tuple kept (Theorem II.120.4), and none at a smaller coefficient (Corollary II.120.5); this is also source 17's Question 2 in its fixed-characteristic form. Open: the prime-cyclic and growing-modulus case (item II.8). Source 29 asks for a bound by the actual affine-span statistics of B in place of $z \prod_i (z + q^i)$ and an efficient deterministic restriction (29 Questions 10–11).
- II.7** *The optimal retention law* (04 Q5). Proposition II.9.6 limits one expectation budget only. Asked: upper-bound examples or a better selection method, and simultaneous guarantees on $|B'|$, its energies and the respected density. [6 October 2026; sources 15–20] Source 17 (its Question 1) asks the same for prime cyclic groups: whether losses of order $\alpha^m \eta^{m-1}$ in the tuple count are needed; its Proposition II.62.2 settles only the scalar certificate. [7 October 2026; sources 40–46] *Source 40's barrier*: within homogeneous positive-Fourier kernels, gain Q forces good survival at most $Q^{-(s-1)}$, attained by Fejér kernels (Theorem II.172.2, Proposition II.172.3). Source 40 asks (its Question 7) whether vertex-dependent kernels or adaptive selection beat the scale $\alpha^s \eta^{s-1}$ with a usable exceptional-set estimate.
- II.8** *Restriction beyond prime cyclic groups* (04 Q6): versions for $\mathbb{Z}/N\mathbb{Z}$, $\mathbb{F}_q^n$ and other codomains, with hypotheses that quantify kernels of the coefficient maps. [6 October 2026; sources 15–20] Source 17 (its Question 4) asks for composite cyclic moduli with explicit torsion dependence (Smith normal forms or gcds of coefficient minors); its fixed-characteristic Section II.63

answers the $\mathbb{F}_p$ -vector-space and weighted parts of this item, not $\mathbb{Z}/N\mathbb{Z}$. The formal all- N proof uses degree-one digit filters with fibres of size at most two (`Proofs15Restriction.lean`, lines 2083–2086, at `0b4890a1c`). *Marked question (the intake’s observation, in neither source; not proved at the write)*: source 17’s Lemmas II.60.3–II.60.5 should carry over verbatim when every prime factor of N exceeds $2L - 2$, since the relevant minors are integers of absolute value at most $2L - 2$ and every $0 < |t| < L$ is then a unit (the intake checked exact averages at $N = 77, 85$; with a factor at most $2L - 2$, unrespected tuples survived at about half the respected rate). Missing: the written proof, and the case of small prime factors. [6 October 2026; sources 21–27] Source 24 (its Question 7) asks for general finite abelian codomains with explicit dependence on the invariant factors; its Theorem II.79.5 settles the elementary abelian case of the Freiman extraction, independently of the dimension. [6 October 2026; sources 28–33] Source 29 (its Question 12) asks for a growing-modulus analogue of its fixed-field theorem, with constants useful as the prime grows, and eventually all cyclic moduli.

Added in the second write, 6 October 2026 (sources 06–10):

- II.9** *The optimal nonuniform transport threshold* (07 Question 1). For fixed $k \geq 2$ and fibre ratio $\kappa > 1$, the largest universal δ forcing order- k relations, and the gain from a separate boundary bound. Proved: $1/(2[1 + (k - 1)\kappa])$ (Corollary II.15.3); sharp only at $\kappa = 1$ (Theorem II.16.1). Suggested: a finite search over fibre sizes and actual value assignments, not independent error profiles. [6 October 2026; sources 34–39] *Answered in source 07’s model by source 34*: $1/(2 + (2k - 2)\kappa)$, which is source 07’s sufficient threshold, is sharp for every $\kappa \geq 1$, already with zero boundary loss, so a separate boundary bound gives no improvement (Theorem II.163.1 and its corollary). The prime-order interface of the formal `lemma_10_9` is a different question.
- II.10** *The largest guaranteed Freiman order at Lemma 10.9* (07 Question 2), under the exact Lean hypotheses (order five proved) and under the ambient package (order nine proved). Five and nine are lower bounds; counterexamples must satisfy the nested local model, not only a scalar defect bound. [6 October 2026; sources 11–14] Source 12 (its Question 9) asks whether $3\varepsilon + r\kappa < 1$ is the correct universal scale for forcing order r on C from order two on S (its Theorem II.35.6), and which relation-complex parameters replace r .
- II.11** *Stability of winding obstructions* (07 Question 3): must a violated relation with total budget close to one come from a few cuts or carry boundaries, after a structural reduction?
- II.12** *Efficient certificates for many relations* (07 Question 4): compressing the root-law linear programs of Theorem II.18.3 over a large family of relations, for instance by translation symmetry or a presentation of the generated group; one relation is a finite linear program, exponentially many are not efficient.
- II.13** *Joint optimization of extraction and transport* (07 Question 5): building the regular component and its source law together, so that the domain is large and the relevant profiles small, accounting for lost cardinality and the relation between energy weights and the chosen law.
- II.14** *Higher-dimensional coherence* (07 Question 6): shared-vertex sampling on cubes or other diagrams in place of nested exceptional sets in bilinear and multilinear exactification; the joint law must be specified first and every marginal proved.
- II.15** *The earlier exponent $\eta^{1/5}$* (07 Question 7): which losses before the local model are necessary, and whether the fifth root can be improved while keeping a large regular component and direction set. Source 07 removes the later square root only.

- II.16** *A sharp vertical-fibre restriction theorem* (10 Question 5 and the question paragraph at the end of Section II.21). How close is $|B|/(k(h_k - 1) + 1)$ to the best bound determined by the defect fibre alone; can the factor k be reduced under additive structure of H_k ; can $|H_k|$ be bounded from a vertical energy profile, how does it grow with k , and when does an order- k homomorphism extend to order $k + 1$ with small loss? Settled only for $H_k = \{0\}$. [6 October 2026; sources 21–27] Also asked by source 24 (its Questions 5–6: the smallest universal vertical-fibre exponent in place of $2k + 1$, and the largest set P with $(kP - kP) \cap F = \{0\}$ for a given symmetric defect set). [6 October 2026; sources 28–33] Also asked by source 31 (its Questions 5 and 8: optimize the retention using the set V_k itself, and replace the worst fibre size K^{2k+2} by a fibre profile). Not advanced: source 31’s restriction is source 10’s (note after its Theorem II.116.1).
- II.17** *Overlaps in the bad-step union* (10 Question 6): Theorem II.21.3 uses a union bound over $E_j = \{d \neq 0 : jd \in F\}$; an exact treatment of their intersections, for example for cyclic prime-power codomains via valuations, would improve the general-codomain retention. [6 October 2026; sources 21–27] For codomains $\mathbb{F}_p^d$ the union over j is avoided altogether by source 24’s linear hashing (Theorem II.79.5), which beats the budget here whenever $Q_k \leq p^{d-1}$ and $k \geq 2$ (note there). [6 October 2026; sources 28–33] Source 31 (its Question 6) asks for its weighted restriction over composite cyclic and general finite abelian targets, charging the kernels of $1, \dots, kL$.
- II.18** *Propagating a modern energy input* (10 Question 7): propagate the Reiher–Schoen retention (almost $\sqrt{\gamma}$, against $\gamma/4$ here) with the exact vertical fibre through the later Bohr-neighbourhood and local-linearity stages, producing a complete chain of inequalities rather than an isolated replacement of the exponent 1164. Related to item II.5. [6 October 2026; sources 21–27] Source 24 (its Question 9) asks the same for its Section 7 interfaces: which later lemmas survive the substitution, with every threshold rechecked. [6 October 2026; sources 28–33] Advanced by source 31: its Theorem II.118.1 is a weighted square-root mass theorem from Reiher–Schoen; it asks (Question 7) to use it, or a sharper weighted BSG theorem, to improve the powers of its weighted extraction.
- Added in the third write, 6 October 2026 (sources 11–14):*
- II.19** *The affine-rigidity envelope and the next energy levels* (11 Questions 1–2). For fixed G, W and attainable t , $\max\{\mathcal{E}(f)/|G|^3 : d(f) = t\}$; how far the radii $1/7$ and $1/3$ extend (a joint optimization of two- and three-error patterns may help); and the next largest graph energies after one-point modifications, first for $\mathbb{F}_p \rightarrow \mathbb{F}_p$.
- II.20** *Near-extremizers at the right scale* (11 Question 3). Answered in substance at the write by Remark W3: for $\theta = \eta/(6t^3) \leq 1/100$ (odd targets) the error support is within $\tau(\theta)|S|$ of a unique coset and has one value off a fraction $\eta/(2t^2(1 - 7t))$ of it. Open: $\theta > 1/100$, and sharpness of the value term.
- II.21** *The exact cutoff for general groups* (11 Question 4). Remark W2: the cutoff 34 cannot simply be removed; the exceptions found have $N \leq 12$, with few homomorphisms or a non-affine quotient of small order, and the formula holds for $\mathbb{Z}/10, \mathbb{Z}/14, \mathbb{Z}/15, \mathbb{Z}/16 \rightarrow \mathbb{Z}/2$. Marked question (the intake’s derivation, in neither source; arithmetic checked at the write): replacing the step $\sum p_w^2 \leq \max p_w$ in Lemma II.28.1 by source 12’s Lemma II.36.1 gives disagreement at most $\rho/(1 - \chi(2\rho))$; the radius $1/7$ is then reached at $\varepsilon = 6/49$ (solve $\sqrt{1 - 4\varepsilon} = 14\varepsilon - 1$; there $3\chi(2\varepsilon) = 3/7 < 1$), and since $\Psi_0(1/30) = 551/4500 < 6/49 < \Psi_0(1/29) = 3080/24389$

the cutoff in Theorem F.16.3 would become 30. Missing: a written proof of each step of that modified argument; the exact cutoff between 13 and 30 (or 34) is open.

- II.22** *Erasures against corrupted values* (11 Question 5): a sharp two-parameter envelope for a prescribed proportion of missing inputs and of corrupted remaining values; deletion and corruption have different second-order costs.
- II.23** *Efficient certified recovery* (11 Question 6): recover the canonical affine map in nearly linear time with an a posteriori certificate matching the cubic bound. [6 October 2026; sources 15–20] Source 17 (its Question 9) asks the same for restriction: estimate the signed objective and the exceptional mass without enumerating all tuples, with a runtime theorem. [6 October 2026; sources 28–33] Source 29 (its Question 8) asks the same for its joint theorem: reconstruct Q, ψ, ρ from approximate derivative data with a checkable certificate.
- II.24** *Higher-order arrangements: extremal geometry, label repair and stability* (11 Question 7; 14 Questions 5–6). Analogues of the affine-rigidity theory for the multilinear arrangement counts, tracking repeated coordinates and torsion (11); a Hamming-distance repair of labels once the domain is near a product coset (14, first for $\mathbb{F}_p^2$); hypotheses under which near equality in the profile-moment bound yields a common coordinate subgroup, coset-supported section indices and approximately additive top interactions (14). Related to item II.3. [6 October 2026; sources 15–20] Source 15’s Questions 2–3 are source 14’s Questions 5–6 (label repair at $O_k(\varepsilon)|A|$ points, with coordinate-omitting corrections; robust joint normal forms when $1 - C/\Gamma$ and $R_8 C^6/R_2^7 - 1$ are small). [6 October 2026; sources 28–33] *Advanced on full products by source 33*: high-agreement repair to $a(x) + B(x, y) + \ell(y)$ with the sharp first and second coefficients $1/s, 2(s-1)/s^2$ (Theorem F.38.2), the sharp cubic for $s = 4$, erasures (Theorem II.142.1). Its further questions are item II.49; the sparse case is item II.25.
- II.25** *Reaching the high-energy endpoint inside the proof* (11 Question 8): a localization or amplification that reaches respected-quadruple density near one without losing more than it gains, with the retained domain and the normalization tracked together. [6 October 2026; sources 28–33] Source 33 (its Question 6) asks the sparse version of its repair theorem: replace near-full density by quantitative mixing (approximately uniform marginals of conditioned arrangement queries, enough common witnesses), with polynomial dependence instead of the invalid-arrangement error $2s\tau$; the most direct route to Gowers’s Sections 12–13.
- II.26** *Extremizers and stability at the extension boundary* (12 Questions 1–2): classify the configurations failing extension with $3\varepsilon + 2\kappa = 1$ (are they governed by a three-part quotient as in Theorem II.35.3?), and the structure forced near the boundary under nondegeneracy assumptions. [6 October 2026; sources 28–33] Source 30 (its Question 6) asks how far its budget $(2k-1)\kappa + 2k\eta < 1$ can be improved; at $k = 2$ source 12’s sharp Theorem II.35.2 already improves it (note after source 30’s Theorem II.131.3).
- II.27** *Prime cyclic groups with the same target* (12 Question 3): the optimal deterministic density–overlap region for $G = H = \mathbb{Z}/p\mathbb{Z}$, especially for Bohr sets with a common spectrum; the universal construction does not settle it.
- II.28** *Bohr radii: constants, measured growth, anisotropy* (12 Questions 4–6): the best $c(a)$ in finite radius selection ($c(7/8) = 1/8$ is proved); carrying the measured growth ratio instead of 4^d through later stages; separate radii for different characters weighted by $|\widehat{g}(\gamma)|^4$. [6 October 2026; sources 28–33] *Advanced by source 30*: at a fixed radius the translation loss is controlled

by the measured growth $|B(3\rho/2)|/|B|$ (Theorem II.129.3), with unequal widths allowed, and exponential dependence on the rank is necessary (Corollary II.135.5). It asks (Questions 4–5) whether the additive structure of the spectra produced in Section 10 forces D_B far below 3^r , and how to choose anisotropic widths before the map is constructed (merged with source 12’s Question 6).

- II.29** *Directional repair* (12 Questions 7–8): hypotheses under which a small global proportion of bad quadruples forces the uniform collision hypothesis of Theorem II.36.2 (directions with few representations are the difficulty; compare source 07’s caveat that collision is not raw energy), and the best repair region in $(\varepsilon, \kappa, \eta)$, including whether $1 - \chi(\chi(\eta))$ is attained.
- II.30** *Measure and infinite-group analogues* (12 Question 12): translation loss and synchronization for finite-measure subsets of locally compact abelian groups.
- II.31** *The range and the examples of the coset envelope* (14 Question 4): the best universal range of ε for $|A\Delta C| \leq \tau(\varepsilon)|A|$ (now $1/100$), the range forcing coordinate splitting, and all exact envelope examples. *Partial answer (intake observation, checked at the write)*: let H be a subgroup, $K \subseteq H$ a coset of a subgroup L , $k = |K|$, $A = H \setminus K$, $m = |A|$ and $\delta = k/m$. Then $|A \cap (A + d)|$ is m for $d \in L$ and $m - k$ for $d \in H \setminus L$, so $E(A) = km^2 + m(m - k)^2$ and $m^3 - E(A) = mk(m - k) = \delta(1 - \delta)m^3$; as $|A\Delta H| = k = \tau(\delta(1 - \delta))m$ for $\delta \leq 1/2$, every such set with $\delta(1 - \delta) \leq 1/100$ attains the envelope (source 14’s Proposition II.43.4 is the case $H = \mathbb{F}_p$, $K = \{0\}$). [6 October 2026; sources 15–20] Source 15 (its Question 1) asks for the best uniform $\delta(\varepsilon)$ with a Cartesian coset within $\delta(\varepsilon)|A|$ when $Q(A) \geq (1 - \varepsilon)|A|^3$: *its leading constant is 1*, by source 14’s Theorem II.43.3 and Proposition II.43.4 (= source 15’s Example II.52.3); the largest valid range is this item. [7 October 2026; sources 40–46] *Advanced by source 45*: the envelope holds for $\varepsilon < 1/9$ in every abelian group, with the canonical subgroup $\{d : |A \cap (A + d)| > m/2\}$, uniqueness, and all positive equality cases, the punctured cosets $C \setminus K$ with K a subcoset of index at least nine (Theorems II.185.4, II.185.8); a nested-hole envelope with leading constant one (Theorem II.185.11); collision equality forces one punctured coordinate (Theorem II.185.15). Source 45 asks (its Questions 6.6–6.10): the largest range ε_* , and separately the largest ranges for uniqueness and for the autocorrelation threshold (at $\varepsilon = 1/4$ uniqueness fails on $\mathbb{Z}/3\mathbb{Z}$; whether $q(d)(1 - q(d)) \leq \varepsilon$ holds universally (proved with 2ε ; equality on punctured cosets shows that no constant below one works); the maximal range of nested-hole repair and the group-sensitive bound between equality parameters; the best bound for a fixed group and cardinality; stability of collision equality and the labels on near-equality domains.

Added in the fourth write, 6 October 2026 (sources 15–20):

- II.32** *Optimal product-property amplification* (15 Question 5). Are the power $3d - 2$ of χ and the exponents of Theorem II.49.6 optimal under PP_γ alone, or can the reference-cube averaging exploit compatibility between side vectors (starting from Proposition II.53.3)?
- II.33** *Weighted near-extremizers of the cubic cap* (15 Question 7): convert near equality in the weighted cap into a rounding theorem under lower-density or nonconcentration hypotheses; exact saturation forces zero–one weights (Theorem II.56.1 and the remark after it).
- II.34** *Nondegenerate and anisotropic arrangements* (15 Question 8): the error term needed when arrangements must have distinct vertices or side vectors from a prescribed family; a fixed side restriction keeps the moment identity, excluding cross-cube coincidences need not.

- II.35** *Restriction for the higher arrangements* (17 Question 5): the complete short-relation lattice of the configurations of Sections 12 and 15, and a Fejér-type filter controlling every relation class; the missing step before source 17's gain can be propagated.
- II.36** *Spectral data and exactness under restriction* (17 Questions 6–7): keep prescribed Fourier information while restricting, and upgrade a $1 - \eta$ respected proportion to an exact Freiman homomorphism of the same order without losing it. *Partly answered* for exactness from quadruple energy, with polynomial loss, by source 10's Corollary II.21.2; the spectral part is open.
- II.37** *The error-rank distribution* (17 Question 8): inputs where most unrespected tuples have high error rank, combining a small low-rank tail with Theorem II.63.5. [6 October 2026; sources 28–33] Source 29 (its Question 9) asks to optimize its exact signed certificate over the full rank profile $(G_{r,e}, U_{r,e})$.
- II.38** *Degenerate arrangements beyond first order* (18 Questions 1–5). The coefficient of p^{-2} (first $d = 2$, small k), equivalences among nonparity loci, the full moment-order distribution, the intersection lattice of the C_d balanced-subset hyperplanes, small primes $p \leq 2d$ and the case $d = 1$. The placements of sources 22 and 27 record the leading coefficient for $d = 1$ and the second coefficient for $d = 2$; those are for the writes that add them. [6 October 2026; sources 21–27] *Answered for $d = 2$* : the coefficient of q^{-2} is $(k^2 + 21k - 6)/2$ for characteristic $p > 4 \cdot 2^k$ (source 27's Theorem F.32.3); for general d it is $S_{k,d} - \binom{k}{2} - kL_d - b_{2,d,p}$ with one hyperplane statistic $b_{2,d,p}$ unknown (its Corollary II.99.2). The same question is source 22's Question 1 and source 25's Question 1. *The case $d = 1$ is answered in its leading coefficient, $(k^2 + 3k)/p$* , by source 22's Theorem II.85.1, which also answers the leading-coefficient part of source 27's Question 10 (the single-pair regime). *Small characteristic*: the first-order count in every characteristic is source 27's Theorem II.96.3, which answers the counting part of source 25's Question 4 (the classification of the additional components in characteristics two and three is not given) and advances source 22's Question 6 (its balanced count for $p \leq 4d$). Still open: $b_{2,d,p}$ for $d \geq 3$; intermediate characteristics $5 \leq p \leq 2k + 2$ (27 Question 4); exact counts in characteristics 2, 3, 5, 7 (27 Question 5); exactness for $d = 1$ (22 Question 2, item II.42). [7 October 2026; sources 40–46] *Source 27's two questions are answered by source 44*: $b_{2,d,p}$ is characteristic-independent for $p > \max(2d, 16)$ and computed for every d in $O(d^3)$ operations from the nine-point grid, $b_{2,8} = 3,280,234,631,541$ (Theorems II.178.1, II.179.1, II.180.1); the core directions are classified for every $p \geq 5$ (Lemma II.175.1), and the core union is counted exactly in every characteristic (Theorems II.176.2, II.176.3). Still open: third-order terms, exact counts beyond the core in small characteristic, exactness for $d = 1$; source 44's own questions are item II.52.
- II.39** *Exact sampling and interpolation* (19 Questions 1–5): classify the maximizers of the finite minimax (how many distinct class sizes); explicit rates in the sharp law $r\mathcal{M}/q \rightarrow C_d$; anchor selection weighing lost mass against slice cost; going below the scale q/σ with algebraic relations among the rows; robust lifting when rows are only approximately polynomial. [6 October 2026; sources 34–39] *Answered for source 39's rule, open for source 19's*: for the rule that keeps sampled points the maximizers are balanced and capped (source 39's Theorem II.155.3, with an explicit cap for affine classes); for source 19's rule the same formula fails in 199 of 2,835 small cases (note there). Rates are advanced by source 39's two-regime limit (Theorem II.157.3). Source 39 asks (its Questions 1–6, 8 and 9): every maximizing profile and attaining row family; explicit finite corrections to the golden-ratio law; the first maximizing size for $t > 2$; t growing

with the sample; algebra-aware recovery rules with their own bounds; compressing labelled candidate lists; nonuniform column costs; robust recovery when the good classes are unknown.

- II.40** *Proper modular boxes without inherited coordinates* (19 Question 6): replace the inherited-coordinate hypothesis of Corollary II.70.8 by the proper-box predicates of the Lean development, with an explicit width loss. The formal local lift (`section16_local_affine_lift`, `Proofs16LocalAffineLift.lean`, line 13, at `0b4890a1c`) avoids the hypothesis with the weaker width $\sqrt{(m/8)^a}/4$ (note after that corollary). [6 October 2026; sources 21–27] *Advanced by source 23*: its Theorems II.103.6 and II.103.7 need no inherited-coordinate hypothesis and keep width $L_m^A \geq (m/3)^A$ on proper modular boxes, conditionally on the slice covers they assume; whether the formal interface accepts their long final axes is not checked (a formalization candidate). Source 26 (its Question 6) asks how its integer-box almost-cover (Theorem I.44.1) can meet the exact-partition and base-loss requirements of this interface.
- II.41** *A consistent family of structural controls for Lemma 16.10* (19 Question 10): controls that keep the outer parameter dependence, absorb the shared-slice output and are stable under restriction, union, sums, an unused coordinate, slices and interpolation; both displayed closing comparisons fail (Section V.80.2; formally `section16_same_dimension_closing_comparison_fails`). `lemma_16_10` is open at HEAD. [6 October 2026; sources 21–27] Also asked by source 23 (its Question 11: substitute the actual class, anchor and budget counts into its gluing theorem and find control functions closed under every step, with a checked recurrence). [6 October 2026; sources 28–33] Also asked by source 28 (its Question 13: an altered induction invariant that closes the Section 16 comparison with synchronized proper partitions). [6 October 2026; sources 34–39] Also asked by source 39 (its Question 10: replace the invalid closing comparison by a valid dimension-dependent recurrence for scale, graph count and exceptional mass, with endpoint-safe controls carrying a slack factor above one). `lemma_16_10` is still open at HEAD `89c1cbc38`.

Added in the fifth write, 6 October 2026 (sources 21–27):

- II.42** *The structure of the degeneracy locus* (22 Questions 2–5; 25 Questions 2, 3, 7; 27 Questions 1–3, 6, 7). Is $\delta_{k,1}(p) = L_k(p)$ for all large p (22; the intake found equality for $k \leq 3$ at the primes it tested, evidence only)? Degree-two Boolean certificates and a feasible-class filtration in every degree with a valid summation by parts, and a generating function for $J_{k,d}$ (22); a much smaller second-order constant than $U_{k,d}$ (25; answered in substance by source 27's $S_{k,d}$ with a cubic remainder, Theorem II.97.8); the intersection lattice of the cross-section hyperplanes, which is source 27's statistic $b_{2,d,p}$, first for $d = 3$ with its 51 hyperplanes (25, 27); arbitrary defining relations w (25); a third-order structural theorem and the codimension in terms of the minimal Boolean degree (27); whether the count stays polynomial beyond eight vertices (27); minimal moment subfamilies keeping the asymptotics (27).
- II.43** *Efficient degeneracy testing* (25 Question 5; 27 Question 8). Detect a nontrivial ternary moment relation without scanning 3^n patterns or 2^m subset sums, using the $k + H_d$ hyperplanes and the core family as preprocessing, and return a short verifiable certificate of degeneracy or nondegeneracy.
- II.44** *The selection step of Lemma 15.5* (25 Question 6; 27 Question 9). A nonnegative selection kernel distinguishing respected arrangements by more than the ratio $1 + 2^{1-n}$ while keeping manageable degeneracy conditions (25; the exponential loss of (II.92.12) is not removed by better counting); bounds by the actual cross-section distribution of a dense collection instead

of the ambient union bound, avoiding the loss of Proposition II.101.1 (27). [6 October 2026; sources 34–39] Source 35 (its Question 4) asks which nonnegative trigonometric polynomial $K \leq 1$ with nonnegative coefficients best balances the universal signal, the coefficient-stratum mass and the point marginal; source 40’s placement records a kernel-class barrier, for its write. Source 35’s degree-weighted selection itself is in Section II.144; its other questions are item II.50. [7 October 2026; sources 40–46] Source 40 is now printed (Section II.164). It asks (its Question 1) for the optimal finite-bandwidth kernel for fixed s , H , Q and how close Fejér is, with certified positivity; source 44 (its Question 6) for an analogue of its core product for arrangements sampled from a dense set, with explicit conditional-concentration hypotheses.

- II.45** *Common base partitions at Lemma 16.10* (23 Questions 9–10). Avoid the product of width exponents over all sampled slices in Theorem II.103.6 by a joint structural theorem giving one common partition directly; and a width-dependent localization rule that improves the constant $1/3$ when a large lower bound for the child width is known.

Added in the sixth write, 6 October 2026 (sources 28–33):

- II.46** *The critical-norm profile beyond the sharp range* (31 Questions 1–4 and 12). The optimal universal relation between $\kappa(f)$ and the best coset-phase fidelity beyond $1 - \kappa < 1/120$, and where other configurations take over from the two-state curve; the optimal odd-order coefficients (Theorem II.107.3 excludes the order-two mechanism; source 38’s placement records the odd-order modulus, for its write); a quantitative classification of near-equality states of the quartic envelope; the exact feasible region of $(\varepsilon, t, z, \beta)$ in Theorem II.108.1; equality in the mixed derivative inequality for two functions, and analogues for higher Gowers norms. [6 October 2026; sources 34–39] *The optimal odd-order coefficients are source 38’s:* $\mathfrak{S}_{\text{odd}}(\varepsilon) = \varepsilon/4 + 3\varepsilon^2/16 + (\sqrt{2}/64)\varepsilon^{5/2} + O(\varepsilon^3)$, and without the fractional term when $\gcd(|G|, 6) = 1$ (Theorem II.150.11). Source 38 asks next (its Questions 7–10): the ε^3 coefficient and whether the three-point family stays extremal; the coprime-to-six cubic term; a constructive reconstruction from sampled derivative data with near-sharp constants; sharp critical stability for U^d , with critical exponent $2^d/(d+1)$.
- II.47** *Logarithmic selection at Section 10* (28 Questions 1–6). Are both logarithmic losses in $\alpha p(\alpha)/20$ necessary ($\Omega(\alpha/\log(1/\alpha))$ or $\Omega(\alpha)$ with a comparable original-domain spectrum)? Can $O(\alpha^{-3})$ frequencies be reduced, or counted by an independent generating set? The best simultaneous dependence on the defect, the retained fraction and the radius; output order eight or any fixed order; which conclusions survive input order four or two; a certified finite construction faster than enumeration. *Marked question (the intake’s observation, in no source; not checked at the write):* does Theorem F.33.1 with Corollary II.126.2 give the conclusion of the formal `theorem_10_13` (Section10.lean, line 473) with the formal spectrum `domainLargeSpectrum` at λMN , a larger retained set ($1.08 \cdot 10^{-4}$ against $1.07 \cdot 10^{-9}$ at $\alpha = 1/6$) and a larger radius? Missing: a check that the order-eight defect 2^{-21} of source 28 is measured as in `DomainApproxHomOfOrder`, and that $\text{Bohr}(\Gamma, \zeta_\alpha)$ contains the formal Bohr set at `section10Zeta`.
- II.48** *Fixed-radius Bohr invariance* (30 Questions 1–3, 7, 10–11). The exponential rate of $\mathcal{L}_r$ ($\sqrt{3}$, 3 or another base); the prime cyclic case, where the Chinese-remainder obstruction is unavailable; joint sharpness of escape and packing; whether the $5/14$ compatibility threshold is optimal and whether target-fibre information improves $\theta < 1/2$; constraints beyond rectangles (convex constraints, covering numbers in place of 3^r); efficient exact certificates for D_B below 3^r .

II.49 *High-agreement repair of arrangements* (33 Questions 1–5 and 7–10). The optimal common-prime quadratic coefficient, between $(3s - 2)/(4s^2)$ and $2(s - 1)/s^2$ (23/512 and 15/128 at $s = 16$); the optimal cubic coefficient for $s \geq 6$; equality and near-equality in the sharp cubic; the activation threshold $1/(240(s - 1))$ and the global feasible pairs (δ, ε_4) ; sharp bounds from row profiles; nonzero increments and nonrepeated vertices; two-direction testing with repair to a biaffine map; higher multilinear arrangements; fast decoding with certified sample complexity.

Added in the seventh write, 6 October 2026 (sources 34–39):

II.50 *Degree-weighted arrangement selection* (35 Questions 2, 3, 5, 6 and 14). Refine the coefficient strata by the rank of the matrix $(A_{j,T})$ so that several low Boolean moments restrict simultaneously; the exact mass of the balance spaces against μ^{s-D_t} ; fixed characteristic with $\alpha\eta \rightarrow 0$, and targets with small torsion; an intrinsic lower bound on the field size for any selection with the stated purity and count; an efficient algorithm finding B' . Section II.144; the kernel question is merged into item II.44. *Marked question (the intake's observation, in no source; not checked at the write):* does Corollary II.145.3 give the conclusion of the formal lemma_15_5 (Sections14_15.lean, line 414) with an explicit N_0 and retention $\alpha^s \eta^{s-1} / (2(s+2)^s)$, $s = 2^{k+4}$? Missing: a check that the ordered and degenerate conventions of `respectedGeneralArrangementCount` and `generalArrangementCount` match source 35's arrangement count, and that its purity $1/(1 + \eta)$ gives the formal $(1 - \eta)$ form.

Added in the eighth write, 7 October 2026 (sources 40–46):

II.51 *One-stage Fejér selection* (40 Questions 2–5). Improve the exceptional constant $C_{k,s,H}$ by identifying scalar-equivalent or coincident zero sets of the coefficient vectors and their intersections (zero sidelengths and coincident vertices kept); whether a field size of order $\beta^{-(2d-1)}(s/(\alpha\eta))^{2s}$ is necessary for a one-stage theorem of this kind or can be reduced at the same mass, for example by stratifying extra-relation ranks (source 35's degree weighting is one such reduction); comparable selection in characteristic $p \leq 2(L - 1)$, separating coefficient collisions from target torsion; configurations whose feature relations form a lattice of rank greater than one. Section II.164; the kernel question is merged into item II.44 and the class barrier into item II.7.

II.52 *Beyond the second Whitney coefficient* (44 Questions 1–5 and 7). The third Whitney coefficient from a fixed grid in $\{-1, 0, 1\}^3$ with a finite rank-three incidence weight, in polynomially many operations; which non-core directions contribute at order q^{-3} on the regular region; short certified recurrences for the eight lattice energies and their combination B_d ; which primes actually change $b_{2,d,p}$ and whether the cutoff 16 is optimal (the intake found the rational value already for $p \geq 7$ at $d = 3$ and $p \geq 11$ at $d = 4$); the largest k for which nondegenerate d -arrangements exist over a fixed field, against the necessary conditions of Corollary II.176.4; the coefficient alphabet $\{-M, \dots, M\}$ in place of $\{-1, 0, 1\}$. Section II.173; source 44's question on relative distributions is merged into item II.44.

II.53 *The top of the torsion-free energy spectrum* (45 Questions 6.1–6.5). Every set at the third level $M_m - 8(m - 3)$ for large m (two models are known: $\{0, \dots, m\} \setminus \{2\}$ and $\{0, 2, 3, \dots, m - 1, m + 1\}$) and the smallest valid threshold; positive real sets with bounded Schur defect s ; sharp edit or containment bounds when $D(A) = O(m)$ or $o(m^2)$, for example whether $D(A) \leq Km$ puts all but $O_K(1)$ points into one progression of length $m + O_K(1)$; a weighted ordered-completion identity; effective hypotheses on $A \subseteq \mathbb{Z}/p\mathbb{Z}$ that allow the three levels to

be transferred by a Freiman 2-isomorphism. Section II.183. Source 57, placed by 7dc1ee29d and not yet written in, records the complete third level (J_m and one further class for $m \geq 7$) and bounded Schur deficits (for its write).

The eight items carry the nine questions: 02 Subsections 11.1–11.3, 03 Research questions 3–4, and 04 Q4–Q7. [6 October 2026; sources 06–10] With sources 06–10 the eighteen items carry nineteen questions and one question paragraph: also 07 Questions 1–7, 10 Questions 5–7 and the paragraph at the end of 10’s Section II.21. [6 October 2026; sources 11–14] With sources 11–14 the thirty-one items carry forty questions and one question paragraph: also 11 Questions 1–8, 12 Questions 1–9 and 12, and 14 Questions 4–6; item II.21 also records the intake’s marked question. [6 October 2026; sources 15–20] With sources 15–20 the forty-one items carry sixty-eight questions and one question paragraph: also 15 Questions 1–3 and 5–8, 17 Questions 1–9, 18 Questions 1–5, and 19 Questions 1–6 and 10; items II.6 and II.8 also record marked questions of the intake. [6 October 2026; sources 21–27] With sources 21–27 the forty-five items carry one hundred and four questions and one question paragraph: also 22 Questions 1–6, 23 Questions 9–11, 24 Questions 1–9, 25 Questions 1–7, 26 Question 6 and 27 Questions 1–10. [6 October 2026; sources 28–33] With sources 28–33 the forty-nine items carry one hundred and fifty questions and one question paragraph: also 28 Questions 1–6 and 13, 29 Questions 5–12, 30 Questions 1–7, 10 and 11, 31 Questions 1–12 and 33 Questions 1–10. [6 October 2026; sources 34–39] With sources 34–39 the fifty items carry one hundred and sixty-nine questions and one question paragraph: also 35 Questions 2–6 and 14, 38 Questions 7–10, and 39 Questions 1–6 and 8–10. [7 October 2026; sources 40–46] With sources 40–46 the fifty-three items carry one hundred and ninety-two questions and one question paragraph: also 40 Questions 1–5 and 7, 44 Questions 1–7, and 45 Questions 6.1–6.10.

Theme III: cube and progression counts (8 questions)

III.1 *The odd-order constant and the higher-dimensional norm gap* (03 Research question 1; 04 Q3). $c_d^{\text{odd}} = \sup \|f\|_{U^2}^4 / \|f\|_{U^d}^4$ over real centered f on odd-order groups (03), equivalently the best comparison of $\|f\|_{U^d}^{2^d}$ with $\|f\|_{U^2}^{2^d}$ for given group orders (04). *Settled for $d = 3$* (dated note after Theorem III.3.4): $c_3^{\text{odd}} = 2^{-1/2}$. Open for $d \geq 4$: monotonicity gives $\|f\|_{U^2}^4 \leq 2^{-1/2} \|f\|_{U^d}^4$ for $d \geq 3$ (04, after Theorem III.3.6), but its sharpness for $d \geq 4$ is not established. The best odd-order leading coefficient is $R_d c_d^{\text{odd}}$. [6 October 2026; sources 06–10] Source 08’s Question V.34.1 asks for the same constant (κ_d^{odd}) and whether $\kappa_3^{\text{odd}} = 1/\sqrt{2}$: yes, by source 04. Source 09’s Research question on the constrained envelope (item III.17) contains the odd-order leading coefficient relative to $\|f\|_{U^d}^4$ as a special case. [6 October 2026; sources 11–14] Source 14 (its Question 11) asks the same for $d \geq 4$: the first surviving centered correlations of U^d , the sharp real mean-zero comparison with lower norms, and torsion-dependent extremizers. [6 October 2026; sources 15–20] Source 18 (its Question 7) asks for the best fourth-order coefficient without order-two characters, “especially in dimension four”; it is settled at $d = 3$ by source 04’s Theorem III.3.4, which source 18 does not cite. [6 October 2026; sources 21–27] Source 21 (its Question 7) asks for the sharp leading real-centered coefficient in $Q_d(\delta + f)$ for $d \geq 4$ and its first torsion-dependent correction. [6 October 2026; sources 28–33] *Advanced, not settled, by sources 28 and 29* (Section III.66): $c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ and $c_d^{\text{odd}} \leq B_d \downarrow 1/2$ (source 29’s Corollary III.69.1; source 28’s weaker $\sqrt{160/323}$), $c_d^{\text{odd}} \geq 1/3$ for every d , so the limit lies in $[1/3, 1/2]$ (source 29’s Proposition III.69.2, answering source 28’s question on a positive lower bound uniform in d); $c_4^{\text{odd}} \geq 0.5587294$ (source 28) and ≥ 0.5587725 (the intake’s exact certificate on $\mathbb{Z}/7\mathbb{Z}$, a review result; numerical searches suggest about

0.55878, evidence only). Real parts of characters are not extremal for $d \geq 4$ (source 28's Theorem III.70.9), which answers source 03's sub-question and source 29's Question 1 in its second sentence. Among sources 01–33 the bracket is $0.5587725 \leq c_4^{\text{odd}} \leq 0.6914416$; sources 34, 35 and 45, placed and not yet written, record upper coefficients 81/16, 5 and 4795/832 (for their writes). Further asked: the exact c_4^{odd} and whether a bounded number of harmonics suffices, the dependence on character orders and attainment on a fixed group, the asymptotics of c_d^{odd} , and stability near true extremizers (28 Questions 7–11); the limit c_∞^{odd} and whether 1/2 is approached, the sharp profile at fixed self-inverse mass, and stability for actual norm near-minimizers (29 Questions 1–4). [6 October 2026; sources 34–39] Advanced by sources 34 and 35: $\|f\|_{U^2}^4 \leq (2/3) \|f\|_{U^4}^4$ (source 34's Theorem III.71.1; coefficient 81/16 in source 29's normalization) and the weaker coefficient 5 (source 35's Theorem III.72.1, the same day); for $5 \leq d \leq 8$ slightly better bounds than B_d (source 34's Remark III.71.10). Among sources 01–39 the bracket is $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$; source 45, placed and not yet written, records $(832/4795)^{1/4} = 0.6454070$. Further asked: the exact c_4^{odd} , its attainment, and the extremizing supports and phases; stronger coupled certificates; the asymptotics and stability for $d \geq 4$ (34 Questions 7–9); whether the full statistic $J(\lambda)$ determines c_4^{odd} , whether an extremizer lives on a finite cyclic quotient, and higher-order gains from the harmonics of D_d of a cosine (35 Q1); the exact c_4^{odd} and bounded Fourier support, the structure near the minimum, and higher-order gains beyond central-binomial moments (35 Q7–Q9). [7 October 2026; sources 40–46] Advanced by source 45: $\|f\|_{U^4}^{16} \geq (4795/832) \|f\|_{U^2}^{16}$ (Theorem III.90.1), so $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ among sources 01–46, the lower end being the batch-121 certificate; source 45's own lower example gives 0.5574336; source 49, placed by f8bc5e2ec and not yet written in, records 29/4, that is $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$ (for its write). Source 45 asks (its Questions 6.11–6.14): the exact c_4^{odd} , its extremizers and whether it is attained on a finite (cyclic) group; a stronger, possibly sum-of-squares, moment certificate; the Fourier support of an extremizer, whether two character pairs suffice and whether order five is intrinsic; stability, and the constants c_d^{odd} for $d \geq 5$ with possible strict gaps.

III.2 *The fifth and sixth centered coefficients* (03 Research question 2). Classify the supports of sizes 5 and 6 for which (III.2.27) has solutions with no trivial character, with multiplicities and the quotient correlations they need; Lemma III.3.3 does this for $d = 3$ on odd-order groups, and (III.2.29) shows that order three enters. [6 October 2026; sources 06–10] The fifth coefficient is answered by source 09 (Theorems III.20.1, III.21.1, Proposition III.20.2): on every finite abelian group and for every $d \geq 3$, only the star and ternary supports survive, with multiplicities Q_d , S_d and correlations M_5 , $T_{3,5}$. Open: the sixth coefficient, asked also by source 08 (its third question, fifth and sixth orders for general d with their torsion dependence) and source 09 (its Research question 1, a dimension-uniform sextic expansion with a seventh-order remainder); source 09's Theorem III.23.1 shows that an isolated order-five term must appear there. [6 October 2026; sources 11–14] Source 13 (its Question 10) asks how far the low-order terms of higher cube expansions can be expressed through lower uniformity norms and a few spectral moments, first classifying five- and six-circuits for $d = 4$. [6 October 2026; sources 15–20] The sixth order is also asked by source 16 (its Question 10: primitive relation modules for six Boolean vertices in arbitrary dimension) and source 18 (its Question 6: six-vertex small-matrix classification with invariant factors and a remainder bound). [6 October 2026; sources 34–39] Also asked by source 34 (its Question 6: classify the full-support lattice types at the first unresolved support degrees with their multiplicities as functions of d , and express the sixth and seventh coefficients in a finite basis of Fourier statistics).

- III.3** *The secondary extremal coefficient* (04 Q1). Between $(9/4)^{1/3}$ and 6 (display (Q1)); does the limit exist, and is the two-frequency value optimal? [6 October 2026; sources 11–14] Settled by source 14: the limit exists and equals $(9/4)^{1/3}$, uniformly over groups of order coprime to 6 (Theorem III.34.1; in source 04’s normalization, Remark W4). The two-frequency value is optimal; the 6 of Theorem III.3.8 stays an explicit upper bound. What remains is in items III.4 and III.23.
- III.4** *Stability for cube extremizers* (04 Q2), beyond the U^2 stability of Corollary III.3.5, and whether near-optimal secondary behaviour concentrates on $\{\pm\xi, \pm2\xi\}$. [6 October 2026; sources 11–14] Answered for the second part: near-optimal secondary behaviour concentrates on $\{\pm\xi, \pm2\xi\}$ in U^2 , with the amplitude and phase forced (source 14’s Theorem III.34.3), and not in L^2 (the remark after it). Source 14 (its Question 3) asks for an effective version, with explicit dependence on the deficit and u/δ , and for the hypothesis that would give L^2 approximation; the constants c, C of its Theorem III.34.1 are not explicit.
- III.5** *Quantitative rounding and derandomization* (03 Research question 8): the group size needed by the sharpness constructions, and an efficient deterministic rounding. [6 October 2026; sources 06–10] Also 08’s sixth question: a deterministic construction with rounding error $o(\eta^4)$ in U^d , not only against single characters. [6 October 2026; sources 21–27] Source 21 (its Question 9) asks the least dimension needed to realize its exponent-five model by sets through a given order, and for deterministic rounding.
- III.6** *Counting that rectifies automatically* (03 Research question 6): a localized version of Theorem III.1.2 that counts ordinary integer progressions with all boundary errors. The lifting step itself is formal (Lemma III.4.5); its interval hypothesis is what a modular norm does not give. [6 October 2026; sources 15–20] Source 20 (its Question 9) asks for a localization keeping two small balanced norms in every error term.
- III.7** *Progression counting with more of the mixed information* (04 Q10): mixed norms, further cancellation, pairwise information, and non-admissible slopes with explicit subgroup averages. [6 October 2026; sources 06–10] Advanced by source 10: its Theorem III.28.2 needs only one invertible coefficient difference (next to the target), pays an explicit kernel factor $K^{1/2^{k-1}}$ for the others, and uses mixed L^p norms; the factor is sharp on $(\mathbb{Z}/2\mathbb{Z})^n$ for three terms (Proposition III.28.4). Explicit subgroup averages, and the pairwise information, remain open.
- Added in the second write, 6 October 2026 (sources 06–10):*
- III.8** *The optimal density factor in progression counts* (06 Question 6). For $k = 3$ the variance factor of Proposition III.5.6 is sharp (singletons); for $k \geq 4$, the best coefficient in place of $\sqrt{\delta} B_k(\delta)$, first within repeated telescoping and mixed-norm Cauchy–Schwarz proofs. Source 10’s mixed-norm bound $\delta S_k(\delta)\eta$ (Corollary III.29.2) is the corresponding linear statement. [6 October 2026; sources 15–20] Advanced by source 20: its Corollary III.45.4 has a coefficient strictly smaller than source 06’s $\sqrt{\delta} B_k(\delta)$ for every $k \geq 3$ (note there), not claimed sharp for $k \geq 4$. Source 20 (its Question 2) asks for the best three-term coefficient at fixed density, for weights and for indicator sets (source 06’s Proposition III.5.6 has coefficient 1 at singletons only).
- III.9** *Torsion constants in the generalized von Neumann bound* (06 Question 7; 10 Questions 1–2 and the question paragraph at the end of Section III.29). The best constant C in $|\Lambda_{\mathbf{a}}(f)| \leq C \|f_j\|_{U^{k-1}}$ for a fixed group, pattern and target, first for four-term patterns on elementary abelian 3-groups (10); the two-target inequality of source 06’s Theorem III.5.1 when slope

differences have kernels (06); keeping the images cG of Lemma III.28.1 instead of G and exploiting their overlaps, exact constants for larger k and general torsion profiles, and the joint choice of telescoping order and L^p exponents (10). Source 10's Theorem III.28.2 answers the one-target form with explicit, not in general optimal, constants. [6 October 2026; sources 15–20] Answered for the norm-conversion step by source 20: its Theorem III.44.1 gives the optimal constant of the directional-to-global comparison for every subgroup tuple, and its Proposition III.46.1 the sharp pair correction $\sqrt{m-1}$. Source 20 asks for the full multilinear operator norm (its Question 4) and for a quotient-adapted baseline removing large torsion costs (its Question 8).

- III.10** *A correct global lower bound for the cube excess* (08 Question 2; 09 Research question 5). The largest c with $Q_3(F) - \delta^8 \geq c\delta^4 \|F - \delta\|_{U^2}^4$ for all $0 \leq F \leq 1$ on odd-order groups; $2 \leq c \leq 15337/1296 < 12$ (08; the upper end is Remark W1). 09 asks for natural hypotheses under which $M_5 \geq 0$, or a sharper bound on its negative part, giving a corrected lower bound. Minimizing $12 - 2s + 6s^2 + s^4$ over the two-frequency family lowers the upper end slightly; that family is not known to be extremal.
- III.11** *Computing the survivor polynomial* (08 Question 4): $\sum_r A_{d,r}(G)z^r$ faster than by enumerating all subsets, keeping small-characteristic exceptions, with certificates a proof assistant can check. [6 October 2026; sources 11–14] Source 13's coloopless polynomial $\sum_j c_{d,p}(j)z^j$ (its Question 8) is the same object; it suggests organizing the enumeration by flats of the dual matroid, with characteristic-dependent minors kept visible.
- III.12** *Stability of quartic-coefficient extremizers* (08 Question 5; 09 Research question 4). Structure of f when $R_d E_4(f) + T_d E_{\langle 2 \rangle}(f)$ (09: $P_d E_4 + T_d T_2$) is nearly $A_d \|f\|_{U^d}^4$: concentration on one or a few characters; on odd-order groups the extremal model is not known. A different problem from item III.4. [6 October 2026; sources 15–20] Also source 16 (its Question 12: near-maximizers of the complete cube polynomial under fixed lower-order norms) and source 18 (its Question 8: stability of B_d -sharpness, separating weights from indicator sets).
- III.13** *Cube expansions localized to intervals, progressions or Bohr sets* (08 Question 7; 09 Research question 6). Which of the three exact cancellations survive when the cube is restricted, with explicit boundary terms; 09 suggests expanding around a weighted reference measure adapted to the interval.
- III.14** *Sparse majorized weights* (08 Question 8): a transfer of the inhomogeneous expansion (Theorem III.13.1) to sparse weights with an explicit error budget, expanding around the majorant model.
- III.15** *Other linear systems* (08 Question 10; 09 Research question 9). For a fixed system of integer linear forms, the least support size at which a centered term survives and the first torsion-sensitive terms, combined with true-complexity estimates to get the correct first nonzero power; progressions need not inherit the cube's three cancellations. [6 October 2026; sources 15–20] Source 20 (its Question 11) asks for the subgroups $L_i(\ker L_j)$ of integer matrix forms through Smith normal forms or determinantal ideals.
- III.16** *The prime-onset function* (09 Research question 2): $h(7)$, $h(11)$, and the gap between (III.23.4) and $h(\ell) \leq \ell + 2$; known $h(2) = 4$, $h(3) = 5$, $h(5) = 6$. [6 October 2026; sources 34–39] Answered by source 34: $h(p) = D_{\text{div}}(p) + 1$, the least order of a nonsingular 0/1 matrix whose determinant is divisible by p (Theorem III.75.2); $h(7) = 7$, $h(11) = h(13) = h(17) = 8$

(Theorem III.76.2); $h(p) \sim h_{\text{cyc}}(p) \sim 2 \log p / \log \log p$, so the gap to $h(\ell) \leq \ell + 2$ is closed to leading order (Theorem III.79.1); universal positivity costs a factor two (Section III.80). Still asked (34 Questions 1–2): is $h(p) = h_{\text{cyc}}(p)$ for every prime, and the second-order term (coefficient between 1 and 3).

- III.17** *The constrained extremal envelope* (09 Research question 3): the largest $\mathcal{C}_d(F)$ at fixed d , δ , $\|F - \delta\|_{U^d}$, $\|F - \delta\|_{U^2}$ and $\max |\widehat{F - \delta}|$. [6 October 2026; sources 11–14] Source 13 (its Question 9) asks the same at $d = 3$ with $\delta, \rho, \eta, \sigma$ fixed, and which values of T_5, B_1, B_2, B_3, T_7 are jointly realizable (Theorem III.31.5). [6 October 2026; sources 15–20] Source 16 (its Question 11) asks for sharp remainder estimates in terms of lower Gowers norms, the density and the torsion profile. [6 October 2026; sources 34–39] Source 34 (its Question 10) asks the same at $d = 4$: $\sup Q_4(F)$ at fixed density and fixed $\|F - \delta\|_{U^4} = u$, bounding the quartic contribution and the remainder jointly through their Fourier phases.
- III.18** *A residual-sensitive inverse step* (09 Research question 7): whether the sixth-order certificate (III.21.11) and estimates of the four Fourier statistics improve a concrete inverse or counting algorithm, with a full cost analysis.
- III.19** *Polynomial colourings of higher degree* (10 Question 8). For $D_\ell > k$ only the bound of Proposition III.30.5 is known; for $k = 4$ and a scalar degree 5 or 6 the largest dimension lies between 4 and 8; start with dimension five. Proposed by source 10, not an established conjecture. [6 October 2026; sources 11–14] Source 14 (its Question 7) restates this problem (scalar degree five, $k = 4$, $4 \leq d \leq 8$, beginning with dimension five); its Proposition III.36.7 rules out the first norm extension in characteristic five but not other quintic maps. [6 October 2026; sources 21–27] Also asked by source 22 (its Question 8). *Advanced by source 22*: the pointwise budget eight is sharp at a prescribed centre ($N_3 + N_5$, Section III.62), so no argument that works centre by centre can lower it; every extension $x_0 + N_3(u) + R(w)$ by an independent block fails (Theorem III.64.2, with the exact excess in Theorem III.64.3); and norm layers of degree divisible by the characteristic carry a quantitative excess (Theorem III.65.3). The range $4 \leq d \leq 8$ is not closed. [6 October 2026; sources 34–39] Also asked by source 38 (its Question 13: can a genuinely coupled quintic construction exceed dimension four, or does a global argument force less than eight?); its six-term count does not resolve the gap.
- III.20** *Stability at the dimension threshold* (10 Question 9): must an avoiding colouring at $d = \sum_\ell [D_\ell/2]^2$ resemble the odd-degree norm construction, first in the cubic four-dimensional case? [6 October 2026; sources 11–14] Source 14 (its Question 8) asks to classify the exact extremizers: all cubic maps at the threshold in dimension four and the possible centre-dependent subspaces $S_z(Q)$ above it; the example $x + y^2$ excludes a fixed kernel. [6 October 2026; sources 21–27] Source 22 (its Question 10) asks to classify all pointwise extremizers for a given evaluation matrix; its Theorem III.63.1 (all scalar quadratic minimizers) is a first instance of source 14’s Question 8.
- III.21** *Actual colours against declared coordinates* (10 Question 10): can a map with more coordinates but a small image beat the full-palette exponent of Theorem III.30.3? [6 October 2026; sources 11–14] Source 14 (its Question 10) asks the same: replace the degree-vector budget by an invariant of the actual image.
- III.22** *Unrestricted symmetric-progression colourings* (10 Question 11). Deng, Tidor and Zhao ask whether $N^{o(1)}$ colours suffice to avoid nontrivial symmetrically coloured four-term progressions

[37]; Shi and Dong give $O(N^{1/4})$ [33]. An open question of the literature, recorded by source 10; its theorem only limits one bounded-degree polynomial model.

Added in the third write, 6 October 2026 (sources 11–14):

III.23 *Beyond the secondary coefficient* (14 Questions 1–2). On groups of exponent five: does $M_{\delta,G}(u) = \delta^8 + 6\sqrt{2}\delta^4u^4 + C_5\delta^2u^6 + o(u^6)$ hold, and is $C_5 = 2^{3/4}/3$ (Theorem III.35.2 gives the exponent and a lower model; the intake’s adversarial search gave 0.56062 on $\mathbb{Z}/5\mathbb{Z}$ and 0.5626 on $(\mathbb{Z}/5\mathbb{Z})^2$ against $2^{3/4}/3 = 0.56060$, numerical evidence only)? Elsewhere, the first term after $C_*\delta^{8/3}u^{16/3}$, where order seven already changes the norm formula. [6 October 2026; sources 21–27] *Source 14’s Question 1 is answered by sources 21 and 23: the limit exists and $C_5 = 2^{3/4}/3$, uniformly in the rank, with an absolute $O(u^8)$ remainder (source 21’s Theorem F.26.1, source 23’s Theorem III.58.1). The terms beyond are item III.27. The “elsewhere” part (source 14’s Question 2) is open, and is also asked by source 21 (its Question 6: exponent-three groups, and mixed odd torsion by the order of the largest character) and source 23 (its Question 8: mixed torsion groups, with and without conditioning on the dominant character order).*

III.24 *Second-minimum direction counts* (14 Question 9): the next attainable $|S_z(Q)|$ in dimensions $d \geq B + 2$, and over nonprime fields in dimension $B + 1$ (Proposition III.36.6 is prime-only).

Added in the fourth write, 6 October 2026 (sources 15–20):

III.25 *The exponent of symmetric counting* (20 Questions 1 and 3). For fixed $k \geq 4$ and density bounded away from 0 and 1, the largest θ with $|\Lambda_k(1_A) - \delta^k| \leq C_{k,\delta}u^\theta$ uniformly over admissible groups ($\theta \geq 2$ is proved; optimal for $k = 3$ on $\mathbb{F}_{29}^{2m}$, Theorem III.48.3); and a prime-cyclic analogue of the sharpness construction.

III.26 *Equality, stability and extensions of the two-function argument* (20 Questions 5–7): equality in Theorem III.43.3 beyond constants and stability near it; an exact optimization of second-order elimination with unequal densities; systems admitting two uniformity norms and several L^p factors.

Added in the fifth write, 6 October 2026 (sources 21–27):

III.27 *The eighth-order term in exponent five* (21 Questions 1–5 and 8; 23 Questions 2 and 7). Does the universal coefficient of u^8 exist, and is it 20/9 (21, 23: Theorem F.26.1 bounds it, Corollary III.55.2 gives at least 20/9; the intake’s search on $(\mathbb{Z}/5\mathbb{Z})^2$ found nothing above the lifted model, evidence only)? Is it 20/9 on every fixed $\mathbb{F}_5^n$, with extremizers depending on one functional? A quantitative eighth-order stability theorem, and explicit bounds turning the deficit below $2^{3/4}/3$ into phase, amplitude and tail errors (21, 23). The u^{10} and u^{12} terms on $\mathbb{Z}/5\mathbb{Z}$ and how far the analytic maximizing branches continue (21). Optimal constants and simultaneous equality cases of the profile inequalities of Theorem III.51.2 (21). [6 October 2026; sources 34–39] *Answered by source 38 in the stated ranges: for $u/\delta \leq 10^{-5}$ the exponent-five maximum reduces exactly to $\mathbb{Z}/5\mathbb{Z}$ on every group of exponent five, every maximizer factoring through a homomorphism onto $\mathbb{Z}/5\mathbb{Z}$, so the universal u^8 coefficient exists and is 20/9 on every $\mathbb{F}_5^n$ (Theorem III.84.1); the u^{10} and u^{12} coefficients are $869/(216 \cdot 2^{3/4})$ and $65759/(5832 \cdot 2^{3/2})$ (Theorem III.85.1), and for every fixed odd exponent m there is a cyclic reduction for $u/\delta \leq 10^{-8}m^{-8}$ (Theorem III.86.1); quantitative off-quotient control (Corollary III.84.2) advances the stability question. Source 38’s own further questions are item III.30.*

III.28 *Pointwise and global pattern minima* (22 Questions 9 and 11–14). For which patterns and degree caps is $q^{\max(n-B,0)}$ attained by one polynomial at every centre; surjectivity of reflection maps beyond complete norm cores, and lower bounds for every fibre; defect formulas for five or more odd norm layers; stability of the zero-defect classification (Corollary III.64.4); norm lines in degrees not divisible by the characteristic. [6 October 2026; sources 34–39] Advanced by source 38 for the linear–cubic–quintic core: an exact six-term count with a quadratic-character correction and a zero-defect classification (Theorem III.88.2). Source 38 asks (its Questions 11–12) for the eight-term and higher defects (degrees 1, 3, 5, 7) and a stability theorem for small extension defect.

Added in the seventh write, 6 October 2026 (sources 34–39):

III.29 *Binary determinants, cyclic detectors and positive supports* (34 Questions 3–5). Can every integer up to $\exp(\frac{1}{2}N \log N - o(N \log \log N))$ be the sole nonunit Smith factor of a binary matrix of order N , or at least can the coefficient of $N \log \log N$ be pushed below one (Theorem III.78.1 has one, through Shitov’s composition)? The exact $h_{\text{pos}}(m)$ over a substantial range, when $h_{\text{pos}}(m) \leq 2h_{\text{cyc}}(m)$ is strict, and its second-order term; the least affinely independent Boolean configuration with a prescribed finite abelian row quotient and all coordinate generators nonzero.

III.30 *Quotient reduction in exponent five and odd exponent* (38 Questions 1–6). The supremum c_5^* of the ranges $u/\delta < c$ with exact five-point reduction (proved: $c_5^* \geq 10^{-5}$) and what first destroys it; whether the odd-exponent cutoff $10^{-8}m^{-8}$ must depend on m , or a sequence of noncyclic extremizers with parameters tending to zero; the cyclic profiles $\mathcal{M}_{1,\mathbb{Z}/m\mathbb{Z}}(t)$ for small odd m and their arithmetic transitions; an exact algebraic description of the five-point branch and the first nonzero term of $\alpha(t) - \pi/10$; optimal constants in the quotient-stability bounds (the factor 256 is not optimized); the constrained weighted profile once the five-point function reaches 0 or 1, and how fast indicator sets approximate it.

The seven items carry the eight questions: 03 Research questions 1, 2, 6 and 8, and 04 Q1–Q3 and Q10. [6 October 2026; sources 06–10] With sources 06–10 the twenty-two items carry thirty-three questions and one question paragraph: also 06 Questions 6–7; 08 Questions 1–8 and 10; 09 Research questions 1–7 and 9; 10 Questions 1–2 and 8–11, and the paragraph at the end of 10’s Section III.29. [6 October 2026; sources 11–14] With sources 11–14 the twenty-four items carry forty-four questions and one question paragraph: also 13 Questions 8–10 and 14 Questions 1–3 and 7–11. [6 October 2026; sources 15–20] With sources 15–20 the twenty-six items carry sixty questions and one question paragraph: also 16 Questions 10–12, 18 Questions 6–8, and 20 Questions 1–9 and 11. [6 October 2026; sources 21–27] With sources 21–27 the twenty-eight items carry seventy-nine questions and one question paragraph: also 21 Questions 1–9, 22 Questions 8–14, and 23 Questions 2, 7 and 8. [6 October 2026; sources 28–33] With sources 28–33 the twenty-eight items carry eighty-eight questions and one question paragraph: also 28 Questions 7–11 and 29 Questions 1–4. [6 October 2026; sources 34–39] With sources 34–39 the thirty items carry one hundred and eleven questions and one question paragraph: also 34 Questions 1–10, 35 Questions 1 and 7–9, and 38 Questions 1–6 and 11–13. [7 October 2026; sources 40–46] With sources 40–46 the thirty items carry one hundred and fifteen questions and one question paragraph: also 45 Questions 6.11–6.14.

Theme IV: floor patterns (7 questions)

- IV.1** *The second-order carry entropy* (01 Question 1; the remainder of 04 Q8). Is there a $-k \log_2 k$ term in $\log_2 C_k$, or is $\log_2 C_k = k^2 + O(k)$? Theorem IV.2.3 leaves exactly this scale; counting the hyperplane intersections that meet the open cube is the suggested route. The leading constant 1 is settled (dated note at 04's Q8). [6 October 2026; sources 06–10] Source 06's Question 2 asks the same; its Theorem IV.7.6 settles the leading constant independently and uniformly modulo M .
- IV.2** *Exact counts, arrangement structure, certified C_5 and A_4* (01 Question 2; 04 Q8, its computational part). A recurrence, an intersection-poset formula or a symmetry-reduced enumeration for C_k and A_k (01); certified counts for $k = 4$ (04): $C_4 = F_4 = 154$ is certified by source 01, A_4 is not. *Intake values, not certified:* $C_5 = 8410$ and $A_4 = 770$, from value-branching floating-point linear programs with every feasibility witness re-evaluated exactly. The infeasibility branches rest on solver status, not on rational certificates. Missing: rational certificates, for instance from source 01's or source 04's certificate generator, whose formats both handle these dimensions in principle. The values satisfy the proved bounds (note in Section IV.6). [6 October 2026; sources 06–10] Source 06's Question 1 asks for a structural formula or recurrence for C_k and D_k (its D_k is the A_k here), from the certified $C_4 = 154$ and $D_3 = 38$, and warns that an OEIS match must identify the objects, not a prefix. Source 06 certifies $C_4 = 154$ a second time; it does not compute C_5 or $D_4 = A_4$.
- IV.3** *The modulus dependence and the realizable profiles* (01 Question 3; 04 Q9). When modular collisions stabilize, and the exact number of translation classes as a function of M (01); which global and fixed-slope profiles actually occur for slopes from a short discrete interval, whether an average multiplicity can replace the worst case 2^k , and small moduli (04). [6 October 2026; sources 06–10] Also source 06's Questions 3 and 4: the ratio $C_{k,M}/C_k$ (or its logarithmic scale) for $M = 2, 3$, and an exact formula for the number $L_k(r, M)$ of affine translation classes in the saturated range $2r \geq M$.
- IV.4** *Reducing the selection loss* (01 Question 4). Which orthogonality or positivity hypotheses allow a phase-removal interface to lose L^{-1} instead of L^{-2} ; for arbitrary complex summands the L^{-2} loss is sharp. Source 04's Lemma IV.6.6 already replaces B_k^2 by $2^k B_k$ through local multiplicity. [6 October 2026; sources 06–10] Source 06's Question 5 asks the same for its Theorem IV.8.1: an orthogonality or energy-weighted decomposition that pays only for the classes carrying energy.
- IV.5** *Polynomial floor entropy beyond the leading term* (01 Question 9): secondary terms of $\log_2 |\mathcal{P}_{n,d}(r)|$ and the transition when $\log r \asymp n$.
Added in the second write, 6 October 2026 (sources 06–10):
- IV.6** *Carry entropy of other coefficient families* (06 Question 11): which finite families $V \subset \mathbb{Z}_{\geq 0}^k$ have carry entropy comparable to rank times the logarithm of their size, and, for signed families, the lower-dimensional floor-boundary obstruction first (source 06's remark after Theorem IV.7.3; source 01's example before Section IV.4).
Added in the fourth write, 6 October 2026 (sources 15–20):
- IV.7** *The best local phase-removal coefficient* (16 Questions 1–4). The largest $c_k(C)$ for cells between $m/(3k)$ and Ckm (the $k \log k$ order is settled by Theorem IV.13.2 and Proposition IV.13.5; a

factor exponential in k remains); a coefficient $2^{-O(k \log k)}$ with cells of size $O(m)$ (source 04's Theorem IV.6.7 keeps short cells at $2^{-k^2+O(k)}$, source 16's Proposition IV.14.2 at a global count); nonuniform windows keeping all weights; localization for nonclassical torsion-valued phases. Related to item IV.4.

Added in the seventh write, 6 October 2026 (sources 34–39):

IV.8 *Symmetry certification beyond the threshold theorem* (36 Questions 1–6, 10 and 11). All endpoint configurations (f, σ) with $\mathcal{A}_f(\sigma) = \vartheta_{k,p}$ beyond products of linear functionals; stability at the threshold, in a metric to be chosen first; a joint rank invariant for simultaneous alternating defects; below-threshold coherent rank reduction for one-function derivative arrays; versions localized to progressions or Bohr sets with explicit boundary errors that would refine Proposition 17.7 (Section IV.10 has source 16's local extraction); removal of lower-order multiaffine components; certification from a coefficient tensor and sampled derivative coefficients with a robust margin; inverse arguments in which the selector arrives with energy a and $p > k/a$ without destroying the advantage.

IV.9 *Small characteristic and composite moduli* (36 Questions 7–9). Repeated-variable identities forced near energy one in small characteristic, so that a sharp threshold certifies the hypotheses of a nonclassical integration theorem; optimal bilinear factors from the elementary divisors of the alternating bicharacter over odd composite exponent, and an exact threshold over $\mathbb{Z}/m\mathbb{Z}$; an explicit characteristic-two version, deciding which parts keep the threshold $1 - 2^{-k}$. Sources 43 and 46, placed and not yet written, record characteristic-two results (for their writes). [7 October 2026; sources 40–46] *Answered for symmetric trilinear forms over $\mathbb{F}_2^n$* by sources 46 and 43 (exact energy $2^{-r/2}$, codimension $r/2$; Section IV.25); over $\mathbb{F}_2$ the threshold $1 - 2^{1-d}$ certifies nonclassical integrability in every degree (source 43's Theorem IV.38.4); on every finite abelian group the orthogonality factor d_B^{-1} and the symmetry threshold $1 - (1 - 1/p_*(G))^k$ (Theorems IV.35.2, IV.36.4). Still asked: a spectral identity detecting the p -repetition conditions in odd small characteristic (43 Q5); integration on composite groups from elementary divisors (43 Q6); a sharp mixed cube inequality controlled by rank C_T over $\mathbb{F}_p$ at degree $p + 1$ (46 Q6).

Added in the eighth write, 7 October 2026 (sources 40–46):

IV.10 *Binary cubic norms and Boolean integration* (43 Questions 1–4 and 7–9; 46 Questions 1–5 and 7–9). Whether the quartic extremum stabilizes, $\mathcal{M}(C_{4,n}) = 11/16$ for every $n \geq 2$ (first $n = 3$; proved: $11/16 \leq M_{4,n} \leq 3/4$); the exact seven-function supremum for a symmetric binary trilinear form, whether it depends only on rank C_T , and whether the exponent $r/4$ and the codimension coefficient two are optimal (43 Q2, 46 Q1); all extremizers of the cubic norm, and stability from near-extremal energy to an exact extremizer in a dimension-free way (43 Q3, 46 Q2–Q3); the families $z \mapsto \Omega_z$ that arise from symmetric d -linear tensors for $d \geq 5$; the ordinary slice-rank repair number $\rho(T)$ between $r/2$ and r ; the extremum over a prescribed root-of-unity alphabet (fourth roots give $7/16 < 1/2$ on $\mathbb{F}_4$); the largest integrable subspaces of the trace tensors for $d \geq p + 2$, and Frobenius-twisted trace families; robustness before exact symmetry, with each loss tracked; a boundary-sensitive local twirl on boxes or Bohr sets; an inverse-theorem regime producing a selector above the certification threshold; removal of multiaffine offsets, given the constant and lower-order terms of `IsMultilinear`. Section IV.25; the odd-characteristic and composite questions are merged into item IV.9. Source 47, placed by `f8bc5e2ec` and not yet written in, records the maximum $1 - (d + 1)/2^d$ for C_d in every degree and dimension, which would answer the first question (for its write).

The five items carry the seven questions: 01 Questions 1–4 and 9, and 04 Q8–Q9. [6 October 2026; sources 06–10] With sources 06–10 the six items carry thirteen questions: also 06 Questions 1–5 and 11. [6 October 2026; sources 15–20] With sources 15–20 the seven items carry seventeen questions: also 16 Questions 1–4. [6 October 2026; sources 34–39] With sources 34–39 the nine items carry twenty-eight questions: also 36 Questions 1–11. [7 October 2026; sources 40–46] With sources 40–46 the ten items carry forty-six questions: also 43 Questions 1–9 and 46 Questions 1–9.

Theme V: integration and formalization (8 questions)

V.1 *A complete, audited propagation through one argument* (01 Question 10; 02 Subsection 11.4; 03 Research question 7; 04 Q11). All four sources ask for a dependency graph of the quantitative parameters, into which the local improvements are substituted. Every later threshold would then be recomputed under the same hypotheses, ending in an explicit final bound, compared with the original argument and with Leng–Sah–Sawhney. Source 02 proposes the length-four proof as a first target; source 03’s Proposition V.12.1 supplies the final bookkeeping. Source 01 adds that the issue flagged at Corollary 16.11 must be resolved first. That issue is still open at HEAD (`corollary_16_11`, `theorem_18_1`). [6 October 2026; sources 06–10] Also asked by source 06 (Question 10: close the structural estimates around Sections 13 and 16 and Theorem 18.1 first, keeping the local gains as parameters), source 07 (Question 8: which bottleneck dominates after its exactification, in a fully tracked bound) and source 09 (Research question 10: locate a step whose final bound actually depends on the cube excess). At HEAD of the second write `corollary_16_11`, `theorem_18_1` and `theorem_18_2` are still open. [6 October 2026; sources 11–14] Also asked by source 12 (its Questions 10–11: reprove the later local-model inputs of Sections 13 and 16 with its Theorem II.40.2, and a verified parameter calculus), source 13 (its Question 11: the best complete bound of the existing architecture after the linear and real-valued replacements) and source 14 (its Question 12: insert its profile and geometric denominators into a whole extraction chain). [6 October 2026; sources 15–20] Also asked by source 15 (its Question 4: how much of the coupled gain survives Sections 15–18, through a parameter ledger carrying $(\beta, \gamma, \chi, \rho_3)$), source 16 (its Question 13: substitute the new cell scale and recurrence thresholds), source 18 (its Question 12: a checked Lemma 15.5 threshold and a checked conditional partition transfer first), source 19 (its Question 12) and source 20 (its Question 10). At HEAD `0b4890a1c lemma_16_10`, `corollary_16_11`, `theorem_18_1` and `theorem_18_2` are still open. [6 October 2026; sources 21–27] Also asked by source 21 (its Question 11: identify a downstream theorem that uses the characteristic-five cube count before claiming an improvement), source 22 (its Question 7), source 25 (its Question 8) and source 27 (its Question 11: a complete Section 15 threshold audit through Lemma 15.6). At HEAD `2dfe46f44 lemma_16_10`, `corollary_16_11`, `theorem_18_1` and `theorem_18_2` are still open. [6 October 2026; sources 28–33] Also asked by source 28 (its Questions 12, 14 and 15: propagate through Section 13, an end-to-end explicit density increment, and a bridge to modern inverse theorems), source 29 (its Question 13: a complete quantitative substitution), source 30 (its Questions 8–9: propagate its radius through Theorem 10.13 and find which losses dominate), source 31 (its Question 13: a checked quantitative application at one progression length) and source 33 (its Question 12: actual propagation through the Gowers pipeline). At HEAD `5d4718772 lemma_16_10`, `corollary_16_11`, `theorem_18_1` and `theorem_18_2` are still open. [6 October 2026; sources 34–39] Also asked by source 34 (its Question 11: recompute a normalized scheme with its cube bound and rigidity threshold), source 35 (its Question 13: the graded selection inserted

into the whole corrected argument), source 37 (its Question 7: rework the degree induction with the short-step estimate, then propagate only verified improvements) and source 38 (its Question 15: a density-increment or transference argument in which one of its local statements survives). `lemma_16_10`, `corollary_16_11`, `theorem_18_1` and `theorem_18_2` are still open at HEAD 89c1cbc38. [7 October 2026; sources 40–46] Also asked by source 40 (its Question 6: the bounds that result from substituting its Corollary II.170.1 into the later steps, with a parameter ledger), source 44 (its Question 9: the complete Section 15 propagation of its principal term and incidence coefficient) and source 45 (its Question 6.16: a complete argument in which one of its local gains survives). `corollary_5_8` is now exact; `corollary_16_11`, `theorem_18_1` and `theorem_18_2` are still open at HEAD 6d4942222.

V.2 Formal libraries, and formalizing sharpness (02 Subsection 11.7; 03 Research question 9; 04 Q12; 05 paragraph 7). A characteristic-independent library: weighted Fourier energy on $G \times \widehat{G}$ and real phase freezing (02); integer linear forms, centered multilinear averages and character constraints with torsion data (03); the low-risk interfaces first, namely moment interpolation, the telescope and the support enumeration, then the selection theorem (04); and sharpness as well as existence, starting with the parity obstruction for $1/3$ and the residual inequality (I.19.4) (05). The write adds one concrete gap. Source 02’s Theorem I.11.1 could become formal now that `corollary_5_6_holds` and `polynomial0n_affine_pullback` exist; what is missing is the transfer of cells back to the input progressions and the selection step. The lifting lemma (Lemma III.4.5) is already formal. [6 October 2026; sources 06–10] Also source 08 (Question 9: the elementary fourth-order bound and the quartic torsion formula as separate verified modules, with the unnormalized target (V.32.1)) and source 09 (Research question 8: a library of reindexing equivalences and integer-lattice certificates for Boolean affine forms, keeping non-prime groups). [6 October 2026; sources 11–14] Also source 11 (its Question 9: the support-pattern and colour-comparison layer as a Mathlib development connected to the Section 6 statements) and source 13 (its Question 12: the finite sharp statements and their extremizers as reusable Lean lemmas, beginning with weighted selection). [6 October 2026; sources 15–20] Also source 15 (its Question 9: the division-free interpolation and the collision-parametrized product step), source 16 (its Question 14: the certificate theorem and the window geometry first), source 17 (its Question 10: choose L by a verified finite search), source 19 (its Question 11: the hypergeometric identity, the marked-sample bound, the minimax construction and the interpolation theorem) and source 20 (its Question 12: the two-function theorem, the index comparison and the second-order telescope, root-free). [6 October 2026; sources 21–27] Also source 21 (its Question 10: the 34-monomial five-point certificate and the sextic support identities by a small trusted evaluator), source 22 (its Question 15: $J_{k,2}$, $\delta_{1,1}(p)$, the weighted cumulative-sum lemma and the evaluation-matrix minimum), source 23 (its Question 12: the semigroup and mixed-radix lower bounds first), source 24 (its Question 10: the selector, walk injection, fibre compression and compiler over general finite sets), source 26 (its Question 5: the pair-counting, residue-partition and signed-mass lemmas, composed into the $k = 1$ instance of `corollary_5_8`) and source 27 (its Question 12: the first-order theorem, then $d = 2$, then the exact count with a verified rational-incidence checker). [6 October 2026; sources 28–33] Also source 30 (its Question 12: the escape theorem, the packing theorem and the margin-preserving extension, with endpoint-safe non-return and opposite-sign tube disjointness as the main obligations) and source 33 (its Question 11: the auxiliary-label correction, affine separation, proper-coordinate independence and the one-error identity, starting from the rational inequality $\varepsilon_s \geq s\delta - 2s(s-1)\delta^2$). [6 October 2026; sources 34–39] Also source 35 (its Question 15: one library for weighted configurations, so that later refinements change only

a rank estimate, a coefficient mass or a finite energy identity), source 36 (its Question 12: the eigenspace-multiplicity proof from finite-dimensional spectral theory, connected to the global phase-extraction predicate), source 37 (its Question 9: certified algebraic extremizers, first the lower-bound track), source 38 (its Question 14: the centered cube coefficients, energy coercivity, the field-fibre count and the Weyl-coset expansion) and source 39 (its Question 7: the sampler at `Section16SampledOrAnchoredOn`, then labelled hereditary refinement with a dependent list type). [7 October 2026; sources 40–46] Also source 40 (its Question 8: the one-feature relation theorem, the positive-kernel moment and the score selection as reusable components, with the finite checks generated from the same definitions), source 41 (its item 5: the finite-group mass and variance lemmas, residue partitions, explicit recurrence and numerical induction composed into the pinned predicate; the repository has since formalized the whole interface by its own route, Section V.1), source 43 (its Question 10: the projective eigenvalue-multiplicity argument, the Boolean primitive formula and a small proof object for the quartic value), source 44 (its Question 8: the smallest trusted checker for the eight-shape formula and $b_{2,8}$), source 45 (its Question 6.15: the energy identity, the unit-Schur-defect lemma, the complement identity and the rational U^4 certificate) and source 46 (its Question 10: certificates for the symplectic decomposition, the residual integrator and the extremal value).

Added in the second write, 6 October 2026 (sources 06–10):

V.3 *Finite corrections to the iteration potential* (06 Question 9). The leading cost of Theorem V.25.2 is optimal for its abstract rule; asked are a minimal discrete correction or an exact dynamic-programming potential with a usable closed form, and the treatment of density-dependent length prefactors and nonmonotone thresholds without worst-case replacement.

The two items carry the eight questions: 01 Question 10, 02 Subsections 11.4 and 11.7, 03 Research questions 7 and 9, 04 Q11–Q12, and 05 paragraph 7. [6 October 2026; sources 06–10] With sources 06–10 the three items carry fourteen questions: also 06 Questions 9–10, 07 Question 8, 08 Question 9 and 09 Research questions 8 and 10. [6 October 2026; sources 11–14] With sources 11–14 the three items carry twenty questions: also 11 Question 9, 12 Questions 10–11, 13 Questions 11–12 and 14 Question 12. [6 October 2026; sources 15–20] With sources 15–20 the three items carry thirty questions: also 15 Questions 4 and 9, 16 Questions 13–14, 17 Question 10, 18 Question 12, 19 Questions 11–12, and 20 Questions 10 and 12. [6 October 2026; sources 21–27] With sources 21–27 the three items carry forty questions: also 21 Questions 10–11, 22 Questions 7 and 15, 23 Question 12, 24 Question 10, 25 Question 8, 26 Question 5 and 27 Questions 11–12. [6 October 2026; sources 28–33] With sources 28–33 the three items carry fifty questions: also 28 Questions 12, 14 and 15, 29 Question 13, 30 Questions 8, 9 and 12, 31 Question 13 and 33 Questions 11–12. [6 October 2026; sources 34–39] With sources 34–39 the three items carry fifty-nine questions: also 34 Question 11, 35 Questions 13 and 15, 36 Question 12, 37 Questions 7 and 9, 38 Questions 14–15, and 39 Question 7. [7 October 2026; sources 40–46] With sources 40–46 the three items carry sixty-eight questions: also 40 Questions 6 and 8, 41 item 5, 43 Question 10, 44 Questions 8–9, 45 Questions 6.15–6.16, and 46 Question 10.

Further limitations stated by the sources (kept in place; listed here for the standing rule). Sharpness of the density transfer holds in the weighted model, not for arithmetic characters (01, Remark I.2.2). The constants 36π and $3/4$ are not claimed optimal (05). Sharpness of the simultaneous exponent is for linear phases, uniform arcs and symmetric widths (05). The coefficient 6 of the $u^{16/3}$ term is not claimed optimal, and the higher-dimensional constant $P_d/\sqrt{2}$ is not claimed sharp (04). The restriction theorem is prime-only and does not prove the Lean Lemma 9.3 or Corollary 9.4

(04). $PP(K, R_0)$ is an imported input (02). The elementary Balog–Szemerédi–Gowers bound is far weaker than Reiher–Schoen (03). R_d is not claimed to be the optimal odd-order constant (03; it is not, for $d = 3$). Finite and numerical checks prove nothing general (all five). No source has a new $r_k(N)$ bound, a priority claim, or Lean verification. [6 October 2026; sources 06–10] *Further limitations of sources 06–10* (kept in place). Source 06: the leading carry entropy rests on Zuev’s count; the ordering remark optimizes bounds, not discrepancy constants; the local phase loss is not substituted into a final theorem. Source 07: five and nine are guaranteed orders, not maximal ones; the sharpness is for the directional defect δ , not for η ; the threshold is not a replacement for an average homomorphism test; the factors 243 and 2548.03968 are not improvements of a global bound. Source 08: R_d is not claimed optimal as a multiplier of t^4 in odd order; 57 is a convenient constant; the sets in its sharpness theorem have densities tending to δ . Source 09: no originality claim; its sixth-order certificates are not inverse theorems. Source 10: no novelty claim for the polynomial method (Führer–Taranchuk credited), the colouring theorem concerns declared polynomial coordinates only, and the Reiher–Schoen variant is labelled as using a published input. All five: finite checks prove nothing general, no Lean compilation, no new bound for $r_k(N)$. [6 October 2026; sources 11–14] *Further limitations of sources 11–14* (kept in place). Source 11: the radii $1/7$, $1/3$ and the cutoff 34 are sufficient, not optimal; “sharp” does not mean every t is a coset density; its Proposition 6.1 corollary needs $\alpha^4 > 8/9$ and does not improve the exponent four; its partial-domain theorem is not a sparse-extension claim; majority decoding and the derivative identities are prior art. Source 12: sharpness is universal, not for prime cyclic groups with the same target or for Bohr sets alone; $3\varepsilon + r\kappa$ and the factor 3 in the repair budget are not claimed optimal; the component lemmas are borrowed and not removed by the repair theorem; no claim of feasibility at $\alpha = 1/8$; Y is not claimed to contain a progression. Source 13: only the flexible-length frontier is claimed optimal; the linear specialization only; the bounded-height budget is not globally optimal; dividing by M is not optimal; the real-valued hypothesis is essential; quartic sharpness is for weights, not indicators at a fixed group size; no rectification to integers; its characteristic-two table differs. Source 14: the truncated expansion is not a finite-parameter bound; no L^2 rigidity; $2^{3/4}/3$ is a lower bound only; envelope sharpness is for an infinite family, not every ε ; its spectral bound gives no coset closeness; its symmetric colouring condition is not Corollary 8.3; the gap is prime-only; the Artin–Schreier example does not improve the bound 8; no peer review. All four: finite checks prove nothing general, no Lean compilation, no new bound for $r_k(N)$, no priority claim. *Superseded*: the first write’s “The coefficient 6 of the $u^{16/3}$ term is not claimed optimal” (source 04) stands as source 04’s statement; the optimal coefficient is $(9/4)^{1/3}$ by source 14 (Remark W4). [6 October 2026; sources 15–20] *Further limitations of sources 15–20* (kept in place). Source 15: no propagation through Sections 15–18 and no improvement of a final bound; the constant 18 and the exponents of its coupled theorem are not claimed optimal; its joint normal form classifies joint equality, not product-property extremizers; its dichotomy gives no label repair, and the saturation remark no quantitative rounding; thirteen floating-point Fourier checks are flagged as such; its questions are not claimed to be recognized open problems. Source 16: the recurrence theorem is external and its threshold not numerical; an exponential-in- k gap remains at Proposition 17.7; the own-step obstruction is for full partitions; the ceiling concerns local-scale conclusions only; the cube identities alone do not improve the inverse theorem. Source 17: prime moduli only, not a drop-in proof of the all- N lemma_9_3; thresholds not optimal or practical; the limitation concerns the scalar signed certificate only; the moment inequality is not claimed new; no equality classification for fractional weights; no efficient algorithm. Source 18: its Lemma 15.5 corollary changes one threshold, not the exponent E_k , and nothing is propagated; the results need the full degeneracy definition; Lau’s preprint is imported; the sufficient q^{-2} and necessary q^{-1} rates do not match; the three-cube circuits are classical. Source 19: C_d concerns this recovery certificate only;

synchronization needs the inherited-coordinate hypothesis; Lemma 16.10 and Theorems 18.1–18.2 are not completed; Maynard’s theorem is imported and Lau’s input optional; no matching nonlinear theorem. Source 20: not a substitute for the asymmetric Corollary 3.3 under its hypotheses; B_k not claimed sharp for $k \geq 4$; indicator sharpness only on $\mathbb{F}_{29}^{2m}$; the constant c_* is crude. All six: finite checks prove nothing general, no Lean compilation, no new bound for $r_k(N)$, no priority claim. [6 October 2026; sources 21–27] *Further limitations of sources 21–27* (kept in place). Source 21: the universal u^8 coefficient is undetermined; 20/9 is proved for the fixed group $\mathbb{Z}/5\mathbb{Z}$; indicator sharpness is a lower example; the profile constants are not optimized; the projection proposition is methodological; its review is “AI-assisted”, not peer review. Source 22: certificate class counts are not success loci; the second coefficient is not determined; the equal-allocation threshold is not claimed to dominate; the $d = 1$ remainder is a union bound with no containment claim; global quintic avoidance is unresolved and 7,810,000 is a lower bound; “zero defect” means $\mathbb{F}_p$ -quadratic, not $\mathbb{F}_q$ -quadratic. Source 23: the Section 16 control-function comparison is not proved; the gluing is conditional on slice covers; no integer-representative fidelity; the threshold is eventual and universal, not a statement about every R ; the localization constant is sharp only for its localization problem; the tertiary cube coefficient is open. Source 24: not a new Balog–Szemerédi–Gowers record; the scalar sharpness concerns the relaxation, not realizable codegree matrices; its hashing theorem is outside its suite; its modern-input corollary imports Reiher–Schoen; nothing is propagated through Sections 8–18. Source 25: no full-arrangement census and no selection simulation; $d \geq 2$ and characteristic above $2d$ are substantive; no global improvement. Source 26: no higher-degree result; Appendix A is not the Section 16 interface; constants not optimal; the cube-root scale and the mechanisms have precedents; its builder is Linux-only. Source 27: the exact formula rests on a finite certificate not checked by a proof assistant; the cubic bound is a union bound; nothing is propagated through Lemma 15.5; polynomiality beyond eight vertices is a question; no claim of geometric irreducibility. All seven: finite checks prove nothing general, no Lean compilation, no new bound for $r_k(N)$, no priority claim. [6 October 2026; sources 28–33] *Further limitations of sources 28–33* (kept in place). Source 28: the logarithmic losses are not shown necessary; the $O(\alpha^{-3})$ count belongs to the new threshold (its old-spectrum corollary keeps the retained fraction and radius, not the count); Y depends on ϕ ; the input defect must be at most 2^{-21} ; c_4^{odd} is not determined; nothing is propagated through Sections 13, 16 or 18. Source 29: the moment inequality is sharp, the norm comparison is not asserted sharp for $d \geq 3$; the joint theorem is an absolute endpoint with row sums at most one, not unrestricted relative-energy stability; the restriction is for fixed fields and does not replace the all-moduli lemma. Source 30: the exponential base is unresolved ($\sqrt{3}$ against 3); the obstruction uses composite cyclic groups, the prime case is open; no improved Theorem 10.13 is asserted. Source 31: the qualitative critical-norm classification is Eisner and Tao’s; the joint graph inequality, the cutoff 1/120, the odd-order envelope and the extraction exponents are not claimed optimal; Theorem II.117.1 is prime-cyclic with a fibre cap and says nothing about compatibility across slices; Appendix A is a corollary of Reiher–Schoen. Source 32: no best recurrence exponent; no parent containment in the variance branch; no higher degree; no integer rectification; the length bound exceeds one only for $N/M > 17^{39}$; its builder is Linux-only. Source 33: full or near-full domains only; F_s for $s \geq 6$ not asserted sharp; the activation thresholds are not optimal; no new bound for $r_k(N)$ or van der Waerden numbers. All six: finite checks prove nothing general, no Lean compilation, no new bound for $r_k(N)$, no priority claim. [6 October 2026; sources 34–39] *Further limitations of sources 34–39* (kept in place). Source 34: c_4^{odd} is not determined; neither endpoint is claimed optimal; the determinant range is eventual (no explicit N_0) and rests on the Alon–Vu matrices; the second-order support term is open; the transport threshold is for source 07’s finite-fibre model and is not asserted at the prime-order interface; nothing is propagated through a full iteration. Source 35: $E_{k,m}$ is a sufficient exponent, not shown optimal, and the selection’s

prime-field transfer needs $p > 2(L - 1)$; the coefficient 5 is not optimal (superseded by source 34); the polynomial obstruction is necessary only, with no matching sufficient theorem in degree two or more; the prime-modulus regime $N \asymp R$ is open. Source 36: odd p only, and integration needs $p > k + 1$; for fixed p and small energy the criterion says nothing; no improvement of the scalar coefficient one; not Proposition 17.7 and not a general inverse theorem; standard Heisenberg and polarization facts are not claimed new. Source 37: the open-gap extremizers can charge endpoints and need not respect the half-open exclusion; the recurrence needs $T \geq 2^{2^{40k^3}}$ and imports the Weyl inequality; the general moment criterion is classical; no record Diophantine bound; no propagation through Corollary 5.6. Source 38: the cutoffs 10^{-5} and $10^{-8}m^{-8}$ are sufficient, not optimal; the analytic series holds on a possibly smaller neighbourhood, not certified numerically; the envelope constant 104 is not optimal; the colouring construction is Shi and Dong's and no better colouring exponent is claimed. Source 39: minimax optimality holds for its certification rule only, and the extremizing families need not satisfy the other hypotheses of the inverse argument; occupancy methods are credited; Lemma 16.10's closing comparison is not resolved. All six: finite checks prove nothing general, no Lean compilation, no new bound for $r_k(N)$, no priority claim. [7 October 2026; sources 40–46] *Further limitations of sources 40–46* (kept in place). Source 40: the barrier is for homogeneous positive-Fourier kernels only; its field-size condition is sufficient, not optimal (source 35 improves its exponent); the small-field test is vacuous, as it says; no density-increment theorem. Source 41: the constants are deliberately weak, and the main bound is nontrivial only for $N/M > 8^{D_k}$; the variance branch may leave the cover; no rectification or optimality; it does not change the formal status. Source 42: the optimality of $1 - 1/C$ is uniform over densities (sparse extremizers), the fixed-density problem is open; no parent containment; the classical inputs are credited. Source 43: the interval $11/16 \leq M_{4,n} \leq 3/4$ is proved, constancy at $11/16$ is a conjecture; odd small characteristic and composite integration are open; the integration criterion and Heisenberg mechanism are established background. Source 44: fixed- k asymptotics, not uniform in k ; core avoidance is not full nondegeneracy; $b_{2,8}$ rests on a finite certificate. Source 45: the third energy level is not classified; the range $1/9$ is not claimed optimal; c_4^{odd} is not determined; the first energy gap is credited to inverse Pollard and Hegyvári. Source 46: the seven-function bound is not claimed sharp; the trace sections were read, not re-derived, at intake; Milićević's 2026 preprint was not audited, as it says. All seven: finite checks prove nothing general, no Lean compilation, no new bound for $r_k(N)$, no priority claim.

V.3 Relationship to the ProveIt formalization

Source 01, delivered Section 14.

V.3.1 The inspected snapshot and normalization

The source inspection is pinned to commit

3a25020a654d196f7f1aa2e37649752c000d0e65

of VladimirReshetnikov/ProveIt, rather than to a moving branch [15]. The original paper was read through the public PDF mirror listed in the bibliography; selected repository files, not the entire repository build, were inspected.

The inspected `Definitions.lean` uses the unnormalized Fourier transform, a balanced indicator, finite partitions, natural-number progressions, and average cell size [16]. Consequently a hypothesis

$|\widehat{\mathbf{1}}_A(r)| \geq \alpha N$ corresponds to $\eta = \alpha$ in this article, not to $\eta = \alpha/N$. A sum of absolute balanced cell sums becomes our D after division by N .

The companion `Proofs02DensityIncrement.lean` develops the positive/negative mass split for the Fourier density increment [17]. The companion `Proofs17FinitePatterns.lean` uses a finite sign-pattern/Sauer–Shelah approach for the inherited floor-pattern bounds [18]. These are natural locations for stronger reusable interfaces; no assertion that they have been replaced or recompiled is made.

[write] **6 October 2026.** At *HEAD* (25df8755d, 6 October 2026) the inspected files are unchanged except `Definitions.lean`, which gained a `Box.IsProper` that no source uses. The ledger now records 98 exact companions and 22 open statements, against 88 and 32 at this source’s pin. Of the statements compared here, `corollary_2_5`, `corollary_17_5`, `corollary_17_6` and `proposition_17_7` have exact companions, and `theorem_18_1` is open. Crosswalk: Section V.1.

V.3.2 Proposed formal interfaces

The dependencies can be organized in the following order.

Interface	Mathematical content	Reusable prerequisite
Real cell mass	$\sum g_j = 2 \sum (g_j)_+$ under $\sum g_j = 0$; weighted mean and occupied mass	Finite sums and order arithmetic
Cell phase envelope	Lemma I.1.2, first for an indicator, then for bounded weights	Complex norm, sine, finite convex combinations
Broken-chord transfer	Theorems I.2.1 and I.2.3 with explicit denominators	Convexity and mean identities
Integer partition	Theorem I.5.1, including the case of one block in a residue class	Finite pigeonhole and quotient/remainder
Fractional patterns	Positive perturbation and exact range factorization	Integer floor, finite minima of positive gaps
Pattern count	Hyperplane regions or an equivalent finite sign-family bound	Dimension and finite set cardinality
Translation quotient	Normalize a pattern by its empty-set value	Finite group action or an explicit canonical representative
Certificate checker	Rational primal/dual checks and exhaustive tree validation	Exact arithmetic and structural recursion

A practical first target is the $s = 0$ discrepancy theorem: its proof needs no trigonometry, no Fourier transform, and no structural additive combinatorics. The next target is the cancellation inequality, followed by the full envelope. Proving the statements over arbitrary finite weighted families prevents repeated normalization and counting arguments later.

For the carry side, one should formalize interior realization before using a strict sign-pattern theorem. The signed-feature counterexample in Section IV.3 is a small regression test against a false boundary shortcut. The exact coefficient-range factorization also needs the open-endpoint surjectivity argument, not merely an upper-bound map.

For progression lengths, retain natural-number inequalities $N \geq L \prod_i Q_i$ and $L \leq \ell \leq 2L - 1$ as long as possible. Introduce square roots and floors only in the corollary. This isolates small-scale cases rather than trying to recover them from real asymptotic estimates. If actual code is added, it should prove a new strengthened statement and derive the old statement as a corollary where appropriate; changing a catalogue definition alone is not a proof.

V.3.3 A dependency warning, not a claimed global repair

The inspected `Sections17_18.lean` records the numbered statements as proposition-valued definitions. Its note attached to Theorem 18.1 flags an unsupported tower estimate in the published Corollary 16.11 as a quantitative dependency [19]. This is a report of the repository’s warning, not an independent conclusion here that a published headline theorem is false. Our local theorems do not use that estimate. In particular, applying Theorem I.4.1 to a supplied partition is unconditional, but asserting the existence of that partition with a given tower exponent would require a separate validated source.

No Lean or Lake executable was available in the working environment, and no new Lean theorem was compiled in producing this package. The document contains a formalization plan, conventional mathematical proofs, and separately described computational checks. It does not present a proposition-valued specification as a kernel-verified theorem.

[write] **6 October 2026.** Checked at HEAD: `theorem_18_1` is still open in the ledger, and its docstring in `Sections17_18.lean` still warns about the unsupported tower estimate in the published Corollary 16.11 (line 168). `FORMALIZATION_STATUS.txt` still lists resolving “the documented Corollary 16.11 bound” among its open obligations, and `corollary_16_11` is open. The dependency warning above is therefore accurate.

V.4 Further research questions and concrete next steps

Source 01, delivered Section 15.

The questions below are posed by this report. They are unresolved within this development; this is not a certification that every formulation is new or currently open in the entire literature.

Question V.4.1 (The second-order carry entropy). *Does $\log_2 C_k$ have a $-k \log_2 k$ correction, or is $\log_2 C_k = k^2 + O(k)$? More generally, determine the coefficient of $k \log k$ if it exists.*

Theorem IV.2.3 leaves exactly this scale between its upper and lower estimates. A promising route is to count intersections of the internal subset-sum hyperplanes that actually meet the open cube, rather than use the unrestricted region bound. The elementary anchor construction is too sparse to decide the leading coefficient, let alone this correction. Threshold-function embeddings give a strong baseline but need not capture all simultaneous carry levels.

Question V.4.2 (Exact counts and arrangement structure). *Can one obtain a recurrence, a useful intersection-poset formula, or a symmetry-reduced exact enumeration for C_k and A_k ?*

The supplied certificate format scales by adding more branches, but its size grows rapidly. Coordinate permutations and complement transformations suggest reductions; any quotient must retain enough information to certify that all orbit representatives are covered. An exact-arithmetic checker in a proof assistant would make such computations useful as formal regression tests, not merely numerical evidence.

Question V.4.3 (The modulus dependence of affine patterns). *For fixed k and coefficient range, when do modular collisions stabilize, and what is the exact number of translation classes as a function of M ?*

Theorem IV.3.2 is uniform in M but deliberately discards these collisions. A finite list of integer-valued normalized patterns exists; modular coincidence is then controlled by divisibility of finitely many coordinate differences. Determining those difference vectors could give an exact piecewise description, including a threshold beyond which no new collisions occur. The offset's fractional part must remain visible.

Question V.4.4 (Can the selection loss be reduced?). *What additional orthogonality or positivity assumptions allow a phase-removal interface to lose only L^{-1} rather than L^{-2} in energy, without changing the desired structural conclusion?*

For arbitrary complex summands the squared pigeonhole loss in Proposition IV.3.3 is sharp: equal aligned summands attain it. A stronger theorem therefore needs additional hypotheses, not just more careful algebra. One possible approach is to retain the sum of squared contributions across translation classes until after a structural selection step. Such a mechanism has not been established here.

Question V.4.5 (Sharpness under arithmetic phase constraints). *How much stronger can the density-tail bound become when ψ is one fixed cyclic character and the cells are proper progressions with a common step and nearly equal lengths?*

The extremizers of Theorem I.2.1 freely rotate cell arcs and assign endpoint phases to occupied points. A genuine character imposes spacing and compatibility restrictions. A quantitative analysis of those restrictions could improve constants or density dependence beyond the abstract sharp bound; it would not contradict that bound's optimality in the larger weighted model.

Question V.4.6 (The optimal finite size-increment tradeoff). *Can one combine the exact density tradeoff (I.3.4) with an optimal finite partition algorithm, including the final incomplete blocks, to characterize the best uniform pair of progression length and increment?*

Our integer partition is transparent but not claimed to have optimal constants. Theorem I.7.2 fixes the square-root exponent for one-frequency phase-flat methods. Remaining improvements may come from choosing unequal block lengths, exploiting rational frequencies, or paying for selected short cells through their occupied mass rather than their ambient size.

Question V.4.7 (Retaining more than one density statistic). *Which finite collection of stop-loss moments most efficiently preserves useful density-tail information through repeated localization steps?*

Theorem I.4.2 supplies an exact optimization method once the statistics are chosen. The research issue is to prove structural lemmas that propagate those statistics at acceptable cost. A two- or three-knot state could be substantially more informative than a single discrepancy number, but a global gain must include the cost of obtaining that state.

Question V.4.8 (Higher-degree phase partitions). *Can polynomial or nilsequence localization furnish partitions with both quantitative minimum cell sizes and small occupied exceptional mass, so that the sharp tail theorem applies without a large selection loss?*

The density transfer itself is already proved for any short-arc phase; what is missing is the required structural partition. Simultaneous linear approximation alone does not solve the higher-degree problem. The polynomial floor-pattern bound in Theorem IV.4.1 controls one finite complexity term but does not construct those partitions.

Question V.4.9 (Polynomial floor entropy beyond the leading term). *For fixed degree d , determine the secondary terms of $\log_2 |\mathcal{P}_{n,d}(r)|$, and identify the transition when $\log r$ is comparable to n .*

The finite upper bound separates a coefficient-range term from a region count, but unlike Theorem IV.1.2 it need not be an exact product. Understanding overlaps between different integer coefficient vectors is essential. The threshold-function lower bound alone does not settle the large-range contribution.

Question V.4.10 (A fully audited quantitative integration). *After independently checking the earlier structural parameter estimates, what explicit global improvement survives if the new density-transfer and translation-class bounds are propagated through one complete argument?*

The first deliverable should be a dependency graph with normalized quantities and verified recurrences, including the issue flagged at Corollary 16.11 in the inspected repository. Only then is it meaningful to compare a resulting global bound with modern benchmarks. This prevents a smaller local factor from being mistaken for a new global theorem.

V.5 Conclusions and result-status ledger

Source 01, delivered Section 16.

The work yields a reusable sharp transfer principle and a more economical floor-pattern count. The density calculation is sensitive to the actual balanced mass $2\delta(1 - \delta)$, to the full distribution of cell densities, and to occupied exceptional mass. The counting calculation separates integral coefficient freedom from fractional carries, treats boundary points correctly, and exhibits a threshold-complexity obstruction to a subquadratic exponent. Both refinements have explicit hypotheses and can be inserted at well-defined proof interfaces.

Claim	Status in this package
Sharp finite weighted density-tail theorem, including equality examples	Proved in Theorem I.2.1; arithmetic extremizers are not claimed.
Occupied-mass exceptional-set bound and optimal forced maximum	Proved in Theorems I.2.3 and I.3.1.
Explicit Fourier density increment with integer-exact length	Proved in Theorem I.6.1, for arbitrary real frequency and bounded weights; no prime-modulus restriction.
Exact range factorization and quadratic-exponent carry upper/lower bounds	Proved by elementary arguments in Theorems IV.1.2, IV.1.4, and IV.2.1.
$\log_2 C_k \sim k^2$ and polynomial-floor leading entropy	Deduced from explicitly identified classical threshold-function inputs; those inputs are not reproved here.

Claim	Status in this package
$C_4 = 154$	Exhaustive exact rational certificates with a Python verifier and a completeness argument; not Lean-verified.
Smaller translation-class budget	Proved in Theorem IV.3.2; subsequent global parameter propagation is not supplied.
Improved record bound for Szemerédi’s theorem	Not claimed.
Priority of every formulation	Not certified by an exhaustive literature search.

V.6 Boundary and normalization checklist

Source 01, delivered Appendix A.

The formulas in this article are intended to be used with the following conditions kept explicit.

1. The phase results assume $0 < \delta < 1$. At $\delta = 0$ or 1 , a bounded function with that mean is constant and the balanced correlation is zero; formulas dividing by $\delta(1 - \delta)$ should not be used.
2. The short-arc theorem uses half-angle $\theta < \pi/2$. The progression partition uses full arc length r in turns, so $\theta = \pi r$, not $2\pi r$.
3. A normalized Fourier coefficient is the unnormalized coefficient divided by N . The normalized discrepancy is likewise the sum of cell balanced masses divided by N .
4. The density-tail event is $q > a$, strictly. Its stop-loss lower bound may vanish at the optimal forced maximum even though a cell with $q \geq a$ is guaranteed.
5. Exceptional occupied mass is $\mathbb{E}(h\mathbf{1}_E)$ in the original probability measure. It is not a conditional density on E .
6. The coefficient-range factorization assumes integral $r_i \geq 1$ and open intervals $(-r_i, r_i)$. Fractional coordinates can lie on a boundary only because Lemma IV.1.1 removes that boundary without changing the pattern.
7. Natural progressions have positive step and no repeated terms. Singletons handle the small-scale case; no nonintegral number is treated as a possible cell length.
8. The affine translation quotient retains the fractional offset. Its modulus-free upper bound does not assert absence of modular collisions.
9. The threshold-function asymptotic is an external theorem. The elementary finite pattern bounds and all density-transfer statements remain valid without it.

V.7 Source and artifact provenance

Source 01, delivered Appendix B.

The repository snapshot was read on 6 October 2026. The paper directory contains both a PDF and a TeX representation. The research arguments use the original paper’s relevant PDF pages and selected Lean source files, not an assumption that every statement in the repository has already been proved. The pinned commit identifies precisely which source comments and normalizations were inspected. No repository files were modified.

The package includes the article source, compiled PDF, certificate data, verification and supplementary-test scripts, result logs, and a README. The article’s source uses an internal bibliography and does not require BibTeX or downloaded repository files to compile. No copies of the copyrighted source papers or font files are redistributed.

V.8 Formalization interface and reproducibility

Source 02, delivered Section 10.

V.8.1 What was inspected

The repository’s `Definitions.lean` defines `fourier` using the unnormalized `ZMod.dft`, defines `difference` with $x - h$, and defines `balanced`, `IsPartition`, `UniformOfDegree`, and the unnormalized `gowersNorm`. The inspected `ProofInfrastructure.lean` provides, among other helpers, `IsPartition.sum_card` and `sum_balanced`. The inspected part of `Proofs02DensityIncrement.lean` contains private helpers for partition sums and the exact equality between total absolute mass and twice positive mass [20].

The normalized U^3 quantity in this article translates to the repository’s degree-two uniformity numerator by

$$\mathcal{U}(f) = N^{-4} \sum_{a,b \in G} \left| \sum_{x \in G} \Delta_a \Delta_b f(x) \right|^2.$$

Thus the degree parameter of `UniformOfDegree` is 2 here, not 3. For the repository’s unnormalized order-three Gowers norm, the eighth power is $N^4 \mathcal{U}(f)$. These normalizations should be established as explicit bridge lemmas before the energy theorem is imported.

V.8.2 Suggested dependency order

The most economical formalization starts with finite weighted real sums: positive/negative mass, the negative-support bound, and Theorem I.9.1. It then proves the real-phase lemma using positive and negative weighted averages. These results have no Fourier dependencies and can be added independently of a full higher-order inverse theorem.

For Theorem II.2.1, first formalize the three identities (II.2.2)–(II.2.4) over `ZMod N`. Keep all statements polynomial and multiplication-based, rather than dividing by $m(f)$ or $\mathcal{U}(f)$; this handles zero cases without extra hypotheses. A later generalization can replace `ZMod N` by an abstract finite abelian group and its character group.

Next prove the two-tetrahedron bijections in Lemma II.3.1, then add graph indicators and balanced indicators as specializations. The final arithmetic-progression wrapper should accept a proved $\text{PP}(K, R_0)$ hypothesis rather than hiding it behind an unverified claim about exact cell counts.

Care is needed with empty cells: the repository’s general partition predicate does not itself require every cell to be nonempty. Empty cells must be removed before using cell means, $M - 1$, or a minimum cell length. Likewise, injectivity of a modular progression parameterization is not the same as nonwrapping in its standard integer representatives.

V.8.3 Verification status

No Lean compiler or Lake executable was available in the working environment. Accordingly, none of the new results is represented as kernel-checked, and no untested Lean proof is included. The source reading was targeted rather than a certification of every theorem in the supplied development. The mathematical proofs in this article are the primary deliverable.

The accompanying `verify.py` independently checks the weighted Fourier identities and both asymmetric forms of the energy inequality on finite cyclic groups, compares spectral and direct convolution energy for small groups, tests phase and tail inequalities, and evaluates exact sharpness examples. It uses the fixed seed 20261006. The run recorded in `verification_results.json` includes 490 random energy cases, 2,500 random phase cases, 3,000 zero-mean moment cases, 1,500 nonzero-mean moment cases, and 1,500 phase-budget optimization cases, together with three exact-form equality families evaluated numerically and a rational moment equality example. These experiments are regression checks, not proofs or substitutes for formal verification.

[write] **6 October 2026.** The suite is shipped as `code/02-energy-freezing-verify.py`; it overwrites `verification_results.json` beside itself, so the README’s rerun route runs it on a copy. At intake it reproduced the recorded run identically (8,990 random cases and the exact families). The corrected Corollary 5.6 that Section I.11 imports is now formalized (note there).

V.9 Further research questions and proposed work

Source 02, delivered Section 11.

The following are proposed research targets suggested by the proven interfaces. Their inclusion is not a claim that each is a previously published open problem.

V.9.1 A correlation-preserving structural theorem for multivalued spectra

Proposition II.4.1 retains all significant derivative frequencies. Can the subsequent energy-to-structure and graph-selection steps preserve a fixed fraction of t_τ while exploiting the denominator κ ? The decisive issue is not merely obtaining a small-doubling subset: it is ensuring that the subset continues to carry the correlation needed for integration. A useful first goal is a theorem whose hypotheses include both additive energy and a specified nonnegative correlation weight, and whose conclusion controls both losses explicitly.

V.9.2 Classify near equality for the coupled pair (f, w)

Proposition II.4.2 gives two quantitative alignments, while Examples II.3.3–II.3.4 show distinct sharp geometries. Existing results about near-maximal Gowers norms [7] are relevant but do not by themselves state a classification of the additional spectral weight in our mixed inequality. One

can ask for a dimension-free theorem describing w and f jointly when the main inequality is nearly saturated, with appropriate treatment of subgroups and quadratic phases.

V.9.3 Retain norm profiles through higher-order integration

The graph-energy step is repeatedly applied to derivatives in higher-degree arguments. A natural target is a weighted family theorem that keeps the distribution of $m(\Delta_{\mathbf{h}}f)$ and $\mathcal{U}(\Delta_{\mathbf{h}}f)$ instead of replacing every slice by a supremum. The immediate difficulty is compatibility: good structural pieces from different slices must agree on overlapping configurations. A local improvement cannot be counted as a global gain until this compatibility cost is controlled.

V.9.4 A complete quantitative ledger for one progression length

An attainable next project is to propagate the present denominators, the sharp real-phase law, and the optimized budget through every step of the length-four proof, with one explicit choice of parameters. This would determine whether a real improvement survives the remaining inverse and recurrence estimates. Only after that full ledger is complete would it be justified to state an improved numerical threshold for that proof. Comparisons should distinguish improved constants within Gowers’s route from stronger bounds obtained by later methods [4, 2].

V.9.5 Sharper recurrence inputs and heterogeneous budgets

Theorem I.11.1 treats PP as a replaceable component. Any better value of K or R_0 transfers automatically to the progression certificate. A separate optimization problem assigns different diameter budgets to cells of different sizes and correlations, using the heterogeneous inequality in Section I.8. The local quadratic bound contains still more information than its linear envelope; exploiting it may improve nonuniform cases without altering the recurrence theorem.

V.9.6 The finite-cell extremal problem

Theorem I.9.1 solves the weighted total-good-mass problem sharply. It does not solve the problem of the largest good cell when M and all allowed cell sizes are fixed. The three-type extremizer explains why a negative cell and a low-positive cell can consume separate parts of the cell budget. A precise finite-dimensional optimization, including integer cardinalities, could strengthen the $M - 1$ corollary and produce exact finite- N certificates.

[write] 6 October 2026; sources 06–10. *Advanced by source 06.* With M fixed and the cell masses free (the weighted model), the problem is solved by source 06’s Theorem I.21.1: the exact best lower bound for the largest high cell is $\min\{P_+/b(M - 1), S/(M - 2)\}$, attained by explicit atomic extremizers; its second extremizer is a three-type configuration of exactly the kind described above (cells at b , one cell at the threshold, one negative cell). Source 06 realizes its extremizers on finite uniform spaces when the parameters are rational. Still open: prescribed allowed cell sizes and integer cardinalities at a fixed N (Section V.2, item I.6).

V.9.7 A characteristic-independent Lean library

The main analytic results work on every finite abelian group and the two-tetrahedron argument uses no field division. A useful library contribution would formalize weighted Fourier energy, its

normalization on $G \times \widehat{G}$, and real-valued phase freezing independently of the prime-cyclic presentation. Regression examples should include even cyclic groups, subgroup spectral rectangles, empty weights, zero functions, and wrapping versus nonwrapping progression charts.

V.10 Conclusion

Source 02, delivered Section 12.

The strongest unconditional analytic conclusion of this article is the mixed weighted inequality (II.2.1), with its exact norm denominators and coefficient-one equality examples. The strongest elementary density conclusion is the sharp tail bound (I.9.1), coupled with the sharp aggregate real-phase law (I.8.3). Together they strengthen identifiable interfaces in Gowers’s argument, including Proposition 6.1 and Lemma 5.15, and yield an explicitly optimized progression certificate under a clearly stated partition input.

The remaining challenge is structural, not merely algebraic: local gains must survive extraction, integration, recurrence, and iteration. The article makes those gains available without presenting that uncompleted propagation as a new global theorem.

V.11 Source audit and normalization checklist

Source 02, delivered Appendix A.

The repository branch reference observed during this session was

66c02f8a1d26f553deac5a91dada1739e0d15064.

The specific inspected blobs are recorded below, so the source comparison is not dependent only on a moving branch name.

File below the supplied repository paths	Git blob SHA
<code>sz-thm-gowers-proof.tex</code>	41085a0efde8c1932e86e80c791984f52841c22e
<code>Definitions.lean</code>	202260e0d7ec6f033c1758347381c34a6f0d9212
<code>ProofInfrastructure.lean</code>	ebd9e7ed02d81de2e17b97b4223f861b785ed5d8
<code>Proofs02DensityIncrement.lean</code>	85b5c3ad8769b9769e1939ae5c05f0757f0678b5

[write] **6 October 2026.** Checked at HEAD (25df8755d): the four blob identifiers are those of commit 66c02f8a1. The transcription, `ProofInfrastructure.lean` and `Proofs02DensityIncrement.lean` are unchanged at HEAD; `Definitions.lean` has changed (blob 97113b7), by an added `Box.IsProper` that source 02 does not use. Source 02’s delivery README records no pin; this branch reference is its provenance (Section F.4).

The targeted paper passages were the corrected Corollary 5.6 and nearby phase-partition statements, Lemma 5.15, and Proposition 6.1. The transcription includes editorial changes; a theorem imported from that edited source is labeled as such above rather than silently attributed to the exact original printed formulation.

Quantity	This article	Paper/Lean convention
Fourier coefficient	$\mathbb{E}_x f(x) \overline{\chi(x)}$	$N \widehat{f}(\chi)$
Derivative-graph statistic	T	$N^3 T$
Order-three cube quantity	$\mathcal{U}(f)$	$N^4 \mathcal{U}(f)$
Graph additive energy	$\mathcal{E}(\mathbf{1}_\Gamma)$	$N^3 \mathcal{E}(\mathbf{1}_\Gamma)$
Balanced L^2 mass	$m(f) = \delta(1 - \delta)$	$N m(f)$ before averaging

V.12 How local improvements affect an iteration

Source 03, delivered Section 9.

The estimates above remove real losses, but they occur at different places in the proof. The cube theorem improves a counting consequence of uniformity. The DRC theorem improves extraction of a subfamily from intersection data. The Fourier theorem converts an already established correlation into a density increment on an ordinary progression. Their parameters are not interchangeable. In particular, a larger common-neighborhood core does not by itself provide an improved correlation theorem for arbitrary high Gowers norms.

Figure 1 displays two of the local comparisons using the literal formulas proved in the text. For cube counts, retaining the centering changes the first possible error power, while classifying its supports further reduces its coefficient. For DRC, retaining the original success criterion and changing the exponent from five to three gives a growing advantage as the density parameter decreases.

Figure 1: Evaluations of proved local bounds. Left: relative cube-count error bounds for $d = 3$, $\delta = 1/2$, comparing the triangle inequality, the cancellation of degrees one through three, and the exact quartic types on an odd-order group. Right: guaranteed core fractions at the same threshold $\delta^2 m/2$ and the same 90% good-pair requirement. These are upper or lower bounds as labelled, not measurements of extremal examples or claims that each curve is attainable.

V.12.1 An explicit abstract recurrence

The following elementary calculation explains which parameters must be tracked before any global conclusion can be stated. It is a conditional recurrence theorem, not a substitute for the analytic density increment theorem needed to supply its hypotheses.

Proposition V.12.1 (Density and length bookkeeping). *Let $c > 0$, $p > 1$, $C > 0$, $q \geq 0$, and $0 < \beta < 1$. Suppose positive numbers $\delta_i \leq 1$, $N_i > 0$ satisfy, for $0 \leq i < R$,*

$$\delta_{i+1} \geq \delta_i + c\delta_i^p, \quad N_{i+1} \geq C\delta_i^q N_i^\beta.$$

Then

$$R \leq \frac{(1+c)^p}{c(p-1)} (\delta_0^{1-p} - 1). \quad (\text{V.12.1})$$

Writing $B = \max\{0, -\log(C\delta_0^q)\}$, one also has

$$\log N_r \geq \beta^r \log N_0 - B \frac{1 - \beta^r}{1 - \beta} \quad (0 \leq r \leq R). \quad (\text{V.12.2})$$

Consequently, for an integer $T \geq R$ and $H \geq 1$, the condition

$$\log N_0 \geq \beta^{-T} \left(\log H + \frac{B}{1 - \beta} \right) \quad (\text{V.12.3})$$

ensures $N_r \geq H$ at every $r \leq R$.

Proof. The potential u^{1-p} decreases at a controlled rate. Since $\delta_i \leq 1$,

$$\begin{aligned} \delta_i^{1-p} - \delta_{i+1}^{1-p} &\geq (p-1) \int_{\delta_i}^{\delta_i + c\delta_i^p} t^{-p} dt \\ &\geq \frac{(p-1)c\delta_i^p}{(\delta_i + c\delta_i^p)^p} \geq \frac{(p-1)c}{(1+c)^p}. \end{aligned}$$

Summing and using $\delta_R^{1-p} \geq 1$ gives (V.12.1). The densities are increasing, so $\log N_{i+1} \geq \beta \log N_i - B$. Iterating this affine inequality gives (V.12.2). Under (V.12.3), $\beta^r \log N_0$ is at least $\log H + B/(1 - \beta)$ for $r \leq T$, which proves the last assertion. $\square$

For fixed constants, the familiar double-exponential length budget is visible in (V.12.3): the number of iterations occurs in the exponent of β^{-T} , which already bounds a logarithm of the starting size. Improving C or q changes the additive length cost B . Improving the density growth exponent p can change the scale of the number of iterations. These are different effects. To extract a better global Szemerédi bound from this report one would have to identify, and prove throughout the later sections, the corresponding updated values or functions of all these parameters. We have not carried out that full replacement of the higher-order inverse and localization arguments.

[write] **6 October 2026; sources 06–10.** *Two further iteration statements.* Source 10's Proposition V.42.1 bounds the number of steps of the same recurrence by $(\delta_0^{1-p} - 1)/(1 - (1+c)^{1-p})$, and source 06's Lemma V.25.1 with $G = 1$ by $1 + (\delta_0^{1-p} - 1)/(c(p-1)) + p \log(1/\delta_0)$ (its (V.25.3)). *Comparison (second write).* With $q = p - 1$, $1 - (1+c)^{-q} = q \int_0^c (1+u)^{-q-1} du$ lies between $qc(1+c)^{-q-1}$ and qc , so the coefficients of δ_0^{1-p} satisfy $1/(cq) \leq 1/(1 - (1+c)^{-q}) \leq (1+c)^p/(cq)$: source 06's leading coefficient is the smallest and source 10's lies between it and the one in (V.12.1); source 06's bound has the additional term $1 + p \log(1/\delta_0)$ and counts the densities $\delta_0, \dots, \delta_{t-1}$, whereas the bound here counts steps. For $p = 2$, $c = 1/320$ the coefficients are 320,

321 and $321^2/320 \approx 322.003$. Source 06 also proves that the leading term of its double-logarithmic length budget is optimal for its abstract local rule (its Section V.25), and source 10’s Proposition V.42.2 is the length recursion (V.12.2) with variable parameters.

The same distinction applies to the exact quartic identity. It is stronger information about cubes with a prescribed balanced Gowers norm. It does not imply that every set lacking arithmetic progressions has a large ordinary Fourier coefficient. Gowers’s motivating examples address precisely why higher-order structure is needed. The role of the improved count is to make the uniformity branch and its constants more precise.

V.13 The Lean development and a concrete formalization route

Source 03, delivered Section 10.

V.13.1 Pinned source and status of the inspection

All repository comparisons refer to revision

3a25020a654d196f7f1aa2e37649752c000d0e65

of ProveIt, inspected on 6 October 2026. The requested paper is at `Combinatorics/Ramsey/Papers/sz-thm-gowers-proof`; the Lean files are at `Combinatorics/Ramsey/Lean/GowersSzemerédi`. The adjacent source inventory, `gowers-proof-status.json`, reports 88 numbered statements with exact companion declarations and 32 open statements at that revision [22].

[write] 6 October 2026. *Stale since the pin.* At HEAD (25df8755d, 6 October 2026) the inventory records 98 exact companions and 22 open statements. The ten statements closed since 3a25020a6 are `corollary_5_6`, `corollary_5_7`, `lemma_5_9`, `lemma_5_10`, `corollary_5_11`, `lemma_5_14`, `lemma_16_1`, `lemma_16_3`, `lemma_16_5` and `lemma_16_6` (compared at the write). `theorem_1_3`, `theorem_18_1` and `theorem_18_2` are still open, so the conclusion of the next paragraph stands. Crosswalk: Section V.1.

Those counts are a source inventory, not a certification of the whole development. The facade exposes numbered results as propositions, usually with companion theorems whose names end in `_holds`. Defining a proposition neither proves it nor adds it as an axiom. The inventory explicitly separates exact companions from conditional, restricted, or otherwise related results. In particular, the quantitative headline `theorem_1_3` and final statements `theorem_18_1` and `theorem_18_2` are marked open there. This inspection therefore does not support describing the repository as a completed formal proof of the full quantitative theorem.

The files directly relevant to our comparisons contain substantive companion proofs. We inspected their definitions and proof scripts; we did not compile the Lean project. The new mathematical statements in this report have written proofs and independent mathematical reviews, together with the finite checks described in the appendix. No new machine-checked Lean proof is claimed or supplied.

[write] 6 October 2026. The “independent mathematical reviews” mentioned here and in Section V.15 are not part of the delivery and are not recorded anywhere in the repository; this report relies on the printed proofs, the intake’s checks and the write’s notes, not on them.

V.13.2 Normalization map

The following conversions prevent a common source of false improvements. Let $N = |G|$, and take $d \geq 1$.

Quantity	This report	Inspected repository convention
Fourier transform	$\mathbb{E}_x f(x) \overline{\chi(x)}$	Unnormalized sum, equal to N times this transform
Gowers norm	$\ f\ _{U^d}$	<code>gowersNorm</code> d $f = N^{(d+1)/2^d} \ f\ _{U^d}$
Uniformity parameter	$\ f_A\ _{U^d}^{2^d} \leq \alpha$	<code>UniformSetOfDegree</code> A $\alpha (d-1)$
Cube count	$Q_d(\mathbf{1}_A)$	<code>cubeCount</code> $= N^{d+1} Q_d(\mathbf{1}_A)$
Cube arguments	$x + \sum_i v_i h_i$	A minus convention in <code>cubeArgument</code> ; negating all h_i gives the same average

Both cube conventions count all parameter tuples, including degenerate cubes. This is why the rounding lemma can bound the exceptional tuples by a collision probability instead of changing the definition of the norm. Changing to unlabelled, injective, or symmetry-quotiented cubes would require an additional counting theorem.

V.13.3 Useful existing declarations

The source provides the following starting points in namespace `LeanProofs.GowersSzemerédi`. These are concrete interfaces to reuse or generalize, rather than assertions that the proposed additions have already been formalized.

Partition discrepancy and Fourier increment.

`Proofs02DensityIncrement.lean` proves `corollary_2_5_holds`. Its private `cor25_large_scale` already obtains the stronger $\rho/4$ increment and $\sqrt{\rho N/(128\pi)}$ length before weakening its conclusion. General finite weighted sums, followed by Theorem I.14.1, would expose the asymmetric information without repeating the Fourier argument.

Multilinear norms and cube expansion.

`Proofs03GowersCS.lean` contains the public homogeneous theorem `gowers_cauchy_schwarz`, which already allows functions beyond the unit disc. `Proofs03Minkowski.lean` contains the triangle inequality and private distributive expansion helpers. `Proofs03CubeUpper.lean` proves `lemma_3_10_holds` from that triangle inequality. Exporting a general expansion indexed by vertex subsets is a natural first step toward the exact quartic theorem.

Selection from many cells.

`Proofs05_10.lean` contains `lemma_5_15_holds`. Its assumptions and conclusion match the symmetric discrepancy extraction discussed in Section I.14. The general theorem should be stated with real nonnegative cell weights and asymmetric cell-sum bounds, then specialized to cardinalities.

Dependent random choice.

`Proofs07DRC.lean` proves `lemma_7_4_holds` using ordered samples with replacement, indexed by `Fin5`. Its internal score bound already has constant $11/16$ multiplying $\delta^{10} n^2$. The main new ingredient for the cubic theorem is a pointwise polynomial minorant, followed by the exact three-sample counting identity. Merely exposing the internal five-sample constant would give a smaller change.

V.13.4 Recommended order of implementation

First formalize the finite weighted selection theorem over an arbitrary finite index type. Prove positivity of its denominators once, and keep the pointwise inequalities separate from the division steps. This produces immediately reusable specializations to Lemma 5.15 and balanced indicators.

Second formalize the cubic certificate. Its good-region proof is a polynomial identity followed by nonnegativity; its bad-region proof may use concavity or a direct monotonicity argument. Keep the sampling identity generic in the number of witnesses. Specialization to three witnesses then replaces only the numerical part of the current DRC proof.

Third export the general cube expansion and prove the single-coordinate cancellation lemma. Nonempty supports of at most three selected vertices, or four vertices with nonzero XOR, leave one variable occurring in exactly one centered factor after a coordinate reflection. The corresponding reindexing is a bijection and uses no division by two. The first quartic upper bound then follows directly from Gowers–Cauchy–Schwarz, before any Fourier classification is needed.

Fourth formalize the two nonzero four-vertex types. One may begin over $\mathbb{Z}/N\mathbb{Z}$ to match existing files, then generalize to finite abelian groups. The extra quotient energy requires explicit handling of order-two characters; assuming an invertible doubling map is appropriate only for the odd-order specialization. The combinatorial formulas for R_d, T_d are separate finite enumeration theorems.

Finally integrate the progression-count telescope, the proper progression partition, and the four-edge compression statement. Each has a clear finite interface. The generalized von Neumann theorem should state invertibility of slope differences explicitly; the progression partition should carry its lower and upper integer lengths in its output. This order establishes useful lemmas early while avoiding dependence on the unfinished quantitative headline.

V.14 Further research questions and topics

Source 03, delivered Section 11.

The following questions are proposed continuations of the proved results. Some are deliberately scoped finite problems, while others concern the larger proof architecture. A question proposed here is not being presented as a previously published open problem unless a source is identified.

Research question V.14.1 (The odd-order leading constant). For fixed $d \geq 3$, determine

$$c_d^{\text{odd}} = \sup_{\substack{G \text{ finite abelian, } |G| \text{ odd} \\ 0 \neq f: G \rightarrow \mathbb{R}, \mathbb{E}f=0}} \frac{\|f\|_{U^2}^4}{\|f\|_{U^d}^4}.$$

The exact quartic theorem reduces the best leading coefficient on odd-order groups to $R_d c_d^{\text{odd}}$. Is the supremum attained or approached by a real part of a character, by several Fourier modes, or by a different construction?

[write] **6 October 2026; sources 28–33.** *Advanced for $d \geq 4$, not settled* (sources 28 and 29, Section III.66). Source 29 proves $\|f\|_{U^d}^{2^d} \geq 2^{-m} \binom{2m}{m} \|f\|_{U^2}^{2^d}$, $m = 2^{d-2}$, hence $c_4^{\text{odd}} \leq (8/35)^{1/4}$ and $c_d^{\text{odd}} \leq B_d \downarrow 1/2$, and $c_d^{\text{odd}} \geq 1/3$ for every d (Corollary III.69.1, Proposition III.69.2); source 28 proves $c_4^{\text{odd}} \geq 0.5587294$ and that a real part of a character is not extremal for $d \geq 4$ (Corollary III.70.8, Theorem III.70.9); the intake’s certificate gives $c_4^{\text{odd}} \geq 0.5587725$. So $0.5587725 \leq c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ among sources 01–33; later placed sources record better upper bounds (item III.1).

[write] **6 October 2026; sources 34–39.** *The upper end improved again* (sources 34 and 35, Sections III.71–III.72). Source 34 proves $\|f\|_{U^2}^4 \leq (2/3) \|f\|_{U^4}^4$, that is the coefficient 81/16 in source 29’s normalization (Theorem III.71.1); source 35, the same day, proves the coefficient 5 (Theorem III.72.1); for $5 \leq d \leq 8$ source 34’s coupled bounds slightly improve source 29’s (Remark III.71.10). So $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$ among sources 01–39; source 45, placed and not yet written, records $(832/4795)^{1/4} = 0.6454070$ (item III.1).

[write] **7 October 2026; sources 40–46.** *The upper end improved again* (source 45, Section III.89): $\|f\|_{U^4}^{16} \geq (4795/832) \|f\|_{U^2}^{16}$ (Theorem III.90.1), so $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ among sources 01–46; source 49, placed by `f8bc5e2ec` and not yet written in, records $29/4$, that is $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$ (for its write) (item III.1).

The universal bound $c_d^{\text{odd}} \leq 1$ follows from monotonicity. Our cosine example gives a positive explicit lower bound. The order-two character that attains the unrestricted coefficient is unavailable here, so the sharp universal result does not settle this restricted problem. A practical first project is a systematic search over small odd cyclic groups, followed by an inequality explaining any apparent extremizer. Numerical optimization would be evidence, not a proof of the supremum.

[write] **6 October 2026.** *Settled for $d = 3$ (cross-source finding).* Source 04’s Theorem III.3.4 gives $c_3^{\text{odd}} = 2^{-1/2}$, attained exactly by the real parts $2\operatorname{Re}(c\xi)$ of nontrivial characters (the question’s first alternative); proof in the note after that theorem. The best odd-order leading coefficient for $d = 3$ is $R_3 c_3^{\text{odd}} = 6\sqrt{2}$, as source 04 proves directly. For $d \geq 4$ the question is open; it coincides with source 04’s Question 3 (Section V.2, item III.1).

Research question V.14.2 (Classify the fifth and sixth centered coefficients). For each $r = 5, 6$, classify the supports $S \subseteq \{0, 1\}^d$ of size r for which the character system (III.2.27) can have solutions with no trivial character. Derive multiplicities as functions of d and identify the necessary quotient correlations and Fourier phase invariants.

The coordinate-reflection test removes every support with a coordinate occupied by exactly one selected vertex or by all but one. For surviving supports, Smith invariant factors identify possible small-torsion obstructions. A successful classification should distinguish actual vanishing of a centered correlation from mere rational independence of its defining forms. The fifth-order examples discussed at the end of Section III.2 give concrete starting cases.

[write] **6 October 2026; sources 06–10.** *Fifth order answered, sixth order open.* For $r = 5$ the question is answered by source 09’s Theorems III.20.1 and III.21.1 with Proposition III.20.2: two support types, multiplicities Q_d and S_d , and the correlations M_5 (order-two coupling χ, χ^2) and $T_{3,5}$ (order-three characters). For $r = 6$ it remains open; source 09 shows that an isolated order-five term occurs there (Theorem III.23.1) and asks the same question (Section V.2, item III.2).

Research question V.14.3 (The sharp fixed-threshold DRC profile). Let $F(\delta)$ be the largest guaranteed fraction $|K|/n$ under the exact hypotheses and success criterion of Lemma 7.4. Determine the correct order of $F(\delta)$ as $\delta \downarrow 0$. Can the exponent 3 in Theorem II.5.2 be improved using constraints specific to intersection matrices?

The scalar optimization proves only that a particular two-witness first-moment certificate cannot give a positive uniform estimate at the original parameters. Actual overlap matrices are symmetric positive semidefinite Gram matrices of indicators and obey further incidence constraints. It is a real additional problem to determine whether those constraints rule out the scalar bad distributions. Conversely, a lower bound on the necessary exponent requires realizable families of sets, not just a distribution of formal overlap values.

Research question V.14.4 (Optimize the entire elementary extraction). Optimize the three parameters $\gamma, \varepsilon, \beta$ in Proposition II.6.2, and compare alternative walk lengths and popularity thresholds. Which size–difference-set tradeoffs can be achieved while retaining only elementary finite inequalities?

The meaningful objective is the pair of conclusions, including the normalization of the difference-set bound by $|A|$ or by $|A'|$. Optimizing one displayed exponent while allowing the selected set to shrink excessively can conceal a loss. Comparison with [12] should remain explicit; the purpose of this project would be a simple formalizable proof or a better constrained tradeoff, not to mistake an elementary refinement for an improvement of the strongest known theorem.

Research question V.14.5 (Allocate phase oscillation by local mass). Suppose a phase partition can be refined at a cost depending on the desired oscillation in each cell. Can one minimize the total refinement cost subject to

$$\sum_j \int_{P_j} |f| |\psi_j - z_j| d\mu \leq \lambda \rho$$

by using local information on $|f|$, rather than a single global oscillation tolerance?

Lemma I.14.3 already provides the exact analytic constraint. The unresolved work is geometric: prove a refinement theorem with a cost function sharp enough for this optimization to matter. One can start with linear phases and known cell masses, then study polynomial phases. The global density factor in Theorem I.15.2 is the simplest instance of retaining this information.

Research question V.14.6 (Local counting that rectifies automatically). Develop a version of Theorem III.1.2 for interval-supported functions or localized norms in which the conclusion directly counts ordinary integer progressions and includes all boundary errors.

The elementary second-difference test gives a clean sufficient condition for rectification, but the global modular norm does not enforce that condition. The target is an explicit statement whose hypotheses reflect both uniformity and support. Any proposed bound should be tested on sets concentrated near the ends of the interval and on small composite moduli before it is fed into the density increment iteration.

Research question V.14.7 (Propagate improvements through a verified dependency graph). Replace the improved local lemmas in the later sections of the proof, record every dependence of density, progression length, dimension, and correlation on earlier parameters, and obtain a complete explicit iteration theorem.

Proposition V.12.1 specifies the final bookkeeping for one common type of increment. The hard work is to prove the hypotheses with the newly propagated functions. An initial useful deliverable would be a symbolic parameter dependency graph accompanied by Lean theorems for each monotone substitution. This would reveal which improvements survive and which are absorbed by later losses, even if the final asymptotic class stays unchanged.

Research question V.14.8 (Quantitative rounding and efficient derandomization). Optimize the group-size requirement for the sharpness constructions at a given error tolerance, including the exact-density version of Corollary III.2.12. Can one derandomize the rounding with an efficient finite algorithm?

The existence problem at a compatible prescribed rational density is already solved by the slow perturbation and small alteration in Corollary III.2.12. Its size requirement is deliberately generous. Sampling directly with a fixed total, a sharper norm estimate for the alteration, or a deterministic conditional-expectation argument might improve it. Independence no longer applies unchanged after conditioning on cardinality, so that approach needs its own estimate.

Research question V.14.9 (A reusable formal library of centered configuration counts). Build a finite-abelian-group library whose basic objects are systems of integer linear forms, centered multilinear averages, character constraint sets, and explicit reindexing bijections. Recover the cube and progression results as specializations.

The key interface should retain integer torsion data. A proof over $\mathbb{Q}$ alone does not control evaluation on all finite groups. At the same time, the library should make cancellation by a single free variable easy, so simple cases do not require a full Smith normal form calculation. This is an achievable software and formalization project with reusable mathematical outputs, independent of completing the entire Gowers proof.

V.15 Reproducibility and verification

Source 03, delivered Appendix A.

The accompanying archive contains the complete LaTeX source and compiled PDF, the figure in vector PDF form, scripts for the figure and finite checks, and the recorded check output. No original third-party paper is repackaged. The repository revision and source paths are recorded so that the comparisons can be repeated against the same input.

V.15.1 What the scripts check

`verify_cubes.py` uses only the Python standard library and exact rational arithmetic. It enumerates every four-vertex support of the Boolean cube for dimensions two through five. In dimension five this means all $\binom{32}{4} = 35960$ supports. It compares a classification from minors with a separate classification from XOR and coordinate patterns. The counts are exactly those in Lemma III.2.5. It also computes the coefficients of the full cube polynomial directly, without using the proposed quartic formula, on cyclic groups of orders two through six in dimensions two and three. The low-degree cancellations, torsion correction, and parity polynomial all pass.

`verify_estimates.py` checks the sharp selection extremizers with exact rational weights, evaluates the cubic certificate including its boundary and tangent cases, constructs proper phase partitions at several finite scales, and enumerates all subsets of $\mathbb{Z}/5\mathbb{Z}$ and $\mathbb{Z}/7\mathbb{Z}$ for the progression bounds at lengths three and four. The norm powers in the latter check are rational; taking roots and comparing the bounds uses floating-point arithmetic with an explicit tolerance. The phase oscillation checks are also numerical. These are clearly distinguished from the exact cube and scalar checks.

Independent written reviews checked the asymmetric selection extremizers, finite progression geometry, Cauchy–Schwarz induction, quartic support classification and Bernoulli rounding, cubic minorant, and four-label counting injection. These reviews and finite computations are useful error checks; the proofs in the article, rather than the tested finite range, justify the theorems for arbitrary parameters.

V.15.2 Building the document

From the extracted directory, run

```
python3 verify_cubes.py
python3 verify_estimates.py
pdflatex -interaction=nonstopmode -halt-on-error gowers_local_refinements.tex
pdflatex -interaction=nonstopmode -halt-on-error gowers_local_refinements.tex
```

The figure is already included, so compiling the document does not require Python or a plotting library. To regenerate the figure, run `make_figure.py` in an environment with NumPy and Matplotlib. The LaTeX source uses standard packages including AMS mathematics, Palatino fonts, microtype, booktabs, and hyperref.

V.16 Quantitative comparisons and what they enable

Source 04, delivered Section 9.

The preceding results address different sources of loss. Their benefits should therefore be read at the interface where each estimate is used. The following table records those interfaces without combining unrelated parameters into a single claimed global improvement.

Interface	Coarse source estimate	Strengthened estimate here
Graph moment, input $\gamma B ^3$	$\gamma^7\beta^{21}p^{15}$	$\gamma^7\beta^{15}p^{15}$; arbitrary moment order and equality cases
Almost-homomorphism restriction, order eight	$(\gamma^7\beta^6\eta/4)^{2^{19}} B ^{15}$	$2^{-95}\gamma^{112}\eta^{15} B ^{15}$, under the explicit size hypothesis in Corollary II.9.5
Three-cube upper bound, $u = \ f\ _{U^3}$	$(\delta + u)^8$	Excess begins with $6\sqrt{2}\delta^4u^4$, with explicit higher terms
k -term progression counting	Error bounded by 2^ku	Error bounded by $u\sum_{j=0}^{k-3}\delta^j$
Section 17 local coefficient	$2^{-2(k+1)^3}$	$2^{-k^2-k\log_2 k-O(k)}$, with an explicit constant

Table 11: Comparisons with the specified local estimates in [1, 23]. The variables and hypotheses are those of the corresponding sections. The improved restriction theorem includes a large-field condition, and the phase theorem includes a characteristic condition.

The field-size requirement in the restriction theorem has a particularly simple interpretation:

$$|B| \geq \Lambda_d(\alpha\eta)^{-2d}.$$

The ambient density does not otherwise enter this sufficient condition. Two elementary decisions are responsible. A rank-two exceptional relation leaves at most $|B|^{2d-2}$ tuples, because its free coordinates can be chosen from B . These contributions are then summed with their nonnegative Fourier weights, whose total is at most one. Thus the number of possible coefficient vectors does

not enter the error bound. Repeated entries are handled separately. These refinements are useful even before any attempt to optimize the kernel.

For an illustrative comparison, take $\gamma = \eta = \beta = 1/2$. The retained fraction of $|B|^{15}$ in the source display is $2^{-8388608}$, whereas the convenient bound here is 2^{-222} . The corresponding sufficient field-size condition here is $p \geq 2^{231}$. These are deliberately transparent evaluations of the proved formulas, not practical finite-size estimates. They show the change in parameter dependence and also the cost of the conservative exceptional-tuple estimate.

Figure 2: Proved bounds and an exact extremizing model at $\delta = 1/4$. Left: the excess above δ^8 in the source triangle-inequality bound and the two refined bounds of Theorems III.3.6 and III.3.8. The refined curves nearly coincide at small u because they have the same sharp leading term. Right: after subtracting that leading term, the explicit two-frequency family of Proposition III.3.9, divided by $\delta^{8/3}u^{16/3}$, tends to $(9/4)^{1/3}$. The figure evaluates formulas; it is not a statistical fit.

The cube results answer two precise local extremal questions. The best universal leading coefficient in the real centered, odd-order setting is $6\sqrt{2}$. In the setting without 2- or 3-torsion, the first possible correction after that leading term has optimal exponent $16/3$. What remains undetermined is the exact coefficient of this correction and the existence of a universal asymptotic expansion for the extremal envelope. These are local conclusions with explicit models, independent of any claim about the best quantitative bound for arithmetic-progression-free sets.

[write] **6 October 2026; sources 11–14.** The exact coefficient is now determined: $(9/4)^{1/3}$, by source 14 (Remark W4).

V.17 Further research questions and a proposed program

Source 04, delivered Section 10.

The questions below are proposed research targets arising from the calculations. The list distinguishes exact optimization problems from larger integration projects. It is not a claim that each formulation is already recognized as an open problem in the literature; a more extensive priority review should accompany work toward publication.

V.17.1 Extremal cube counts

Q1. Does the secondary extremal coefficient exist, and what is it? Fix $0 < \delta < 1$, and let $M_\delta(u)$ be the supremum of $Q_3(W)$ over prime cyclic groups of order greater than 16 and weights $0 \leq W \leq 1$ satisfying $\mathbb{E}W = \delta$ and $\|W - \delta\|_{U^3} = u$. Theorems III.3.8 and Proposition III.3.9 imply

$$(9/4)^{1/3} \leq \liminf_{u \downarrow 0} \frac{M_\delta(u) - \delta^8 - 6\sqrt{2}\delta^4 u^4}{\delta^{8/3} u^{16/3}} \leq \limsup_{u \downarrow 0} \frac{M_\delta(u) - \delta^8 - 6\sqrt{2}\delta^4 u^4}{\delta^{8/3} u^{16/3}} \leq 6. \quad (\text{Q1})$$

Determine whether the limit exists. Is the two-frequency value $(9/4)^{1/3}$ optimal? A useful first step is a sharper estimate of the quintic correlation in terms of the exact loss in the norm-gap inequality, instead of the separate bounds used above.

[write] **6 October 2026; sources 11–14.** *Settled by source 14*, by a route close to the one suggested here (it sharpens the loss in the norm gap by eight further Fourier slots and balances it against the quintic correlation): the limit exists and equals $(9/4)^{1/3}$, and the two-frequency value is optimal (Theorem III.34.1; in this normalization, with prime cyclic groups of order above 16 and norm exactly u , Remark W4). Item III.3.

Q2. What is the correct stability statement for cube extremizers? Corollary III.3.5 controls the fourth-power Fourier mass outside one conjugate pair, equivalently a U^2 remainder. This does not alone control an L^2 remainder: many small Fourier coefficients can have little fourth-power mass but substantial second-power mass. Determine the strongest stability conclusion for bounded weights that nearly attain the leading cube bound, and identify any additional hypothesis needed for a stronger metric. For near optimal secondary behavior, test whether concentration on frequencies $\{\pm\xi, \pm2\xi\}$ follows.

[write] **6 October 2026; sources 11–14.** *Answered for the secondary scale by source 14*: near-optimal secondary behaviour forces concentration on $\{\pm\xi, \pm2\xi\}$ in U^2 , with amplitude and phase alignment (Theorem III.34.3), and the indicator examples show that no L^2 conclusion follows. Item III.4.

Q3. What replaces the sharp norm gap in higher dimensions? For $d \geq 4$, determine the best constant in the comparison of $\|f\|_{U^d}^{2^d}$ and $\|f\|_{U^2}^{2^d}$ for real centered functions, specifying the allowed group orders. Combine it with the exact coefficient P_d of Proposition III.3.2. The Boolean support matroid gives a finite organizing device for the next correlations, but their values and sharp norm bounds require additional harmonic analysis. Separate large-characteristic behavior from the extra identities produced by small torsion.

[write] **6 October 2026.** For $d = 3$ the comparison is Theorem III.3.4; for $d \geq 4$ this is source 03's Research question V.14.1 (which asks for the constant over odd-order groups). Merged in Section V.2, item III.1.

[write] **6 October 2026; sources 28–33.** *Advanced for $d \geq 4$, not settled* (sources 28 and 29, Section III.66). Source 29 proves $\|f\|_{U^d}^{2^d} \geq 2^{-m} \binom{2m}{m} \|f\|_{U^2}^{2^d}$, $m = 2^{d-2}$, hence $c_4^{\text{odd}} \leq (8/35)^{1/4}$ and $c_d^{\text{odd}} \leq B_d \downarrow 1/2$, and $c_d^{\text{odd}} \geq 1/3$ for every d (Corollary III.69.1, Proposition III.69.2); source 28 proves $c_4^{\text{odd}} \geq 0.5587294$ and that a real part of a character is not extremal for $d \geq 4$ (Corollary III.70.8, Theorem III.70.9); the intake's certificate gives $c_4^{\text{odd}} \geq 0.5587725$. So $0.5587725 \leq c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ among sources 01–33; later placed sources record better upper bounds (item III.1).

V.17.2 Restriction and moment estimates

- Q4. Can the size threshold be substantially lowered?** Theorem II.9.1 requires $|B| \geq \Lambda_d(\alpha\eta)^{-2d}$. The proof already controls exceptional relations in expectation using their Fourier weights. Can their contribution be made to reflect the additive structure of B , rather than the uniform rank-two bound? Can a kernel with a more favorable coefficient distribution reduce the required size without weakening the retained tuple count? Any proposed improvement must handle repeated entries as well as extra relations among distinct entries.
- Q5. What is the true optimal retention law?** The bound $\kappa_d \alpha^{2d} \eta^{2d-1} |B|^{2d-1}$ has the natural parameter powers for the single-kernel expectation budget in Proposition II.9.6. That proposition does not establish optimality among all selection procedures. Construct upper-bound examples, or find a different selection method with better powers. Also ask for useful simultaneous guarantees on $|B'|$, its ordinary additive energies, and the density of respected relations.
- Q6. How far does restriction extend beyond prime cyclic groups?** The interpolation theorem already applies to arbitrary finite abelian groups. The restriction theorem uses a field to turn two independent linear equations into a uniform bound on the number of solutions. Develop versions for $\mathbb{Z}/N\mathbb{Z}$, finite-field vector spaces, and maps into other groups. The appropriate hypotheses should quantify kernels of the relevant coefficient maps, rather than silently treat nonzero determinants as invertible. A weighted formulation would also allow nonuniform input measures.
- Q7. Can the cross-section profile be propagated through the proof?** For arrangements the gain is governed by $\sigma = \mathbb{E}_r \beta_r^3$, not just by the global density. Track this profile through subsequent restrictions and changes of variables. Determine which operations preserve useful control of σ , and whether a collection of higher cross-section moments gives a stronger interface than a single density parameter. Equality models in Section II.10 provide tests against overly optimistic exponents.

V.17.3 Patterns, counting, and integration

- Q8. Determine the asymptotics of the fractional pattern counts.** The proved estimates imply

$$\frac{1}{2} \leq \liminf_{k \rightarrow \infty} \frac{\log_2 F_k}{k^2} \leq \limsup_{k \rightarrow \infty} \frac{\log_2 F_k}{k^2} \leq 1, \quad (\text{Q2})$$

and the same bounds for A_k . Determine the leading constant, or improve the gap in these bounds. Relate the particular affine arrangements here to established results on threshold patterns and subset-sum arrangements before assigning novelty. Exact certified counts for $k = 4$ are a concrete computational next step; exploiting symmetries is likely to matter more than merely using a faster numerical solver.

[write] 6 October 2026. *Answered by source 01* (cross-source finding of the intake, checked at the write). The F_k here is source 01's C_k and the A_k here is source 01's A_k : the definitions are identical. Source 01's Theorem IV.2.3 gives $k^2 - k \log_2 k - O(k) \leq \log_2 C_k \leq k^2 + (\log_2 e - 1)k$. Its Theorem IV.3.1 gives $C_k \leq A_k$ and $\log_2 A_k \leq k^2 + O(k)$. Hence both limits in (Q2) exist and equal 1. The lower half uses one external input, the classical threshold-function count (Zuev; Kahn–Komlós–Szemerédi, as recorded by Baldi–Vershynin [8]), which source 01 cites and does not reprove. Source 01's Proposition IV.5.1 certifies $F_4 = C_4 = 154$, the “concrete computational next step” asked for. A_4 is

not certified (an uncertified recount gives 770), and the secondary term is source 01’s first question; both remain open (Section V.2, items IV.2 and IV.1).

[write] **6 October 2026; sources 06–10.** Source 06 answers the same question independently: its Theorem IV.7.6 gives $\log_2 C_k = (1 + o(1))k^2$ and $\log_2 D_k = (1 + o(1))k^2$ (the same external threshold count), uniformly modulo every $M \geq 2$, and its Section IV.9 certifies $C_4 = 154$ a second time.

- Q9. Which global and local profiles are actually realizable?** The phase-extraction proof uses the uniform bound 2^k for the profiles at a fixed slope and an arrangement bound for all slopes. The slopes there come from a short discrete interval. Determine the joint distribution of profiles in that arithmetic setting, including small moduli M , and test whether an average multiplicity can replace the worst-case local multiplicity. The exact modular formula of Theorem IV.6.3 isolates one source of collisions.
- Q10. Can progression counting use more of the mixed information?** The dynamic program in Section III.4 finds the best bound within a specified telescoping family. It is not an optimality theorem for all counting arguments. Investigate whether mixed uniformity norms, additional cancellations, or information about particular pairs of factors can lower that bound. Any extension to nonadmissible slopes should display the relevant subgroup averages explicitly; the $\mathbb{Z}/2\mathbb{Z}$ example rules out simply dropping the invertibility assumptions.
- Q11. What survives complete propagation through the density increment?** Create a dependency graph for the quantitative parameters of the original proof. Substitute the improved moment, restriction, and profile estimates, and recompute every subsequent threshold with the same hypotheses. The output should be an explicit final function of k and density, with each loss traceable to a proved lemma. Compare the resulting bound with both the original argument and later work [2, 3]; an improvement in the historical proof need not improve the stronger modern theorem.
- Q12. Can the refinements be verified by a proof assistant?** Formalize the lowest-risk interfaces first: exact moment interpolation, the density-weighted telescope, and the finite support enumeration. Then formalize the selection theorem, where the main obligations are finite Fourier orthogonality, independent sampling, and the exceptional rank count. A fully checked dependency chain would clarify which quantitative gains are compatible with the later induction, and would separate a correct theorem statement from a completed formal proof. Appendix V.19 gives a proposed implementation order.

Questions 1, 4, and 8 offer relatively contained starting points: a sharp analytic constant, a finite selection threshold, and a concrete arrangement census. Questions 7 and 11 are integration projects, for which local success must be accompanied by careful propagation of hypotheses. The distinction helps keep a proposed research program testable.

V.18 Closing perspective

Source 04, delivered Section 11.

The strongest conclusions of this investigation are explicit local theorems with complete proofs. Exact moment accounting feeds a polynomial restriction theorem; centered Fourier structure yields sharp cube coefficients and a fractional correction exponent; and simultaneous floor-pattern counting

replaces a cubic exponential local loss by a quadratic one. The sharpness examples identify which aspects have already reached their natural limit and which constants remain to be determined.

The next substantial step is to turn these interfaces into a fully checked quantitative dependency chain. That would establish how much of the local improvement survives later stages of Gowers’s argument, while the extremal and pattern questions above offer independent research directions with precise targets.

V.19 A map to the Lean development

Source 04, delivered Appendix A.

This appendix identifies interfaces in the inspected snapshot [23]. It records a plan for additional work; it is not a report that new Lean declarations have been proved. A declaration defining a proposition, a theorem with a proof term, and a theorem successfully checked by the Lean kernel are different pieces of evidence.

Inspected interface	Proposed strengthening and principal proof obligations
<code>Proofs09Moments.lean;</code> <code>lemma_9_2_holds</code>	Keep the exact second moment before applying the higher-moment inequality. State the arbitrary-order graph version, with $ B $ in the denominator. The proof already computes an exact cardinality before weakening it.
<code>Proofs03CubeUpper.lean;</code> <code>lemma_3_10_holds</code>	Add centered cancellation and the real odd-order norm gap as separate lemmas. Prove the twelve quartic and eight quintic support classifications with explicit finite certificates or a transparent finite case split.
<code>Proofs03ProgressionAverage.lean;</code> <code>theorem_3_2_holds</code>	Generalize the required changes of variables to admissible slopes. Make multiplication automorphisms explicit, and reuse the Gowers–Cauchy–Schwarz infrastructure.
<code>Proofs03ProgressionCount.lean;</code> <code>corollary_3_3_holds</code>	Replace the full subset expansion by a finite telescoping identity. Retain density products and cancel the exact two-factor average.
<code>Proofs09Restriction.lean;</code> <code>lemma_9_3_holds</code> and <code>corollary_9_4_holds</code>	Introduce a prime-specialized version of the strengthened restriction theorem. Formalize the rank-two completion bound, the nonnegative Fourier weights, and the random-selection expectation.
<code>Sections17_18.lean</code>	Add definitions of fractional patterns and normalized profiles, followed by the hyperplane bound and the local phase-extraction theorem with explicit characteristic assumptions.

Table 12: Suggested interfaces for formalizing the proved refinements.

One signature issue deserves explicit review. The inspected definitions of `lemma_9_3` and `corollary_9_4` in `Sections08_09.lean` quantify over nonzero moduli without an explicit primality typeclass. The selection theorem in this article uses primality essentially. It must therefore be formalized as a separate prime-specialized statement, or accompanied by a justified revision of the intended source interface. It is not automatically a proof of the broader existing proposition. The repository already has proofs of those statements through another route; the present claim is a stronger prime-field interface. By contrast, the exact moment inequality itself does hold over arbitrary finite abelian groups.

[write] 6 October 2026. Checked at HEAD: `lemma_9_3` and `corollary_9_4` still quantify over all $N \geq N_0$

without primality and have exact companions, as stated. The table omits one interface that was already formal at source 04's pin: Lemma III.4.5 is `hasNatAP_of_short_modular_sequence` (note there). The other proposed strengthenings are not formalized.

For a practical implementation order, first isolate a normalized and an unnormalized Fourier convention with explicit conversion lemmas. Next prove the exact moment and telescoping statements, which need little specialized finite enumeration. Then introduce a library of finite Boolean support certificates for the cube identities. Finally add the probabilistic selection and floor-pattern arguments. Each step should compile against the pinned toolchain of the repository, and the final verification report should name the checked declarations and the commit. None of those future verification steps is represented as complete here.

V.20 Reproducibility and supplementary checks

Source 04, delivered Appendix B.

The source archive contains the complete L^AT_EX manuscript, its compiled PDF, the figure source and PDF, a provenance manifest, and three independent verification programs. The programs are deliberately supplementary to the proofs. In particular, testing finitely many functions cannot prove the norm-gap theorem, and checking small groups cannot prove the restriction theorem for all sufficiently large primes.

V.20.1 Energy, cube, and coefficient checks

`verify_refinements.py` uses the Python standard library. The recorded run checked all 8 470 nonempty graphs of partial maps $\mathbb{Z}/n\mathbb{Z} \rightarrow \mathbb{Z}/n\mathbb{Z}$ for $n = 2, 3, 4, 5$, giving 59 290 exact integer instances of the energy inequality for moment orders $2, \dots, 8$. It also enumerated the three-cube support ranks over the rationals and over $\mathbb{F}_2, \mathbb{F}_3, \mathbb{F}_5, \mathbb{F}_7$, and counted parallelograms through dimension seven. These computations exhibit the different support count in characteristic two.

The kernel checks use exact rational arithmetic for the selected coefficient ratios and the central-binomial inequality, and exact integer arithmetic for the convenient powers of two in Corollary II.9.5. The complete two-frequency polynomial in Proposition III.3.9 is independently recovered with rational coefficients.

Floating-point checks are identified separately in the results file. They test the Fourier identity and norm gap on 40 real centered functions on small odd cyclic groups, the cosine examples, and 36 density-weighted progression identities, including an admissible example modulo 25. The largest recorded Fourier-identity discrepancy is less than 1.1×10^{-16} , and the progression identity discrepancy is less than 3.4×10^{-17} . The asserted numerical tolerance is 2×10^{-11} . These are consistency checks, not rational certificates for arbitrary functions.

The supplied `verify_selection.py` checks the selection expectation bounds directly by exact rational Fourier expansion in 10 examples over $\mathbb{F}_3, \mathbb{F}_5, \mathbb{F}_7$, covering 40 584 ordered additive tuples. It treats each distinct selected point only once and includes 504 distinct unrespected six-tuples. These checks use the degree-one kernel and supplement the proof of the general weighted selection lemma; the large-degree constants are checked separately.

V.20.2 Exact floor-pattern certificates

`pattern_census.py` verifies the supplied `pattern_census.json` using only rational arithmetic from the Python standard library. It obtains

$$(F_1, F_2, F_3) = (1, 2, 10), \quad (A_1, A_2, A_3) = (2, 6, 38).$$

Every branch in the hyperplane enumeration has one of two certificates: a rational point satisfying all relevant strict inequalities, or nonnegative rational weights whose combination proves that those strict inequalities are infeasible. The verifier checks both sides of every split, so it checks completeness as well as feasibility. There are 450 certified branches in the supplied record. Generating the certificates uses a numerical linear-programming solver to propose candidates, but accepting them and verifying the saved census does not use numerical tolerances.

V.20.3 Build and verification commands

From the extracted archive directory, the following commands rebuild the article and check its supplementary records:

```
latexmk -pdf -interaction=nonstopmode -halt-on-error \
  gowers_quantitative_refinements.tex
python3 -S verify_refinements.py --output verification_results.json
python3 -S verify_selection.py --report selection_verification.json
python3 -S pattern_census.py --verify pattern_census.json
```

The prebuilt vector figure is included, so rebuilding the article does not require Python plotting libraries. To regenerate the figure, run `python3 make_figures.py`; that optional step requires NumPy and Matplotlib. Certificate generation additionally requires SciPy. The source manifest records the inspected repository commit and the relevant Git object identifiers. The archive does not redistribute the original paper or the full repository.

V.21 Relation to the Lean development

Source 05, delivered Section 7.

V.21.1 Inspected source and a conservative integration plan

The relevant files are `Proofs02Partition.lean`, `Proofs02PhasePartition.lean`, and `Proofs02DensityIncrement.lean`; the first and third were inspected in detail in the ranges relevant to these results. The existing density-increment file imports the phase-partition file. The repository uses `NatAP`, its carrier and properness predicate, and a finite partition relation. Its partition construction already groups residue classes into blocks with lengths at least L and less than $2L$, matching the integer mechanism used here [25].

The efficient formalization route is to keep that construction and expose a parameterized theorem, rather than duplicate it for each numerical constant. The mathematical contract should assume $2L(L-1)M \leq rs$ in the modular version and conclude a partition with cell lengths in $[L, 2L-1]$

and image diameter at most s . The proof then invokes the existing small-image-step lemma with $Q = \lfloor r/L \rfloor$.

The sharp capped result becomes a separate integer calculation with $U = \lfloor \sqrt{rs/M} \rfloor$ and $K = \lceil U/2 \rceil$. The optimality example can be formalized independently using the cardinality of a disjoint union of two-element cells. It does not require complex analysis.

For the density theorem, the main additional interfaces are the exact identity $\sum |\mathbf{1}_A - \delta| = 2\delta(1 - \delta)N$, a midpoint or disk-center phase estimate, and the capacity-sensitive positive-mass lemma. The existing file already proves the zero-sum identity, density bounds, positive/negative mass equality, and nonzero Fourier-coefficient bounds by both the set and its complement [26].

V.21.2 Recommended separation of proof layers

There are four natural layers. The first is integer combinatorics: proper progressions, residue classes, lengths, and disjointness. The second is phase approximation on $\mathbb{R}/\mathbb{Z}$ or $\mathbb{Z}\text{Mod } N$. The third is finite weighted real and complex inequalities. The fourth specializes to Fourier coefficients and density increments. Keeping these layers separate permits the same weighted lemmas to be used with later polynomial-phase partitions.

For a minimum-risk first contribution, formalize the sharp $1/3$ modular theorem and the strengthened Corollary 2.4 before introducing the spectral-energy material. The simultaneous box lemma is another independent milestone. The algebraic obstruction is mathematically self-contained, but its Lean implementation would additionally need algebraic-number and resultant or norm infrastructure; it need not block the upper partition bounds.

V.21.3 Verification status

No new Lean file in this package is claimed to compile, and no new theorem has been kernel-checked here. The package supplies ordinary mathematical proofs, an exact-arithmetic implementation of the finite partition constructions, and a formalization roadmap. We did not perform a whole-repository proof audit or infer the status of the complete Gowers development from the inspected modules.

The observed `main` reference during this work was

327773149bd272239f1f6c0015f76d5097512c88.

The accompanying source-audit file records the content hashes of the compared files. The partition module was also fetched explicitly at that commit. The other inspected contents are identified by their returned blob hashes; the moving branch is not treated as a permanent identifier.

[write] 6 October 2026. Checked at HEAD: the cited blobs are correct and unchanged (291b149 for `Proofs02Partition.lean`, 85b5c3a for `Proofs02DensityIncrement.lean`, 41085a0 for the transcription). One defect of the shipped audit file `05-phase-partitions-SOURCE_AUDIT.md`: it says the commit-pinned read of `Proofs02Partition.lean` “included lines 580–780”, but that file has 702 lines; the blob and the construction it describes (blocks of lengths at least L and less than $2L$) are correct. The audit file is shipped unchanged (README).

V.22 Reproducible computation and the limits of testing

Source 05, delivered Section 8.

The companion implementation `code/phase_partitions.py` uses Python integers and rational fractions for all partition decisions. It implements the exact scale (I.16.2), the capped $1/3$ theorem, the simultaneous ceiling condition (I.18.2), and the tolerance allocation (I.19.10). An independent checker verifies complete coverage, no repeated points, proper arithmetic progressions, one common difference, the claimed cell lengths, the number-of-cells bound, and exact circular arc widths.

The completed exact tests comprise 13,325 one-phase cases, 11,440 capped cases, 320 simultaneous cases, and 200 tolerance-allocation cases. The one-phase tests vary the interval length from 1 to 41, all slopes with denominators from 2 to 11, and five rational widths. Of the simultaneous cases, 166 have minimum length greater than one. The seeded random tests use dimensions from one to four. These checks test rounding and implementation; they are not substitutes for the proofs in Sections I.16 and I.18.

Fourier diagnostics use 80 decimal digits. There are 60 correlation-and-popularity cases and 96 spectral-energy cases. Twenty-four spectral cases have a non-singleton guaranteed minimum length, including six genuinely multifrequency cases at larger sizes. The larger examples are modular pullbacks of intervals, with their Fourier coefficients computed by a geometric-series formula independently of the partition construction. All tested inequalities passed with positive observed margins. These are numerical diagnostics, not exact certificates for transcendental inequalities.

The verification files distinguish exact structural tests from high-precision diagnostics and explicitly record that new Lean verification was not performed. To reproduce the results, run the commands in the package README. No source paper, repository file, or font file is redistributed.

V.23 Further research questions

Source 05, delivered Section 9.

The following questions arise naturally from the proved results. Unless explicitly stated otherwise, they are research directions formulated here; we do not assert that they are all previously recognized open problems.

1. Exact finite partition profiles. The universal constant $1/3$ with the fixed upper cap is settled above, but the exact best lower length for each triple (r, s, M) and each slope can be much larger. Determine an efficient characterization of the feasible pairs of minimum and maximum lengths, taking account of residue-class sizes rather than only a worst-case blocking lemma. The explicit obstruction at total size nine explains one universal constant, not the full profile.

2. Best constants in the simultaneous minimax theorem. The exponent and the symmetric dependence on ε are sharp, but the upper constant obtained from the elementary algebraic norm argument is very poor. Determine the optimal leading constants, first for one or two phases, and the extent to which requiring a common difference across the whole partition changes them. One must specify the order of the limits in N and ε .

3. Anisotropic lower bounds. The lower construction depends on $\prod_i \varepsilon_i$. Is there a matching minimax upper bound in all highly anisotropic regimes, up to dimension-dependent constants and an additive one? A coordinate with a very loose tolerance can cease to be a genuine constraint, so a

naive product formula may require a regime decomposition. Weighted Diophantine approximation is the natural language, but no such theorem is assumed here.

4. Optimal density-sensitive correlation transfer. The disk radius and the capacity inequality are separately sharp, but their simultaneous extremizers need not arise from an indicator and a linear phase. Determine the exact feasible region of block positive mass, Fourier correlation, density, and phase width. Even a finite-dimensional extremal formulation could improve the trade-off (I.17.9) and identify which constant losses are genuine.

5. Adaptive selection of frequencies and tolerances. The continuous allocation problem is solved by Proposition I.19.3, but selection of the frequency subset and optimization of the exact ceiling formula are not. Develop an algorithm that balances captured energy, coefficient imbalance, dimension, and the final integer progression length. Its correctness should be stated relative to a certified Fourier input rather than floating-point estimates alone.

6. Higher-degree and nilsequence interfaces. Apply the residual-variance inequality to valid higher-degree localization theorems. The challenge is to track density-sensitive oscillation budgets together with geometric complexity and exceptional cells. A useful target is an explicit theorem where all losses are parameterized, so that an improvement of a partition result propagates mechanically through the density argument. This would still need a separate analysis before it implied any global Szemerédi improvement.

7. Formalizing sharpness as well as existence. A Lean formalization should include the parity obstruction proving optimality of $1/3$, not just the existence theorem. This makes the quantitative API resistant to later accidental strengthening. The next independent target is the exact residual inequality (I.19.4); it isolates a reusable finite-probability fact without depending on the full higher-order proof.

8. Interval-localized spectral extraction. On a proper interval, restricted characters have a nontrivial Gram matrix. Corollary I.19.4 provides an explicit scalar-norm correction, but a large value of κ can erase the gain from several correlations. Establish useful certified conditioning bounds for specific frequency configurations, and optimize the linear combination using more of the Gram matrix than its largest eigenvalue. This would turn the abstract extension into an effective local Fourier theorem.

V.24 Conclusion

Source 05, delivered Section 10.

The finite localization step admits stronger statements than the corrected repository currently exports. The lower constant $1/3$ in the capped partition theorem is exactly optimal; the new Corollary 2.4 retains the same upper cell size with a better lower size and correlation retention; and the density increment uses the true mass $2\delta(1 - \delta)$ instead of a unit bound. Simultaneous localization has a clean, sharp exponent, and a residual-variance inequality turns an appropriate Fourier-energy hypothesis into a multiplicative increment with a density-sensitive tolerance budget.

These are local quantitative results with complete proofs and reproducible computational checks. Their place in the larger program is to provide stronger interfaces and clearer bottlenecks, not to bypass the higher-order structural work needed for a new global theorem.

V.25 An explicit potential for density-dependent iteration

Source 06, delivered Section 6.

The iteration in the proof of Gowers' Theorem 18.2 estimates every density increment by the one available at the starting density [1]. Tracking the increasing density instead gives a sharper bound. We first prove a general deterministic lemma; it separates this bookkeeping improvement from the local structural theorem that supplies the increment.

Lemma V.25.1 (Discrete potential). *Let $0 < \delta_0 \leq 1$ and $t \geq 1$. Let F be positive, nondecreasing, and continuously differentiable on $[\delta_0, 1]$. Let G be nonnegative and nonincreasing there. Suppose*

$$\delta_0 < \delta_1 < \cdots < \delta_{t-1} \leq 1, \quad \delta_{i+1} \geq \delta_i + F(\delta_i).$$

Then

$$\sum_{i=0}^{t-1} G(\delta_i) \leq G(\delta_0) + \int_{\delta_0}^1 G(u) \left(\frac{1}{F(u)} + \frac{F'(u)}{F(u)} \right) du. \quad (\text{V.25.1})$$

Proof. For $x < y$ with $y - x \geq F(x)$, put $r = F(y)/F(x) \geq 1$. Monotonicity gives

$$\begin{aligned} \int_x^y \left(\frac{1}{F(u)} + \frac{F'(u)}{F(u)} \right) du &\geq \frac{y-x}{F(y)} + \log r \\ &\geq \frac{1}{r} + \log r \geq 1. \end{aligned}$$

The last inequality follows because $r^{-1} + \log r$ is nondecreasing for $r \geq 1$ and equals one at $r = 1$. Since $G(u) \geq G(y)$ on $[x, y]$, the same integral weighted by G is at least $G(y)$. Apply this observation to the interval preceding each summand except the first, and add. $\square$

Taking $G = 1$ gives a useful count alone:

$$t \leq 1 + \int_{\delta_0}^1 \frac{du}{F(u)} + \log \frac{F(1)}{F(\delta_0)}. \quad (\text{V.25.2})$$

For $F(u) = cu^p$ with $p > 1$, this becomes

$$t \leq 1 + \frac{\delta_0^{1-p} - 1}{c(p-1)} + p \log \frac{1}{\delta_0}. \quad (\text{V.25.3})$$

The logarithmic correction makes the integral estimate valid for the discrete process without assuming infinitesimal steps.

V.25.1 A power-law density increment and length loss

Theorem V.25.2 (Explicit iteration budget). *Suppose a hereditary configuration problem has the following valid local alternative. At any density $0 < \delta \leq 1$ and length $N \geq N_* > 1$, either the desired configuration exists, or restriction to a subprogression gives density and length satisfying*

$$\delta' \geq \delta + c\delta^p, \quad N' \geq N^{a_0\delta^q}, \quad (\text{V.25.4})$$

where $c > 0$, $0 < a_0 \leq 1$, $p \geq 1$, and $q \geq 0$ are fixed. Assume the same alternative applies after each restriction, and fix an initial density $0 < \delta_0 \leq 1$. Set

$$A = \log(1/a_0), \quad L = \log(1/\delta_0).$$

For $p > 1$, put $r = p - 1$ and define

$$\begin{aligned} B(\delta_0) = A + qL + \frac{A\delta_0^{-r} - 1}{c} & \\ + \frac{q\delta_0^{-r}(rL - 1) + 1}{r^2} + pAL + \frac{pq}{2}L^2. \end{aligned} \quad (\text{V.25.5})$$

For $p = 1$, define instead

$$B(\delta_0) = A + qL + \left(\frac{1}{c} + 1\right) \left(AL + \frac{q}{2}L^2\right). \quad (\text{V.25.6})$$

Then a sufficient initial length is

$$\log \log N \geq \log \log N_* + B(\delta_0). \quad (\text{V.25.7})$$

All logarithms in these formulas are natural.

Proof. Writing $H = \log \log N$, the length conclusion in (V.25.4) loses at most

$$G(\delta) = A + q \log(1/\delta)$$

from H at one step. Apply Lemma V.25.1 with $F(u) = cu^p$. Its integral is

$$\int_{\delta_0}^1 (A + q \log(1/u)) \left(\frac{1}{cu^p} + \frac{p}{u} \right) du. \quad (\text{V.25.8})$$

For $p > 1$, the elementary identities

$$\int_{\delta_0}^1 u^{-p} du = \frac{\delta_0^{1-p} - 1}{p - 1}$$

and

$$\int_{\delta_0}^1 u^{-p} \log(1/u) du = \frac{\delta_0^{1-p}((p-1)L - 1) + 1}{(p-1)^2}$$

evaluate (V.25.8) and give (V.25.5). Direct integration for $p = 1$ gives (V.25.6).

If no desired configuration exists, apply the local alternative repeatedly. After every finite number of restrictions, (V.25.1) and (V.25.7) leave $\log \log N_i \geq \log \log N_*$, so the local alternative remains applicable. Every step increases density by at least $c\delta_0^p > 0$. Such a sequence cannot stay at most one indefinitely, which is a contradiction. $\square$

A nonincreasing density-dependent threshold $N_*(\delta)$ causes no change: use $N_*(\delta_0)$ as the common threshold. A fixed length prefactor is also explicit. If the local length conclusion is

$$N' \geq C^{-1} N^{a_0 \delta^q}, \quad C \geq 1,$$

use the stronger working threshold

$$N_{\text{work}} = \max \left\{ N_*, \exp \left(\frac{2 \log C}{a_0 \delta_0^q} \right) \right\}. \quad (\text{V.25.9})$$

At every retained density, this implies

$$\log N' \geq a_0 \delta^q \log N - \log C \geq \frac{a_0 \delta^q}{2} \log N.$$

Thus Theorem V.25.2 applies with a_0 replaced by $a_0/2$ and N_* replaced by N_{work} .

V.25.2 Optimal leading order and the scope of the improvement

For fixed a_0, c, p, q with $p > 1$, formula (V.25.5) has the expansion

$$B(\delta) = \frac{\delta^{1-p}}{c} \left(\frac{A + q \log(1/\delta)}{p-1} - \frac{q}{(p-1)^2} \right) + O((\log(1/\delta))^2 + 1). \quad (\text{V.25.10})$$

Its leading term is optimal for the abstract local rules (V.25.4). Indeed, take the slowest allowed density sequence

$$\delta_{i+1} = \delta_i + c \delta_i^p$$

and charge exactly $G(\delta_i)$ at each step until a fixed positive target δ_* is reached, choosing $\delta_* + c \delta_*^p < 1$ so that the last step stays below 1. Since G/F is nonincreasing,

$$\int_{\delta_i}^{\delta_{i+1}} \frac{G(u)}{F(u)} du \leq \frac{G(\delta_i)}{F(\delta_i)} (\delta_{i+1} - \delta_i) = G(\delta_i).$$

Summing gives a lower bound by the main integral, up to a constant depending on the fixed target. Lemma V.25.1 exceeds that integral by only $O((\log(1/\delta))^2 + 1)$. Consequently, the leading coefficient in (V.25.10) cannot be improved using only the local recurrence and its charged length loss. Additional structural information would be necessary.

For comparison with the scale in Gowers' final iteration, suppose a valid local theorem supplies

$$\delta' \geq \delta + (\delta/2)^p, \quad N' \geq N^{(\delta/2)^p}. \quad (\text{V.25.11})$$

Then $c = a_0 = 2^{-p}$ and $q = p$. For fixed $p > 1$ and $\delta \rightarrow 0$, the leading double-logarithmic cost is

$$\frac{2^p p}{p-1} \delta^{1-p} \log(1/\delta).$$

Freezing density throughout gives a cost asymptotic to

$$2^p p \delta^{-p} \log(1/\delta).$$

Their ratio is asymptotic to $\delta/(p-1)$: the potential saves one power of the starting density in the double-logarithmic threshold. This changes neither the tower height nor the local structural input.

In particular, the repository snapshot explicitly records that its edited proof of Theorem 18.1 no longer establishes the displayed tower exponent after its revision of Corollary 16.11 [41]. Specializing (V.25.11) to that particular exponent is therefore conditional on a valid local increment theorem; Theorem V.25.2 itself has the complete proof given above.

The two refinements in these sections are complementary. The extraction theorem preserves the information already present in a partition, including the occupied negative mass and any discarded exceptional set. The iteration theorem preserves the subsequent increase in density. Both identify exactly which additional information would be required for a larger improvement.

[write] **6 October 2026; sources 06–10.** Iteration bookkeeping is also in source 03’s Proposition V.12.1 and source 10’s Propositions V.42.1 and V.42.2; the leading coefficients of the step counts are compared in the note after source 03’s proposition (the coefficient here is the smallest). The statement about Theorem 18.1 is still true at HEAD: `theorem_18_1`, `theorem_18_2` and `corollary_16_11` are open in the ledger.

V.26 Compatibility with the Lean development

Source 06, delivered Section 8.

The new mathematical statements in this report have not been added to the repository or compiled in Lean. The purpose of this section is to give an implementation map grounded in inspected definitions and proof endpoints, so that a subsequent formalization has a precise starting point. All names below belong to the namespace `LeanProofs.GowersSzemerédi` in the pinned snapshot [41].

V.26.1 Normalization and statement boundaries

The repository’s `gowersNorm d f` is unnormalized:

$$\|f\|_{U^d(G)} = \frac{\text{gowersNorm } d \ f}{N^{(d+1)/2^d}}.$$

Its predicate `UniformOfDegree f alpha d` corresponds to

$$\|f\|_{U^{d+1}}^{2^{d+1}} \leq \alpha.$$

Both the normalization and the index shift must be preserved when translating the quadratic counting criterion. The development’s `progressionAverage` is an unnormalized double sum, so the normalized discrepancy formulas here acquire a factor N^2 .

The existing endpoint `theorem_3_2_holds` lives in `Proofs03ProgressionAverage.lean`. The exact source companion `corollary_3_3_holds` is in `Proofs03ProgressionCount.lean`; it currently retains the 2^k factor. The source’s monotonicity and progression-existence companions are in `Proofs03Basic.lean` and `Proofs03ProgressionExistence.lean`. The public `gowers_cauchy_schwarz` in `Proofs03GowersCS.lean` supplies the mixed-cube inequality used in the localized phase proof.

V.26.2 A practical sequence of formalization steps

1. **Introduce a generic weighted extraction theorem.** Formalize Theorem I.21.1 using finite positive weights and cell averages, independently of cyclic groups. Derive `lemma_5_15_holds`

and its stronger replacements as special cases. The proof needs finite-sum identities, non-negativity, and pigeonhole arguments. The rational extremizers provide explicit sharpness witnesses.

2. **Replace the subset expansion in progression counting.** First add the indexed telescoping theorem without changing the existing uniformity assumptions. Then prove the two-target Cauchy–Schwarz induction and the quadratic bound. Keeping the first-order theorem separate is useful because it needs uniformity only for the later inputs, whereas the convenient homogeneous quadratic statement assumes a common higher norm bound.

3. **Expose finite carry families.**

The source defines `floorDotPattern` and `floorAffinePattern`. The two exact companions are `corollary_17_5_holds` and `corollary_17_6_holds`. Their proofs appear in `Proofs17FinitePatterns.lean`. That file splits the intercept into integer and fractional parts but does not use the exact split of every slope developed here. New finite-image definitions for $C(V)$ and $D(V)$ would make Theorems IV.7.3 and IV.7.4 natural cardinality statements. The one-sided perturbation lemma should be formalized before invoking the region count.

4. **Parameterize localized phase removal by a pattern bound.** The proof in `Proofs17LocalizedPhaseRemoval.lean` already isolates the raw inequality with a factor L^2 and a numerical lemma requiring $L^2c < 1/4$. Expose a version whose input is any valid pattern bound $L \leq K$; instantiate it with $c = 1/(8K^2)$. This permits a local replacement without rewriting the Fourier and cube algebra.
5. **Keep the Section 18 dependency conditional until its inputs are proved.** The actual theorem `section18_cyclic_density_increment_holds_of_theorem_18_1` has an explicit Theorem 18.1 hypothesis. Writing its exponent as ε , it obtains a density gain $\varepsilon/4$ and a progression size at least $(\varepsilon/4)N^\varepsilon$. The size prefactor must be retained or absorbed by a proved threshold estimate. The potential in Section V.25 is a separate, reusable way to perform the remaining iteration once a stable local theorem with explicit hypotheses is available.

The interval and affine transfer modules already document an additional quantitative issue: embedding a progression of length L into a cyclic group of order M changes ambient density by the factor L/M . A proof that repeatedly uses the new modulus cannot keep the old density without accounting for this factor. Our modular existence criterion does not remove that obligation.

V.26.3 What a completed formalization would certify

The existing audit distinguishes ordinary theorem companions from conditional implications and checks their axiom dependencies. A formalization of the proposed refinements should retain that distinction. There are three different goals: proving each auxiliary inequality, proving that its hypotheses hold at a particular use site, and proving that all constants survive the complete iteration. The first two can be made substantially more transparent by the exact interfaces above; the third remains a separate quantitative theorem.

[write] **6 October 2026; sources 06–10.** *Checked at HEAD (764740f07):* every declaration named above exists, with the roles described (`theorem_3_2_holds`, `corollary_3_3_holds`, `corollary_3_6_holds`, `gowers_cauchy_schwarz`, `corollary_17_5_holds`, `corollary_17_6_holds`, `lemma_5_15_holds`, `sectio`

n18_cyclic_density_increment_holds_of_theorem_18_1 in Proofs18QuantitativeSzemerédi.lean).
None of this source’s statements is formalized.

V.27 Further research questions and a concrete program

Source 06, delivered Section 9.

The questions below arise directly from the proved results. Unless a separate literature status is given, “question” means that the issue is not settled in this report; it does not assert that no answer has ever appeared elsewhere. This qualification is particularly relevant to small chamber counts and to inequalities obtainable by standard Cauchy–Schwarz arguments.

1. **Exact carry enumeration and a combinatorial interpretation.** Find a structural formula or recurrence for C_k and D_k , beginning with the certified values $C_4 = 154$ and $D_3 = 38$. The arrangement has normals indexed by nonempty subsets, integer thresholds, and a distinguished unit cube. Its symmetries, intersection lattice, and periodic extension are natural tools. An OEIS investigation should identify the underlying objects and definitions, not merely match a short numerical prefix. The exact certificates here provide a small benchmark for a symmetry-aware enumerator.
2. **The next term in carry entropy.** The leading coefficient in $\log_2 C_k \sim k^2$ is now determined by the threshold reduction and arrangement bound. Determine the order and coefficient of the next term, or prove a substantially smaller upper/lower gap. The current elementary upper bound is $k^2 + O(k)$; a sharper use of the threshold embedding or of the geometry internal to the unit cube may distinguish C_k from the unrestricted threshold count.
3. **Quantify information lost modulo a fixed modulus.** Although $C_{k,M}$ has the same leading entropy as C_k for every $M \geq 2$, this leaves open a large range of possible ratios $C_{k,M}/C_k$. Determine that ratio, or its logarithmic scale, for $M = 2$ and $M = 3$. The exact factorization (IV.7.6) means that any such result immediately improves modular pattern bounds without changing the integer-part argument.
4. **An exact affine orbit formula.** The nonaffine decomposition is injective because singleton carries vanish. Affine carries do not have that property. Classify precisely when two fractional affine carry maps differ by an integer linear map modulo M , and use this classification to determine $L_k(r, M)$ in the saturated range $2r \geq M$. This is a finite equivalence problem that can be explored with the certified carry families before seeking an asymptotic theorem.
5. **Avoid the square of the pattern count analytically.** The proof of Theorem IV.8.1 uses one Cauchy–Schwarz step over classes and one choice of a class, giving L^2 . Is there useful orthogonality, an energy-weighted decomposition, or additional structure among the realized classes that reduces this loss? The entropy lower bound rules out subquadratic enumeration of all classes, but it does not rule out an analytical argument that pays only for the classes carrying significant energy.
6. **Optimal density dependence in higher progression counts.** For $k = 3$, the variance factor in the quadratic discrepancy bound is sharp, as singletons show. For $k \geq 4$, determine the best coefficient depending on k and δ that can replace $\sqrt{\delta}B_k(\delta)$. One can first ask the narrower question within the family of repeated telescoping and mixed-norm Cauchy–Schwarz proofs. This would separate improvements of the method from a sharp extremal theorem about all sets.

7. **Torsion-sensitive forms of the two-target inequality.** When multiplication by a slope difference has a kernel, the variable changes in the proof cease to be measure-preserving bijections. Determine the best replacement constants in terms of those kernels and their interactions. Three-term progressions are the first test case; longer systems may require data beyond individual kernel cardinalities. This would extend the present theorem to moduli excluded by $\gcd(N, (k-1)!) = 1$.
8. **Use the mass of all dense cells.** The sharp extraction theorem quantifies the total mass above each threshold, not just the size of one selected cell. Can a branching density-increment argument exploit this mass to improve a structural or counting bound? The extremizers show that an improvement from the same scalar data alone is impossible; one must retain geometric information about the collection of high-density cells.
9. **Optimal finite corrections to the iteration potential.** For the power-law recurrence, the leading integral cost is already optimal. Determine a minimal discrete correction, or an exact dynamic-programming potential, with a useful closed form for finite starting density. A companion problem is to incorporate a density-dependent length prefactor and a nonmonotone admissibility threshold without replacing them everywhere by their worst initial values.
10. **Close the quantitative dependency chain in the inspected formalization.** The highest-impact repository task is to complete the outstanding structural estimates around Sections 13 and 16, establish the needed form of Theorem 18.1 with explicit thresholds, and only then combine extraction, transfer, and iteration. The local improvements here should be retained as parameters rather than immediately weakened to one coarse tower expression. A second route is to plan a formal treatment of modern inverse-theorem inputs, making clear which substantial theorems are being imported.
11. **Other integer-valued configuration families.** Theorem IV.7.3 already handles finite non-negative integer coefficient families V . Study which families have carry entropy comparable to the rank times the logarithm of their size, and which have additional cancellations. For signed families, first resolve the lower-dimensional floor-boundary obstruction identified after that theorem. Such a generalization could support localized arguments for configurations other than a Boolean cube.

For immediate implementation, the weighted extraction theorem and the indexed telescoping estimate are the smallest independent formalization tasks. The exact carry decomposition is the next natural target; it has an elementary proof, useful finite certificates, and a direct downstream consumer in phase removal. A global improvement requires the additional structural inputs identified above, with their actual density and scale dependence preserved.

[write] 6 October 2026; sources 06–10. These eleven questions are merged into Section V.2 with credits (items IV.2, IV.1, IV.3, IV.4, III.8, III.9, I.11, V.3, V.1 and IV.6). Question 7 is partly advanced by source 10’s Theorem III.28.2, which handles kernels for one distinguished function.

V.28 Verification and the Lean integration boundary

Source 07, delivered Section 9.

V.28.1 Exact finite checks actually performed

The supplementary `checks.py` uses only Python’s standard library. All decisions use integers or `fractions.Fraction`; the sole decimal parameter `ratio` is for display. The recorded run produced `verification.json`, with all checks passing.

Check	Completed instances
All maps $\phi, \psi : \mathbb{Z}/4\mathbb{Z} \rightarrow \mathbb{Z}/3\mathbb{Z}$, all order-two source relations	6,561 function pairs; 419,904 relations
Equal-total word pairs in 220 unequal-fiber or punctured examples, using both the original and a second starting law	24,200 relation–law pairs
Primal profile versus exact one-variable dual	16,472 equalities
Nested-to-average envelope, including empty targets	9,059 applicable cases
Collision-to-mode inequality	1,936 cases
Sharp cyclic winding family, $2 \leq k \leq 20$, $2 \leq m \leq 5$	76 examples
General allowance at $\eta = (40k)^{-5}$, $2 \leq k \leq 1000$	999 rational endpoint checks

The randomized finite suite has the fixed seed 20261006 and includes both unstructured values and nearly affine examples. It recorded 6,058 strict relation certificates, so its tests are not confined to vacuous large-error bounds. The exhaustive singleton suite recorded 5,880 strict certificates and 157,464 violated relations, each with budget at least one. These are finite sanity checks on normalization, strictness, and source-law handling. They do not establish any universal statement by themselves; the general proofs are Sections II.14–II.19.

The inequalities for the order-five, order-nine, and relaxed order-two endpoints were also evaluated exactly. For example, the first budget at $\eta = 360^{-5}$, $\theta = 1/36$, is

$$18 \left(\frac{71}{1296} + 360^{-5} \right) = \frac{331257600001}{335923200000} < 1.$$

The original hypothesis is strict, but checking this closed endpoint gives a slightly stronger numerical verification of the corollary.

[write] **6 October 2026; sources 06–10.** Rechecked at the second write in exact arithmetic: $q(1/36) = 71/1296$, $18(71/1296 + 360^{-5}) = 331257600001/335923200000 < 1$, and $360^{-5} = (40 \cdot 9)^{-5}$, which is why Corollary II.17.6 follows from Theorem II.17.5 at $k = 9$.

V.28.2 What was inspected in the repository

The baseline is commit `ae0e895748209f0dd079c6b5ca6df6c6fc065a81`. The relevant files and roles are:

Section10.lean

Its local-model definition records the two nested agreement conditions. Its shift-regular definition includes fiber saturation, symmetry, factor-two fiber comparability, and overlap. The catalogue entry `lemma_10_9` concludes `FreimanHom 2 B' psi`.

Proofs10Shift.lean

The file contains `lemma_10_9_holds`. Its proof includes explicit handling of nonempty terminal fibers; this note does not attribute a vacuity bug to that proof. The proposed refinement replaces its two-step exceptional-set organization with averaged path marginals.

Audit.lean

Its comments distinguish an axiom-boundary audit from discharging the hypotheses of conditional results and from matching the numbered catalogue to the paper. This distinction is retained here.

The statements and proof source were read, but no Lean build or audit was run for this article. In particular, the existence of the old companion proof is not evidence that the new order-five or order-nine theorem has been formalized. The references [42, 43, 44] and the machine-readable source manifest identify the comparison precisely.

[write] 6 October 2026; sources 06–10. At HEAD (764740f07) Section10.lean, Proofs10Shift.lean and Audit.lean are unchanged since the pin ae0e89574; lemma_10_9 is at line 335 and lemma_10_9_holds at line 717. The ledger has changed since the pin (4 statements closed: lemma_16_1, lemma_16_5, lemma_16_6 and lemma_16_9), none of them in Section 10.

V.28.3 A concrete formalization route

A practical integration should first prove a finite counting version of the four-edge theorem and only then introduce arbitrary paths and optimized profiles. A proposed module decomposition is:

1. **Directional kernels.** Define internal target fibers, boundary counts, and nonnegative rational edge defects. Prove the identities (II.13.3)–(II.13.4), with positivity hypotheses attached only to denominators actually used.
2. **Transport bounds.** Prove the simple domination lemma $\sum \mu_s f \leq c(s) \sum \mu f$ for $0 \leq f$, and derive the factor-two and additive-invariance instances. The full profile optimization can be postponed; it is unnecessary for the five/nine corollaries.
3. **A shared-endpoint finite sample.** Represent paths by finite lists or `Fin`-indexed vertices, with two explicit endpoint variables and independent internal variables. Prove a weighted union bound before translating it into existence of a successful sample.
4. **The local interface theorem.** Prove Lemma II.17.1, then the factor-two order- k criterion and the order-five consequence. Keep these separate from the stronger theorem using `DomainInvariant` and a fiber lower bound.
5. **Exact constants and audits.** Derive the real-power comparison once, discharge the rational polynomial estimates, and run the namespace axiom audit on the resulting new theorem declarations. Do not relabel an unproved proposition-valued catalogue entry as a completed theorem.

Two technical design choices deserve explicit tests. First, when a path returns to its starting index, its terminal *sample* must not be identified with its initial sample; otherwise the intended pair marginals can change. Second, restricting to previously successful equations is not the same as restricting to surviving indices. Only the latter restriction is used in the marginal bound. The file `FORMALIZATION.md` in the package records these obligations separately from completed mathematics.

V.29 Further research questions and priorities

Source 07, delivered Section 10.

The following are proposed problems arising from this framework. Except for the sharp balanced threshold already settled in Theorem II.16.1, we make no claim that these are previously catalogued open problems or that the listed approaches resolve them.

Question V.29.1 (Optimal nonuniform threshold). *For fixed $k \geq 2$ and $\kappa > 1$, what is the largest universal δ -threshold forcing order- k relations when fiber sizes vary by at most κ ? How does a separate boundary bound improve it?*

The bound $1/\{2[1 + (k - 1)\kappa]\}$ is proved, but only its balanced specialization is shown sharp. A promising finite search would optimize fiber sizes and actual value assignments, rather than arbitrary independent error profiles. The latter relaxation may exaggerate what a single ϕ can realize simultaneously.

Question V.29.2 (The strongest order at the original interface). *What is the maximal guaranteed Freiman order under the precise assumptions of the recorded Lemma 10.9, and under the fuller ambient-invariance package?*

Five and nine are lower bounds on the guaranteed order, not maximality results. The exact nested envelope, the actual value of ρ , optimized word ordering, and nonuniform directional defects can all improve the sufficient certificate. Counterexamples must also satisfy the nested local model, not merely a scalar defect bound.

Question V.29.3 (Stability of winding obstructions). *If constant fibers and a violated order- k relation have total budget close to one, must their error sets resemble a small collection of cuts or carry boundaries after an appropriate structural reduction?*

The cyclic construction has a concrete wraparound boundary. Near equality in the union bound suggests that edge-failure events should be almost disjoint in a shared-endpoint experiment, but translating that observation into structural information about ϕ requires additional work.

Question V.29.4 (Efficient certificates for many relations). *Can the root-law linear programs for a large family of relations be compressed into a small reusable set of certificates, perhaps by exploiting translation symmetries or a presentation of the generated group?*

Theorem II.18.3 gives a correct finite optimization for one relation. It does not give an efficient algorithm when the number of relations is exponential in the number of directions. A useful implementation would report rational primal witnesses whenever it certifies a relation.

Question V.29.5 (Joint optimization of extraction and transport). *Can one construct the regular component and its source law together, so that the extracted domain is large and its relevant transport profiles are small, instead of first paying for coarse fiber comparability?*

Changing the source law affects the hypothesis under which local errors are controlled. The alternative-root result avoids silently changing that hypothesis, but it does not solve the joint extraction problem. A successful method would need to account explicitly for lost cardinality and for the relation between the original energy weights and the chosen law.

Question V.29.6 (Higher-dimensional coherence). *Can shared-vertex sampling on cubes or more general finite diagrams replace repeated nested exceptional-set arguments in bilinear and multilinear exactification steps?*

The two-path proof suggests a diagrammatic error budget, but additional compatibility equations can correlate the required marginals. The right problem is to specify a joint sampling law first and prove every face or edge marginal under that law, rather than assume independent tests can be glued automatically.

Question V.29.7 (Improving the earlier extraction exponent). *Which quantitative losses before the local model are necessary, and can the appearance of $\eta^{1/5}$ itself be improved while retaining a sufficiently large regular component and direction set?*

The present method removes the later square root; it does not improve the earlier fifth-root construction. This is a more consequential target than optimizing the last few units in a rounded denominator such as 75.

Question V.29.8 (An end-to-end quantitative payoff). *After substituting the transport-sensitive exactification theorem, which later bottleneck becomes dominant, and does any improvement remain in a fully tracked final bound?*

Answering this requires a complete dependency ledger through the later Bohr-set, multilinear, and density-increment steps. The initial deliverable should be a mechanically checkable parameter recurrence, followed by a comparison with the unchanged proof, before any improved global exponent is announced.

Recommended order of work. First formalize the factor-two order-five theorem and its explicit boundary handling. Next build an exact rational profile-certificate tool and search for sharp nonuniform examples. Only then undertake the full parameter propagation and higher-dimensional extensions. These tasks separate near-term checkable improvements from the substantially larger research program.

[write] **6 October 2026; sources 06–10.** The eight questions are items II.9–II.15 and V.1 of Section V.2.

V.30 Conclusion

Source 07, delivered Section 11.

The local algebraic obstruction is a closed diagram with inconsistent edge labels. Once a joint law with shared endpoints is fixed, a violated relation must consume at least one unit of total failure probability. Transport profiles express exactly how an error known under the original law can contribute along a translated path. This yields linear, rather than square-root, error propagation and preserves useful information about higher-order relations.

The concrete consequences are a sharp balanced threshold, an order-five strengthening at the recorded Lemma 10.9 interface, an order-nine conclusion when ambient invariance is retained, and larger explicit local order-two allowances. The article proves those claims and supplies finite exact-arithmetic checks. Their significance is local and structural; an improved global Szemerédi bound would require the additional end-to-end analysis identified above.

V.31 Reproduction commands

Source 07, delivered Appendix B.

From the unpacked directory, the mathematical checks and PDF can be reproduced with

```
python3 checks.py --output verification.json
latexmk -pdf -interaction=nonstopmode -halt-on-error transport_rigidity.tex
```

A Makefile provides `make check`, `make pdf`, and `make clean`. The document uses an embedded bibliography and does not need BibTeX. Recompilation requires the LaTeX packages listed in its preamble. No network access is required for either command once those packages are installed.

V.32 Integration with the supplied Lean development

Source 08, delivered Section 11.

V.32.1 The normalization boundary

The inspected definitions use $\mathbb{Z}/N\mathbb{Z}$, complex-valued functions, the unnormalized Fourier transform, and the unnormalized cube norm [45]. Translating the mathematical notation gives

$$\begin{aligned}\text{cubeCount}(d, A) &= N^{d+1} \mathcal{C}_d(\mathbf{1}_A), \\ \text{gowersNorm}(d, f) &= N^{(d+1)/2^d} \|f\|_{U^d}, \\ \text{UniformSetOfDegree}(A, \alpha, d-1) &\iff \|\mathbf{1}_A - \delta\|_{U^d}^{2^d} \leq \alpha \quad (d \geq 1).\end{aligned}$$

The last equivalence uses the successor-dimension identity for the iterated difference sum. It is already the normalization step used by the existing proof of Lemma 3.10.

For $d \geq 2$, the proposed replacement conclusion is therefore

$$\text{cubeCount}(d, A) \leq N^{d+1} \left[\delta^{2^d} + \sum_{r=4}^{2^d} \binom{2^d}{r} \delta^{2^d-r} \alpha^{r/2^d} \right]. \quad (\text{V.32.1})$$

The dimension restriction avoids both the U^1 seminorm issue and the truncated natural subtraction in the expression $d-1$ at $d=0$. Dimensions zero and one already have elementary exact counts and should remain separate cases rather than being forced through this theorem.

V.32.2 A proposed proof decomposition

No new Lean file is included as if it were verified. The following are proposed lemma boundaries, not claims that these identifiers already exist. They are intended to let the existing analytic development carry most of the proof.

Suggested lemma or module	Mathematical obligation
<code>cubeForm_subset_expansion</code>	Expand the finite product into a sum over subsets of Boolean vertices.
<code>cubeProjection_three_uniform</code>	Build the affine equivalence implementing the unit-minor argument for three distinct vertices.
<code>centeredCubeTerm_eq_zero</code>	Factor averages for subsets of cardinality one, two, or three.
<code>centeredCubeTerm_norm_le</code>	Pad omitted vertices with 1 and apply the existing cube Cauchy–Schwarz inequality.
<code>cubeCount_fourthOrder_le</code>	Combine cancellation, the cardinality strata, and the normalization factor N^{d+1} .
<code>cubeQuartic_torsion_formula</code>	Add the Fourier classification of four-vertex subsets and the two closed counting formulas.

A useful implementation order is to prove the first four statements for the current cyclic setting before generalizing the entire API to finite abelian groups. The elementary fourth-order improvement does not require Fourier analysis, classification of finite abelian groups, or any torsion assumptions. The exact quartic formula is naturally a second, separate layer.

For the indicator theorem, the function `balanced A` is real-valued inside `C`. Recording that property explicitly lets parity conjugations simplify before the subset expansion. The existing cube argument uses a minus sign, while the counting convention uses a plus sign; negating all increments gives the required measure-preserving equivalence.

The proof of the analytic upper bound can be isolated from real-power arithmetic by first proving a statement in a nonnegative parameter t with a hypothesis on the normalized balanced norm. Only at the final step need one substitute $t = \alpha^{1/2^d}$. That separation reduces the chance that a bookkeeping error in roots or normalization obscures the combinatorics.

V.32.3 What was inspected and what was not verified

The two main source files used for this integration analysis were `Definitions.lean` and `Proofs03CubeUpper.lean`. Their inspected Git blob identifiers begin with `97113b7afa69` and `c017515bdd43`, respectively; complete identifiers and source URLs are in the accompanying provenance file. The latter file proves `lemma_3_10_holds` by applying Minkowski [46]. The analysis is not a repository-wide axiom audit.

No Lean executable was available in the working environment, and no Lean build or kernel verification of the new results was performed. The repository was not modified. The deliverable contains mathematical proofs, exact finite checks, and this integration plan, rather than an untested formalization presented as complete.

[write] **6 October 2026; sources 06–10.** At HEAD (`764740f07`) `lemma_3_10_holds` is still proved in `Proofs03CubeUpper.lean` (line 82) by the Minkowski bound; the statements of this source are not formalized.

V.33 Exact checks and reproducibility

Source 08, delivered Section 12.

The accompanying file `verify_cube_refinements.py` uses only Python’s standard library. All its asserted comparisons use integers or `Fraction`; it does not approximate trigonometric values or compare floating-point cube counts.

The following checks were run successfully in preparing this memorandum. First, the program enumerates every four-element subset in Boolean dimensions 2 through 6, verifying the R_d, T_d, F_d formulas on a total of 673,227 subsets. It also checks the unit-minor property on all 5,580 triples in dimensions 2 through 5.

Second, it classifies all three-cube five-element supports into 48 containing a parallelogram and eight exceptional supports, and it verifies the missing-pair multiplicities 12, 12, 4 for six-element supports.

Third, it computes the complete coefficients of $\mathcal{C}_3(\delta + \eta f)$ by direct averaging for explicit integer-valued, mean-zero functions on cyclic groups of orders 3 through 9. This verifies the vanishing of degrees one through three, the all-group quartic formula, and, in odd order, the full three-cube identity. Additional quartic checks use the groups $(\mathbb{Z}/2\mathbb{Z})^2$, $(\mathbb{Z}/2\mathbb{Z})^3$, $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$, and $(\mathbb{Z}/3\mathbb{Z})^2$. These cover examples with several order-two characters as well as odd-order noncyclic groups.

Finally, two independent Fourier enumerations verify (III.10.3). One enumerates all eight frequencies; the other uses the four-parameter kernel formula (III.10.4). For a single cosine on $\mathbb{Z}/11\mathbb{Z}$, the same exact method gives

$$\mathcal{C}_3(\delta + \eta \cos(2\pi x/11)) = \delta^8 + \frac{3}{2}\delta^4\eta^4 + \frac{1}{32}\eta^8. \quad (\text{V.33.1})$$

The order-two quartic coefficient is checked algebraically in dimensions 2 through 7.

To rerun the tests from the extracted archive, use

```
python verify_cube_refinements.py --output verification_results.json
```

The default enumeration stops at dimension six. The optional argument `-max-d 5` shortens the quartic enumeration. Running the program rewrites only the chosen output JSON file; it makes no network requests and does not access the repository.

These checks are useful for catching coefficient, sign, and torsion mistakes. They are not proofs of statements quantified over all groups or all dimensions. Those statements are supported by the arguments in the preceding sections. The finite counterexample identity has its own explicit exhaustive certificate, whose relation to the Fourier equations is given above.

V.34 Further research questions

Source 08, delivered Section 13.

The following questions are proposed directions arising from the present results. Unless explicitly connected to a cited source, their appearance here does not assert that they are established open problems in the literature. The priority order favors tasks that can produce a concrete theorem or a checkable counterexample.

V.34.1 Optimal odd-order constants

Question V.34.1. *For $d \geq 3$, determine*

$$\kappa_d^{\text{odd}} = \sup_{\substack{G \text{ finite, odd order} \\ f: G \rightarrow \mathbb{R}, \mathbb{E}f=0, f \neq 0}} \frac{E_4(f)}{\|f\|_{U^d}^4}.$$

Is $\kappa_3^{\text{odd}} = 1/\sqrt{2}$?

[write] **6 October 2026; sources 28–33.** *Advanced for $d \geq 4$, not settled* (sources 28 and 29, Section III.66). Source 29 proves $\|f\|_{U^d}^{2^d} \geq 2^{-m} \binom{2m}{m} \|f\|_{U^2}^{2^d}$, $m = 2^{d-2}$, hence $c_4^{\text{odd}} \leq (8/35)^{1/4}$ and $c_d^{\text{odd}} \leq B_d \downarrow 1/2$, and $c_d^{\text{odd}} \geq 1/3$ for every d (Corollary III.69.1, Proposition III.69.2); source 28 proves $c_4^{\text{odd}} \geq 0.5587294$ and that a real part of a character is not extremal for $d \geq 4$ (Corollary III.70.8, Theorem III.70.9); the intake’s certificate gives $c_4^{\text{odd}} \geq 0.5587725$. So $0.5587725 \leq c_4^{\text{odd}} \leq (8/35)^{1/4} = 0.6914416$ among sources 01–33; later placed sources record better upper bounds (item III.1).

[write] **6 October 2026; sources 34–39.** *The upper end improved again* (sources 34 and 35, Sections III.71–III.72). Source 34 proves $\|f\|_{U^2}^4 \leq (2/3) \|f\|_{U^4}^4$, that is the coefficient 81/16 in source 29’s normalization (Theorem III.71.1); source 35, the same day, proves the coefficient 5 (Theorem III.72.1); for $5 \leq d \leq 8$ source 34’s coupled bounds slightly improve source 29’s (Remark III.71.10). So $0.5587725 \leq c_4^{\text{odd}} \leq 2/3$ among sources 01–39; source 45, placed and not yet written, records $(832/4795)^{1/4} = 0.6454070$ (item III.1).

[write] **7 October 2026; sources 40–46.** *The upper end improved again* (source 45, Section III.89): $\|f\|_{U^4}^{16} \geq (4795/832) \|f\|_{U^2}^{16}$ (Theorem III.90.1), so $0.5587725 \leq c_4^{\text{odd}} \leq (832/4795)^{1/4} = 0.6454070$ among sources 01–46; source 49, placed by f8bc5e2ec and not yet written in, records $29/4$, that is $c_4^{\text{odd}} \leq (4/29)^{1/4} = 0.6094183$ (for its write) (item III.1).

Norm monotonicity gives $\kappa_d^{\text{odd}} \leq 1$. The single-cosine calculation (V.33.1) gives $\kappa_3^{\text{odd}} \geq 1/\sqrt{2}$. The best odd-order leading coefficient in a fourth-order bound purely in t is $R_d \kappa_d^{\text{odd}}$, not automatically R_d . A useful first step is a constrained Fourier optimization on odd cyclic groups, followed by a proof of any proposed inequality. Small-group optimization alone would not settle the supremum over all groups.

[write] **6 October 2026; sources 06–10.** *Answered for $d = 3$.* This κ_d^{odd} is source 03’s c_d^{odd} . Source 04’s Theorem III.3.4 gives $\kappa_3^{\text{odd}} = 2^{-1/2}$, attained by real parts of characters (proof in the note after that theorem), so the answer to the last sentence of the question is yes. For $d \geq 4$ it is open (Section V.2, item III.1).

Question V.34.2. *What is the largest constant c such that*

$$\mathcal{D}_3(F) \geq c \delta^4 E_4(F - \delta)$$

for every odd-order group and every $0 \leq F \leq 1$ with $\delta = \mathbb{E}F > 0$?

The results here give $2 \leq c \leq 15337/1296 < 12$. The lower endpoint follows from Theorem III.12.1; the upper endpoint follows from the explicit weight in (III.10.5). Optimizing the two-frequency family gives a slightly stronger upper bound by minimizing $12 - 2s + 6s^2 + s^4$, but there is no reason to assume this family is globally extremal. A proof separating local and global optimizers would already clarify the geometry of the cube polynomial.

[write] **6 October 2026; sources 06–10.** The failure of the constant 12 is kept on record as Remark W1; the question is item III.10 of Section V.2, merged with source 09’s question on a corrected lower bound.

V.34.2 Higher coefficients and arithmetic dependence

Question V.34.3. *Compute the complete fifth- and sixth-order coefficients for general d , including their dependence on the torsion of G .*

The quartic coefficient only sees order-two characters. For larger supports, integer minors can have additional prime factors, and Fourier relations can couple several multiples of a frequency. A concrete program is to classify support matrices up to cube symmetry, compute their integer relation lattices, and produce exact character-sum profiles. The desired output is a proved formula with orbit counts, not just a table of numerical values in sample groups.

Question V.34.4. *Can the survivor polynomial $\sum_r A_{d,r}(G)z^r$ be computed substantially faster than enumerating all subsets of V_d ?*

Proposition III.14.2 reduces much of the large-prime case to column dependence. Symmetry reduction, deletion–contraction ideas, and certified integer normal forms may make dimensions four and five tractable. Small-characteristic exceptions must be retained rather than inferred from the rational calculation. It would be valuable to output compact certificates that a proof assistant can check independently of the enumeration engine.

V.34.3 Stability and explicit constructions

Question V.34.5. *Describe near-extremizers for the quartic coefficient $R_d E_4(f) + T_d E_{\langle 2 \rangle}(f)$ relative to $\|f\|_{U^d}^4$.*

On groups with an order-two quotient, the exact extremal model supplied here is a real character. A stability theorem would quantify whether a nearly optimal ratio forces concentration on one character or on a small collection of characters. On odd groups, the correct model is not yet determined here. This question concerns a small-norm perturbation of a constant, rather than near-maximal U^d norm under an L^∞ bound; those are distinct extremal problems.

Question V.34.6. *Derandomize the indicator sharpness construction while keeping its fourth-order asymptotic coefficient.*

The rounding proof is existential and uses very large prime groups. A deterministic construction should guarantee rounding error $o(\eta^4)$ in U^d , not merely small discrepancy against individual Fourier characters. The collision estimate gives a clear quantitative target against which an explicit construction can be measured.

V.34.4 Localization, sparse weights, and formalization

Question V.34.7. *Which exact cancellations survive when cube averages are localized to intervals, progressions, or Bohr neighborhoods?*

Global three-vertex independence is the key input to the fourth-order bound. Restricting the parameter domain destroys that independence in general. A localized theorem would need either specially compatible averaging measures or explicit boundary and correlation errors. Establishing such a result is a more plausible route toward density-increment applications than directly substituting the present global estimate into an unrelated step.

Question V.34.8. *Can the inhomogeneous estimate be transferred to sparse majorized weights with an explicit error budget?*

For a relative counting theorem, the means and the majorant cannot be treated as interchangeable constants. One should first expand around the actual majorant model and identify which low-order correlations are controlled by its pseudorandomness assumptions. The finite character-kernel criterion may then organize the remaining balanced terms, but it does not supply the required majorant estimates by itself.

Question V.34.9. *Can the elementary fourth-order improvement and the quartic torsion formula be formalized as separate verified modules in the supplied development?*

The first task needs finite product expansion, affine equivalences, and the existing cube inequality. The second adds finite Fourier analysis and the classification of four vertices. A useful milestone is a theorem with the original unnormalized conclusion (V.32.1), together with tests that instantiate both odd moduli and even moduli. General finite abelian groups can be treated after the normalization and subset-expansion interfaces are stable.

V.34.5 From vanishing supports to sharper configuration bounds

Question V.34.10. *For a fixed non-cube system of linear forms, can one combine the exact full-support criterion with a true-complexity estimate to obtain the correct first nonzero power of the balanced uniformity parameter?*

This would separate two sources of quantitative loss: terms that should be zero before any norm inequality is used, and terms that are genuinely present but estimated inefficiently. The work of Gowers–Wolf and Manners [29, 14] supplies relevant norm-control theory, but the leading-power problem depends on the particular system and its arithmetic. It should not be assumed that arithmetic progressions inherit the same three cancellations as a full additive cube.

V.35 Conclusion

Source 08, delivered Section 14.

The main gain is a sharp change of scale in the error term of the selected cube-count lemma. Centering removes the first three perturbative orders, and the first surviving order is exactly controlled by parallelograms and order-two Fourier mass. The resulting exponent $4/2^d$ is optimal even for sets in odd prime cyclic groups.

The more detailed three-cube calculation reveals a second lesson: the next coefficient is signed. A positive fourth-order expansion does not imply a global lower bound with the same coefficient. The explicit two-frequency counterexample makes that obstruction quantitative.

These results leave the global Szemerédi problem unchanged, but provide a more precise local component, a finite-support classification framework, and concrete next problems with a path to computational and formal checks.

V.36 Build and source provenance

Source 08, delivered Appendix B.

The source document is self-contained LaTeX with an internal bibliography. From the extracted archive, compile it with

```
pdflatex -interaction=nonstopmode -halt-on-error fourth_order_cube_counts.tex
pdflatex -interaction=nonstopmode -halt-on-error fourth_order_cube_counts.tex
```

Two passes resolve references and the table of contents. The archive also includes `build.sh`, the exact-arithmetic verifier, its captured JSON output, a README, and `source_provenance.json`. It does not redistribute the original Gowers paper or any font files.

The original paper was checked at printed pages 483 and 485, corresponding to PDF pages 19 and 21 in the linked 124-page copy. The repository source inspection was read-only and took place on 6 October 2026. The provenance file identifies inspected blobs; it does not claim that the entire repository was frozen or audited at a single commit.

V.37 Reproducible exact checks

Source 09, delivered Section 11.

The supplied computations use exact integers and rational numbers. They are tests of the formulas and finite certificates, not a substitute for the all-dimension classification proofs.

V.37.1 Direct finite-group cube averages

The standard-library script `verification/verify_expansion.py` was run successfully on 24 specified examples. It covers cyclic groups of orders two through nine in dimension three, several cyclic groups in dimensions two and four, and product groups including $(\mathbb{Z}/2\mathbb{Z})^2$, $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$, and $(\mathbb{Z}/3\mathbb{Z})^2$. For each case it constructs a deterministic integer-valued mean-zero function and enumerates every parameterized cube.

The coefficient of δ^{m-s} is computed directly as the s th elementary symmetric polynomial of the m evaluated function values, averaged over cube parameters. The script compares the first five coefficients with the formulas in Theorem III.21.1. This avoids both numerical roots of unity and Fourier rounding error. For the right-hand side it evaluates equivalent convolution formulas, including the quotient averages on $G/2G$ and $G/3G$ for the torsion statistics. The recorded file `results.json` contains every input and exact output.

The same script checks the Stirling formulas for $2 \leq d \leq 14$ and all $5^8 = 390625$ frequency assignments needed for the two-frequency polynomial in Appendix III.26.

V.37.2 Exhaustive small-cube lattice census

The optional SymPy script `verification/verify_lattices.py` was also run successfully with SymPy 1.14.0. It uses exact Smith normal forms for every four- and five-vertex subset in dimensions three and four. The five-vertex census is particularly informative:

Five-vertex type	$d = 3$	$d = 4$
Parallelogram plus independent fifth vertex	48	1200
Full-support real circuit (star)	8	160
Full rank, index one	0	2672
Full rank, index two	0	320
Full rank, index three	0	16
Total	56	4368

The index-two five-vertex configurations are a useful warning: their lattices are not primitive, but their moments still vanish because a character coordinate is forced to be trivial. Counting only nonprimitive supports would overcount the fifth-order contribution.

For four-vertex subsets the surviving counts are $(12, 2)$ in dimension three and $(100, 40)$ in dimension four, matching (P_d, T_d) . The same script checks the determinant, Smith invariants, and full modulo-five kernel certificate in Theorem III.23.1. Its complete output is `lattice_results.json`.

V.37.3 What was and was not verified

Both scripts completed with all assertions passing. The manuscript proofs handle arbitrary dimension and arbitrary finite abelian groups; the scripts do not exhaust those infinite families. No Lean compiler was available in the execution environment, no new theorem was checked by Lean, and no repository files were modified. The supplied formalization roadmap is therefore a proposal, not a verification certificate.

V.38 Integration with the supplied Lean development

Source 09, delivered Section 12.

V.38.1 Pinned source audit

The inspected repository checkpoint is commit

`7d99e5deeb209a4671060990cb1ea3d672d57064`.

The relevant directory is

`Combinatorics/Ramsey/Lean/GowersSzemerédi`.

The following are observations from source inspection, not claims that we rebuilt the repository:

Definitions.lean

Defines `fourier` as the unnormalized discrete Fourier transform, `balanced` as indicator minus density, `cubeForm` with parity conjugation and the argument $s - e \cdot x$, `gowersNorm` as an unnormalized cube-sum root, and `cubeCount` by parameterized additive cubes. The inspected blob is `97113b7afa6925a2dd4b76641eeaef09597ab6a`.

Sections01_03.lean

Contains the proposition-valued statement `lemma_3_10`. A proposition-valued catalogue entry alone is not a proof; here there is also a separate proof file.

Proofs03CubeUpper.lean

Proves `lemma_3_10_holds`. It imports `Proofs03Minkowski` and `Proofs03Cubes`, identifies indicator and constant norm powers, and applies `gowersNorm_add_le`. The inspected blob is `c017515bdd43b3c7dd8a5d0e90747a20403d4ddc`.

Proofs01_03.lean

Contains the finite Fourier identities, including Parseval and the fourth-moment/additive-quadruple identity. These are natural inputs for the exact quartic theorem.

V.38.2 Normalization and sign conventions

For $G = \mathbb{Z}/N\mathbb{Z}$, the dictionary is

Manuscript quantity	Repository quantity
$\widehat{f}(r)$	N^{-1} <code>fourier f r</code>
$\ f\ _{U^d}$	$N^{-(d+1)/2^d}$ <code>gowersNorm d f</code>
$\mathcal{C}_d(\mathbf{1}_A)$	$N^{-(d+1)}$ <code>cubeCount A</code>
$\ f_A\ _{U^d}^{2^d} \leq \alpha$	<code>UniformSetOfDegree A</code> α $(d-1)$, for $d \geq 2$

The manuscript uses $x + v \cdot h$ whereas `cubeForm` uses $s - e \cdot x$. Replacing every side variable by its negative converts between them. Real-valued functions make parity conjugation harmless, but a formal proof must still discharge the corresponding real-cast and conjugation identities. The indicator count includes degenerate parameterized cubes; it is not a count of distinct vertex sets.

V.38.3 A staged implementation plan

The most economical first formal target is Theorem III.17.2, not the entire lattice classification. It needs only a subset expansion, three-vertex uniformity, and the existing Gowers–Cauchy–Schwarz infrastructure.

A proposed first module, `Proofs03BalancedExpansion.lean`, would prove that mixed cube sums supported on one, two, or three distinct Boolean vertices vanish for a real mean-zero function. Prove explicit coordinate reindexing equivalences rather than relying on field linear algebra over $\mathbb{Z}\text{Mod } N$. This avoids an unnecessary primality assumption. Then sum by subset cardinality and recover (III.17.2). A safe initial theorem should assume $d \geq 2$ and $\alpha \geq 0$ explicitly; this avoids accidental dimension-zero or real-power edge cases.

A second module, `Proofs03QuarticCircuits.lean`, would classify four-element Boolean subsets, count the two types, and prove their Fourier formulas. It can initially state a torsion-aware theorem for arbitrary N ; an odd-modulus corollary then removes the order-two term. Using an integer matrix or explicit coordinate-block normal form is essential. A theorem asserting independence over $\mathbb{Z}\text{Mod } N$ merely from rational rank would be false.

A third module, `Proofs03QuinticCircuits.lean`, would implement the rank-four and rank-five cases separately. The two especially important obligations are the primitive-minor argument for a

parallelogram plus a fifth vertex, and the index-two case with a forced trivial Fourier coordinate. The general character-kernel formula could be developed either first as a reusable library theorem or afterwards as a unification of the small cases.

A final `Proofs03CubeRefinement.lean` would combine these results with explicit binomial tails. The output theorem should coexist with `lemma_3_10_holds`, with the old theorem recovered as a corollary by adding back nonnegative omitted terms. There is no reason to delete a valid existing interface.

V.38.4 Recommended proof obligations and audit discipline

Useful public lemmas would include joint uniformity of at most three Boolean affine forms over an arbitrary finite abelian group; Fourier orthogonality for an integer matrix of forms; conversion of cube sums to normalized averages; counting disjoint nonempty coordinate blocks; and the binomial-tail inequality (III.16.5).

These should be genuine proved lemmas, not axioms or proposition placeholders. After implementation, build the exact pinned dependency set, audit the types of the new public theorems, inspect the axiom closure, and run the repository’s own status checks. A successful small experimental script is not a substitute for these steps, and the present package does not claim they have been carried out.

[write] **6 October 2026; sources 06–10.** At HEAD (764740f07) the inspected files still play the roles described; `lemma_3_10_holds` is at line 82 of `Proofs03CubeUpper.lean`. None of this source’s statements is formalized.

V.39 Further research questions and a prioritized program

Source 09, delivered Section 14.

The following are precise continuations of the proved results. They are proposed research targets, not assertions that each formulation is historically new or currently unsolved in the entire literature.

V.39.1 Complete the sixth-order coefficient

Research question V.39.1 (A dimension-uniform sextic expansion). Classify all six-vertex Boolean subsets that admit a full-support character tuple, and express the coefficient of δ^{m-6} in a finite basis of Fourier or higher-order statistics with closed formulas for their multiplicities as functions of d .

Theorem III.23.1 proves that an order-five term must occur. There will also be real relations and possibly several independent character parameters. A useful first computational stage is an orbit census by coordinate-pattern multisets, followed by integer-lattice certificates for each orbit. The real challenge is a finite normal-form classification that does not grow with the ambient dimension. The goal should be an exact sixth coefficient and a seventh-order remainder, not merely a longer numerical table.

V.39.2 Determine the prime-onset function

Research question V.39.2 (Support-efficient torsion). Determine $h(7)$ and $h(11)$, and improve the general bounds between (III.23.4) and $h(\ell) \leq \ell + 2$.

[write] **6 October 2026; sources 34–39.** *Answered by source 34:* $h(7) = 7$, $h(11) = h(13) = h(17) = 8$ (Theorem III.76.2), $h(p) = D_{\text{div}}(p) + 1$ (Theorem III.75.2) and $h(p) \sim 2 \log p / \log \log p$ (Theorem III.79.1); item III.16.

A determinant divisible by ℓ is necessary but not sufficient: the corresponding modulo- ℓ kernel must have full support, or balancing makes the term vanish. This extra support condition should be included from the start in a search. A practical certificate would contain the binary matrix, a nonzero determinant, its Smith invariants, and an explicit full-support kernel vector. The exact order-five example supplies a model for such a certificate.

V.39.3 Optimize constants at a fixed density and norm ratio

Research question V.39.3 (The constrained extremal envelope). For fixed d , density δ , and prescribed $(\varepsilon, \tau, \rho)$, determine or tightly bound

$$\sup\{\mathcal{C}_d(F) : 0 \leq F \leq 1, \mathbb{E}F = \delta, \|F - \delta\|_{U^d} = \varepsilon, \|F - \delta\|_{U^2} = \tau, \|\widehat{F - \delta}\|_\infty = \rho\}.$$

The coefficient A_d is optimal when all groups are allowed, but the unsigned fifth-order estimate need not be jointly sharp with it. Order-two characters maximize the universal fourth coefficient while forcing the quintic term to vanish. This incompatibility suggests that a coupled bound may improve (III.21.7). The odd-order problem is especially natural: determine the best leading coefficient relative to ε^4 , rather than relative to the exactly known Fourier energy τ^4 .

V.39.4 Stability of nearly extremal quartic corrections

Research question V.39.4 (Structure near the universal fourth-order maximum). If

$$P_d \mathbf{E}_4(f) + T_d \mathbf{T}_2(f) \geq (1 - \eta) A_d \|f\|_{U^d}^4,$$

what quantitative structural conclusion follows as $\eta \rightarrow 0$?

The order-two character example is an exact extremizer, but uniqueness and stability have not been proved here. One must understand both near-equality in norm monotonicity and concentration on the two-torsion spectrum. It would be useful to separate a statement valid for all real functions from stronger statements using $0 \leq \delta + f \leq 1$.

V.39.5 A useful corrected lower bound

Research question V.39.5 (Replace the false quartic lower bound). Find natural hypotheses under which M_5 is nonnegative, or bound its negative part more sharply in terms of the fourth-order statistics and density, so that a nontrivial corrected cube lower bound follows.

Nonnegative Fourier coefficients make all subset moments nonnegative, but this is a strong restriction. A less restrictive condition on the relative phases of a_χ and a_{χ^2} may be sufficient. The explicit expression (III.21.3) identifies the relevant phase interaction, and Proposition III.22.2 shows why an unconditional positivity argument cannot work.

V.39.6 Boundary-sensitive interval analogues

Research question V.39.6 (Cubes restricted to an interval). Develop a version of the expansion for cubes constrained to lie in $[N]$, with explicit boundary weights, and determine which of the first three cancellations survive exactly or approximately.

The current proof averages over a whole finite group. Conditioning on all vertices lying in an interval destroys the uniformity argument used in Lemma III.17.1. A direct transplantation would be incorrect. One possible route is to expand relative to a weighted reference measure adapted to the interval, rather than to a constant function, and explicitly retain the resulting lower-order boundary terms.

V.39.7 Algorithmic use of the measured residual

Research question V.39.7 (A residual-sensitive inverse step). Can the sixth-order certificate (III.21.11), together with an efficient estimate of the four Fourier statistics, improve a concrete inverse or counting algorithm in a useful parameter regime?

The question requires a complete cost and parameter analysis. A norm lower bound by itself does not deliver structure. A convincing result would specify the input access model, the cost of estimating $E_4, T_2, M_5, T_{3,5}$, the residual threshold, and the quantitative gain after an available inverse theorem is invoked.

V.39.8 Formalize primitive Boolean affine maps first

Research question V.39.8 (A reusable Lean library for arithmetic configurations). Build a library of exact reindexing equivalences and integer-lattice certificates for Boolean affine forms, then formalize Theorems III.17.2 and III.21.1 over arbitrary finite abelian groups.

The initial cancellation theorem is an accessible first milestone. The general character-kernel identity and a sound bridge from Smith normal form to finite-group character constraints would have much broader reuse. It is important to preserve non-prime groups in the interface: they expose the precise arithmetic phenomenon that the paper identifies.

V.39.9 Beyond diagonal cube counts

Research question V.39.9 (Colored cubes and other linear systems). For other finite systems of integer linear forms, identify the least support size at which a mean-zero expansion can contribute, and classify the first torsion-sensitive terms.

The proof mechanism is the same as Proposition III.18.1, but the first nonzero order need not be four. The heterogeneous theorem suggests applications to colored configuration counts and joint distribution tests. A useful result should state the primitive-lattice hypotheses explicitly, rather than replacing them by a characteristic-dependent rank test.

V.39.10 From a local gain to a global theorem

Research question V.39.10 (Locate an actual quantitative dependency). Identify a step in a complete progression argument whose bound depends on the local excess $\mathcal{C}_d(F) - \delta^m$ in such a

way that replacing a first-order estimate by the fourth- or sixth-order estimate changes the final quantitative conclusion.

This is the necessary bridge to a stronger Szemerédi-type result. It may turn out that the paper’s dominant losses lie elsewhere, in which case the local sharpening has no effect on the final asymptotic bound. The correct research procedure is to write and audit the full dependency recurrence, not to infer a global improvement from a better constant or exponent in an auxiliary lemma.

[write] **6 October 2026; sources 06–10.** The ten questions are merged into Section V.2 (items III.2, III.16, III.17, III.12, III.10, III.13, III.18, V.2, III.15 and V.1).

V.40 Conclusion

Source 09, delivered Section 15.

Balancing contains more information than a triangle inequality retains. For full cube counts, three exact cancellations move the first error to degree four. The next two homogeneous coefficients admit a complete arithmetic description: parallelograms and stars give ordinary Fourier statistics, while primitive failures of indices two and three give explicit torsion corrections. The multiplicities are simple Stirling-number expressions, and the residual is sixth order with a sharp exponent.

The small-order classification also explains its own limitations. The fifth-order term can be negative; the universal fourth coefficient is attained by a torsion example; and a determinant-five configuration appears one order later. These facts make the refinement more than a formal binomial improvement: they identify exactly which information controls the first deviations from a constant and which arithmetic features a correct generalization must preserve.

The resulting package provides proved local mathematics, exact computational checks, and a concrete route toward formalization. The questions above separate the immediately actionable extensions from the additional work needed for a genuinely stronger global progression bound.

V.41 Proof and artifact dependency map

Source 09, delivered Appendix C.

The logical dependence is as follows. The analytic input is Gowers–Cauchy–Schwarz, the finite Fourier inversion formula, and ordinary finite-dimensional integer linear algebra. Three-vertex primitive uniformity gives the fourth-order bound immediately. The small determinant bounds give the four- and five-vertex classifications; coordinate-block counting gives their multiplicities. Combining these with the subset expansion gives the main exact theorem. Sharpness uses explicit characters and two-frequency functions, with random rounding for indicator transfer. The order-five obstruction has its own determinant and kernel certificate.

The numerical files are independent cross-checks of those mathematical steps. The optional finite table in Appendix III.26 is the one additional exact identity supported by a full explicit enumeration. The source audit and formalization plan do not enter any mathematical proof and do not assert a successful Lean build.

V.42 What the local gains do to a quantitative iteration

Source 10, delivered Section 10.

A better local lemma is useful only after its hypotheses and losses have been propagated through the later argument. We record two exact bookkeeping statements to make that distinction concrete.

Proposition V.42.1 (A reciprocal-density bound on the number of steps). *Suppose $c > 0$, $a \geq 1$, and $0 < \delta_0, \dots, \delta_t \leq 1$ satisfy $\delta_{i+1} \geq \delta_i + c\delta_i^a$ for $0 \leq i < t$. If $a = 1$, then*

$$t \leq \frac{\log(1/\delta_0)}{\log(1+c)}.$$

If $a > 1$, then

$$t \leq \frac{\delta_0^{-(a-1)} - 1}{1 - (1+c)^{-(a-1)}}. \quad (\text{V.42.1})$$

In particular, if $\delta_{i+1} \geq \delta_i + \delta_i^2/320$, then $t \leq 321(\delta_0^{-1} - 1)$.

Proof. For $a = 1$, iteration gives $\delta_t \geq (1+c)^t \delta_0$. For $a > 1$, put $q = a - 1$ and $u = c\delta_i^q \in (0, c]$. Then

$$\delta_i^{-q} - \delta_{i+1}^{-q} \geq c \frac{1 - (1+u)^{-q}}{u}.$$

The function in the fraction is nonincreasing in u , since

$$\frac{1 - (1+u)^{-q}}{u} = q \int_0^1 (1+su)^{-q-1} ds.$$

Thus each decrement is at least $1 - (1+c)^{-q}$. Sum over i and use $\delta_t^{-q} \geq 1$. For $a = 2$, the denominator is $c/(1+c)$; substitution of $c = 1/320$ gives the stated specialization. $\square$

The last estimate sharpens the $640\delta_0^{-1}$ dyadic count displayed in the source's proof of Theorem 2.6, while keeping precisely the same increment hypothesis. It is an elementary refinement of that bookkeeping, not a new form of Roth's theorem. If an argument tries to force a contradiction by performing more steps, it must allow $\lfloor 321(\delta_0^{-1} - 1) \rfloor + 1$ attempted increments, and must verify that the size assumptions remain available at every one.

[write] **6 October 2026; sources 06–10.** The transcription's count $640\delta_0^{-1}$ is in the proof of Theorem 2.6 (exact companion `theorem_2_6_holds`, `Proofs02Roth.lean`). The step counts of source 03's Proposition V.12.1 and source 06's Lemma V.25.1 are compared with this one in the note after source 03's proposition; source 03's (V.12.2) is the next proposition with constant parameters.

Proposition V.42.2 (Exact propagation of length losses). *Suppose $N_{i+1} \geq b_i N_i^{\vartheta_i}$, where $N_i > 0$, $b_i > 0$, and $0 < \vartheta_i \leq 1$. Let $P_t = \prod_{i=0}^{t-1} \vartheta_i$, with $P_0 = 1$. Then*

$$\log N_t \geq P_t \log N_0 + \sum_{j=0}^{t-1} \left(\prod_{i=j+1}^{t-1} \vartheta_i \right) \log b_j.$$

For positive target thresholds $M_0, \dots, M_T$, a sufficient condition for $N_t \geq M_t$ for every $0 \leq t \leq T$ is

$$\log N_0 \geq \max_{0 \leq t \leq T} \frac{1}{P_t} \left[\log M_t - \sum_{j=0}^{t-1} \left(\prod_{i=j+1}^{t-1} \vartheta_i \right) \log b_j \right].$$

For constant $\vartheta \in (0, 1)$, constant $b \in (0, 1]$, and $M \geq 1$, the simpler sufficient condition is

$$\log N_0 \geq \vartheta^{-T} \left(\log M + \frac{\log(1/b)}{1 - \vartheta} \right) - \frac{\log(1/b)}{1 - \vartheta}.$$

Proof. Take logarithms and repeatedly substitute the preceding inequality. This yields the first formula by induction. Solve each of the finitely many resulting lower bounds for $\log N_0$ and take their maximum. For constant parameters the geometric sum evaluates explicitly; its lower bound for $\log N_t$ decreases with t under the displayed condition, so it is enough to check $t = T$. $\square$

For Theorem I.24.2, if the continuous square-root expression is at least two, its floor is at least half that expression. One may therefore take

$$\vartheta_i = \frac{1}{2}, \quad b_i = \frac{1}{2} \sqrt{\frac{\lambda_{\gamma,i}}{2\pi}},$$

provided the appropriate correlation hypothesis is available at stage i . This gives a direct route for comparing choices of the retained correlation fraction γ . It also shows why a claimed improvement in a final tower exponent cannot be inferred from a local constant alone: one must supply the entire sequence of b_i, ϑ_i, M_i and the number of permitted density increments.

V.42.1 The particular limitation in the supplied development

At the pinned snapshot, the edited text places an explicit warning before Theorem 18.1: after replacing an estimate in Corollary 16.11 by the bound supplied by its argument, the displayed assembly no longer establishes the intended quantitative exponent. The source ledger also leaves Corollary 16.11 and Theorems 18.1–18.2 open [48]. These are statements about the repository’s present proof chain. They do not negate the published theorem of Gowers or the subsequent quantitative literature.

The results of this report do not discharge those later dependencies. They can replace specific finite lemmas and reduce some input losses, but a new global bound for $r_k(N)$ would require a separate completed argument through the multilinear extraction, local inverse step, interval transfer, and iteration. The precise propagation formula above identifies what that future argument must certify.

V.43 A map to the Lean development and reproducible checks

Source 10, delivered Section 11.

V.43.1 What has actually been verified

The general results above have mathematical proofs in the article. Independent review checked the noninvertible reindexing, mixed-norm induction, strict tail threshold, exceptional-set denominator, integer partition bounds, diagonal correction in the random selection, and the two representation-counting injections. That review corrected an asymptotic wording issue: when density varies, the length comparison is multiplicative, as stated in Section I.24.

[write] **6 October 2026; sources 06–10.** The independent review mentioned here is not part of the delivery and is not shipped; nothing in this report rests on it (as for source 03’s reviews). The intake reran the four diagnostic scripts on a copy (all exit 0, outputs identical).

The package also contains independent finite diagnostics. Their role is to expose errors in formulas, normalization, and boundary cases; they do not establish a theorem for all finite groups. The executed checks include the following.

Family	Cases	What is checked
Density profiles	1,230	Exact cap and variance inequalities.
Density tails	4,098	The strict-threshold mass estimate.
Exceptional sets	2,532	The retained-cell density guarantee.
Sharp tail examples	45	Exact equality for three-point profiles.
Phase partitions	39,648	Coverage, integer lengths, circle approximation, and 1,408,790 individual cells.
Prime-codomain fibres	23,538	Exhaustive small-field function restrictions, the size guarantee, and the Freiman property.
Weighted representations	41	Exact codegree and representation counts.
Mixed-norm averages	432	Arbitrary complex functions, both AP and general coefficient systems.
Heterogeneous AP counts	210	The weighted telescoping bound.
Torsion sharpness	5	Four characteristic-two dimensions and the exact characteristic-three cube value 49/81.
Cubic norm	125	The determinant identity and unique zero.
Polynomial coloring	390,000	Every ordered nontrivial 4-AP in $\mathbb{F}_5^4$.

The rational profile, fibre, determinant, and explicit coloring checks use exact arithmetic. In the phase script the coverage, circle-step, and half-angle checks are exact rational calculations; complex distances are checked numerically with tolerance 10^{-12} . The arbitrary complex Gowers calculations use NumPy and tolerance 10^{-9} , with random seed 20261006. Their cube powers are computed from the defining sums, independently of the induction used in the proof. The torsion sharp examples are also verified exactly.

The file `verification_results.json` records the actual script outputs and their hashes. The file `source_manifest.json` records the pinned source identities. The README supplies the commands needed to rebuild the PDF and rerun the diagnostics.

V.43.2 Suitable formalization units

The current development defines `UniformOfDegree`, `gowersNorm`, `NatAP`, `ModAP`, `FreimanHom`, and the relevant catalogue statements [48]. Its existing modules suggest the following interfaces. This table is a proposed integration map, not a list of newly compiled declarations.

Mathematical unit	Existing source location	Main obligation
Partition cap and tail	<code>Proofs02</code> <code>DensityIncrement.lean</code>	Finite weighted sums; positivity of $2\delta - S$; equality cases.
Phase partition	<code>NatAP</code> and the Section 2 partition modules	Circle approximation, injective integer progression coordinates, and cardinalities with floors retained.

Mathematical unit	Existing source location	Main obligation
Kernel average identity	Generic finite-group infrastructure, with a cyclic specialization	Exact equal-size fibres of the multiplication endomorphism.
Mixed-norm induction	<code>Proofs03</code> <code>ProgressionAverage.lean</code> and the cube infrastructure	Hölder, derivative moments, and the precise invertible-neighbor hypothesis.
Weighted telescoping	<code>Proofs03</code> <code>ProgressionCount.lean</code>	Vanishing of the first two terms and a separate count of repeated progressions.
Weighted energy extraction	<code>Proofs07BalogSzemerédi.lean</code>	Finite random sampling or equivalent counting, diagonal correction, and injectivity of the tuple encodings.
Obstruction fibre and torsion budget	<code>Proofs07</code> <code>FreimanRestriction.lean</code>	The graph projection injection; exact bad-step fibres; translation averaging.
Polynomial obstruction	A new finite-field polynomial module	Coefficient homogeneity, a Vandermonde determinant, Chevalley–Warning, and the norm construction.

For the mixed-norm theorem, it may be easier first to formalize its equivalent version after raising to the power 2^{k-1} :

$$|\Lambda_{\mathbf{a}}(f_1, \dots, f_k)|^{2^{k-1}} \leq K \|f_k\|_{U^{k-1}}^{2^{k-1}} \left(\prod_{i=1}^{k-2} (\mathbb{E}|f_i|^{2^i})^{2^{k-1-i}} \right) \cdot (\mathbb{E}|f_{k-1}|^{2^{k-2}})^2.$$

This formulation avoids fractional powers in the inductive algebra. Taking nonnegative roots can be a final wrapper.

The probabilistic language in Theorem II.20.1 also has an entirely finite interpretation. For a fixed sampled $v \in A$, sample independent integers $u_a \in \{1, \dots, m\}$ and retain a when $u_a \leq r_A(v - a)$. This exactly realizes the required rational membership probabilities. The proof can therefore be phrased using finite sums over $A \times \{1, \dots, m\}^A$, without introducing a general probability-space interface.

The most important source-to-theorem checks remain mathematical: the normalization must match, positivity must justify each reindexing bound, the progression must have the claimed distinctness, and the new theorem’s assumptions must actually be available at its call sites. A successful axiom audit alone would not verify those comparisons.

V.44 Further research questions and proposed next steps

Source 10, delivered Section 12.

The questions below separate proposed refinements of the present theorems from established questions in the wider literature. A question introduced here is not asserted to be previously unknown or to have been recognized as open by the community.

V.44.1 Finite problems closest to the proved results

1. **Optimal torsion constants beyond the sharp families.** For a fixed finite abelian G , coefficient pattern, and target having at least one invertible coefficient difference, determine the least constant C in $|\Lambda_{\mathbf{a}}(f)| \leq C\|f_j\|_{U^{k-1}}$ for 1-bounded functions. Theorem III.28.2 gives an explicit upper bound, and Proposition III.28.4 settles particular families. The next small case is the exact constant for four-term patterns on elementary abelian 3-groups. Small finite optimizations can suggest extremizers, but an analytic extremal proof is the target.
2. **Use restricted direction averages before losing them.** The fibre identity retains the more informative quantity $\mathbb{E}_h \mathbf{1}_{cG}(h)V(h)$. Determine when the images cG arising at successive Cauchy–Schwarz steps have enough compatibility to improve the product of kernel cardinalities. An exact comparison for nested images would already strengthen the generic bound.
3. **Optimize the geometric part of the phase tradeoff.** The density cap is sharp, but the passage from one approximate period to blocks of lengths L through $2L - 1$ may leave room in the constants. Seek the best universal minimum block length for a prescribed phase disc radius, with all integer rounding retained. A useful first goal is a matching obstruction or a better construction at fixed η/δ as $\delta \rightarrow 0$.
4. **Simultaneous correlation data.** If several approximately constant characters or polynomial phases are available on the same partition, their correlations can force a larger conditional second moment than one correlation alone. Determine the best Gram-matrix bound for that moment and combine it with (I.23.3). The geometry must supply the common partition; assuming it for free would conceal the main cost.
5. **A sharp vertical-fibre restriction theorem.** How close is $|B|/[k(h_k - 1) + 1]$ to the best bound determined only by the defect fibre? Can the factor k be reduced under additional additive structure of H_k ? The exact case $H_k = \{0\}$ is settled, but the extremal nonzero-fibre case remains a natural proposed problem.
6. **Exploit overlaps in the bad-step union.** Theorem II.21.3 uses a union bound over $E_j = \{d \neq 0 : jd \in F\}$. Exact intersections between these sets can be substantial. A formula adapted to a cyclic prime-power codomain, using valuations and the distribution of defects in jV , is a concrete route to a better general-codomain retention bound.
7. **Optimize the graph-energy input and its propagation.** The explicit proof here retains a proportion $\gamma/4$ before Freiman extraction; the published Reiher–Schoen theorem retains almost $\sqrt{\gamma}$ [12]. Propagate the latter, with the exact vertical fibre when available, through the later Bohr-neighborhood and local-linearity stages of the supplied proof. The desired output is a complete new chain of numerical inequalities, not an isolated replacement of the exponent 1164.

V.44.2 Polynomial colorings after the exact low-degree answer

8. **Higher degrees.** Theorem III.30.3 completely answers the specified coordinate problem for $D_\ell \leq k$. Above that range, the higher-degree obstruction proved in Section III.30 gives necessary dimension bounds without matching constructions. For $k = 4$, a scalar polynomial of degree five or six has the resulting upper dimension bound eight. Determine the largest

attainable dimension, starting with dimension five. This is a proposed finite extremal problem, not a claimed established open conjecture.

9. **Stability at the dimension threshold.** At $d = \sum_{\ell} \lceil D_{\ell}/2 \rceil^2$, must every avoiding polynomial have some structural feature resembling an anisotropic odd-degree decomposition? Full equivalence to the norm construction may be too strong, but a classification in the first cubic four-dimensional case would test the idea. Coordinate changes and linear changes of the color coordinates should be factored out before comparing examples.
10. **Actual colors versus declared coordinates.** The exact theorem controls the number of polynomial coordinates. Can a map with more coordinates but an unusually small image outperform the full-palette exponent? A useful result would relate avoidance, fiber geometry, and actual image cardinality. The theorem proved here does not supply such a relation.
11. **Unrestricted symmetric-progression colorings.** Deng, Tidor, and Zhao ask whether $N^{o(1)}$ colors suffice to avoid nontrivial symmetrically colored four-term progressions [37]. Shi and Dong’s $O(N^{1/4})$ construction improves the known polynomial exponent [33]. The dimension obstruction here explains a limit of one bounded-degree polynomial-coordinate model. It leaves unrestricted colorings, higher-degree constructions, and more economical treatment of digit information as meaningful directions for further work.

V.44.3 A practical order of work for this repository

The first implementation target should be the optimal partition cap, tail bound, and kernel-fibre averaging identity: they are small, independent facts with clear finite-sum statements. Next come the mixed-norm progression theorem and weighted counting wrapper, where normalization and torsion hypotheses are the main integration risks. The obstruction-fibre injection is another compact structural target.

The weighted energy proof is a larger, but still self-contained, formalization project. Its exact finite sampling and representation injections make its dependencies transparent. The polynomial dimension theorem then forms a separate finite-field development with a complete mathematical endpoint and a useful explicit example.

Finally, any effort to improve the headline Szemerédi estimate should return to the unresolved quantitative dependencies in the source ledger, especially the transition through Section 16. Once those hypotheses and bounds are discharged, the local improvements in this report can be inserted into an audited parameter calculation using Propositions V.42.1 and V.42.2.

[write] **6 October 2026; sources 06–10.** The eleven numbered questions, and the two question paragraphs at the ends of Sections III.29 and II.21, are merged into Section V.2 with credits. The intake dossier counted ten numbered questions for this source; there are eleven (seven in its first subsection, four in its second).

V.45 External inputs, provenance, and reproducibility

Source 10, delivered Appendix A.

The new quantitative deductions rely on elementary finite algebra and analysis except where the following established inputs are explicitly used: Fourier orthogonality and Parseval, finite-field extension norms, and the Plünnecke–Ruzsa sum-difference inequality. The needed Chevalley–Warning statement is proved in the article. The Reiher–Schoen result is used only for the separately

labeled modern-input alternative; the explicit $2^{-209}\gamma^{103}$ corollary uses the energy theorem proved here.

The source comparison was made against the pinned repository files, including the paper transcription, `Definitions.lean`, the numbered Sections 1–3 and 6–7, the relevant density/counting modules, the Section 18 quantitative wrapper, the status ledger, and the axiom audit. The manifest gives exact paths and blob identifiers for these materials. The bibliography points to the original publication separately from the edited repository version.

The main $\text{\LaTeX}$ file contains the complete article and bibliography. Its only external illustration is `figures/phase_frontier.pdf`; the script `verification/make_figure.py` regenerates it and the numerical examples. The plotted points evaluate theorem guarantees and do not represent observed extremal sets. The four mathematical diagnostic scripts can be run separately or through `verification/run_all.py`. None requires network access.

V.46 Finite verification and formalization interfaces

Source 11, delivered Section 12.

V.46.1 What was computed

The accompanying standard-library Python program uses integer arithmetic for every energy and inequality check. The main exhaustive computation subtracts the unique affine map interpolating $0, e_1, \dots, e_n$. Every map then has a unique representative with zero values at those points. Since affine subtraction preserves energy and distance to the affine class, enumerating these normal forms is an exhaustive computation modulo a proved symmetry, not a sample.

Domain and target	Normal forms	Maps represented	Maximum	Extremizers
$\mathbb{F}_2^2 \rightarrow \mathbb{F}_2$	2	16	40	8
$\mathbb{F}_2^3 \rightarrow \mathbb{F}_2$	16	256	344	128
$\mathbb{F}_3 \rightarrow \mathbb{F}_3$	3	27	15	18
$\mathbb{F}_5 \rightarrow \mathbb{F}_5$	125	3125	69	500
$\mathbb{F}_7 \rightarrow \mathbb{F}_7$	16807	823543	211	2058
$\mathbb{F}_3^2 \rightarrow \mathbb{F}_3$	729	19683	489	486

Here “maximum” and “extremizers” refer to non-affine maps. Every computed extremizer was checked to have distance exactly one from the affine class. The six runs represent 846650 maps through 17682 normal forms. Multiple representations of a one-point perturbation by different affine maps in the very smallest cases do not affect the table: actual functions, not descriptions, are counted.

Additional checks comprise all 2176 nonzero labelings of two-point supports on $\mathbb{Z}/17\mathbb{Z}$ into $\mathbb{Z}/5\mathbb{Z}$, 1800 seeded odd-target sparse examples, and 1000 seeded examples with targets of even order, including mixed targets such as $\mathbb{Z}/6\mathbb{Z}$. These verify the stronger comparison and deficit formulas, not just the leading cubics. Three subgroup equality examples and an explicit two-torsion counterexample to the odd formula are also included. The first eight inverse coefficients are checked by exact substitution.

The files `checks/verification_results.json` and `checks/verification_log.txt` record the output. Finite checks do not prove universal statements, do not establish literature priority, and are not Lean kernel checks.

V.46.2 The inspected repository snapshot

The relevant source was inspected at ProveIt’s commit

40f885098a74607b423909dbcb8f070993b7c2a8.

The inspected files have the following blob identifiers [60, 61, 62]:

Paper transcription	41085a0efde8c1932e86e80c791984f52841c22e
Sections06_07.lean	57b79242466ca9ddf5c36c76b828d7c5557f58ca
Proofs05_10.lean	6a49bbe6a307e6a4a20ca5d014e173fcd20fc22d

The statement file explicitly distinguishes proposition-valued definitions from proofs. It defines `functionGraph`, `proposition_6_1`, and `lemma_6_2`; the latter uses `Finset.addEnergy`. The existing convention represents a partial map by a total map together with a finite domain. That convention is compatible with Theorem II.32.1.

V.46.3 A practical formalization decomposition

The proposed extension should preserve this interface rather than reinterpreting the normalizations. A useful dependency order is:

1. Prove the derivative-collision identity for a function graph over finite additive commutative groups, and affine-subtraction invariance. Keep cardinalities in $\mathbb{N}$ before introducing normalized real quantities.
2. Formalize the six support-pattern classes and their exact counts. The only changes of variables needed are bijections between G^3 and additive quadruples, so no primality hypothesis belongs here.
3. Introduce nonzero error fibers, M, A, C, J , and prove the two color inequalities. Make the no-two-torsion assumption explicit in $C \leq A$; it is not needed for $C \leq M$.
4. Formalize the two comparison inequalities and their integer-valued master bounds. Derive the real cubic inequalities only afterwards. The coset equality case reduces to the elementary equality case of $E(S) \leq |S|^3$.
5. Formalize the anchor average and majority correction using finite probability or normalized finite sums. Then prove the unique-root comparison without importing an analytic power-series theory.
6. Add the partial-domain corollary and instantiate the result after `proposition_6_1`. The vector-space quotient proof can be a separate file, avoiding unnecessary linear algebra in the general-group stability theorem.

No Lean executable was available in the working environment, and no Lean build was run for these new results. The package therefore includes a formalization plan, not a purported verified patch. No repository files were modified. Statements read in the repository and computations run locally have been kept separate from claims of kernel verification.

V.47 Further research questions

Source 11, delivered Section 13.

The following are proposals arising from the proved results. They are not claims that each formulation has previously appeared as an open problem.

Research question V.47.1 (The full small-distance energy envelope). For fixed G, W and an attainable affine distance t , determine

$$\max\{\mathcal{E}(f)/|G|^3 : d(f) = t\}.$$

How far can the odd-target radius $1/7$ and the involution-target radius $1/3$ be enlarged? The current comparison proof loses information when three-error gains are bounded independently of two-error losses. A sharp joint optimization of these patterns may improve the radii without changing the cubic near zero.

Research question V.47.2 (The next energy levels). After excluding affine maps and one-point perturbations, determine the next largest graph energies and all extremizers, first for $\mathbb{F}_p \rightarrow \mathbb{F}_p$. Two-point supports allow constant, opposite, and unrelated error values. The exact support-pattern formulas suggest a manageable finite classification, but a proof must also exclude functions farther from every affine map.

Research question V.47.3 (A complete near-extremizer theorem at the right scale). Combine (II.27.1)–(II.27.3) with a quantitative coset-stability theorem for $E(S) \geq (1 - \theta)|S|^3$. Seek bounds in relative symmetric difference that remain meaningful when $t \rightarrow 0$. The natural parameter supplied by the current argument is η/t^3 , not just η .

[write] **6 October 2026; sources 11–14.** *Answered in substance* by composing Corollary II.27.1 with source 14’s Theorem II.43.2: Remark W3 gives, with $\theta = \eta/(6t^3) \leq 1/100$, a unique subgroup coset C with $|S \triangle C| \leq \tau(\theta)|S|$ and a single error value off a further $\eta/(2t^2(1 - 7t))$ fraction of S , in exactly the parameter η/t^3 asked for; it is written in neither source. Item II.20.

Research question V.47.4 (Small arbitrary groups and mixed torsion). Remove the sufficient condition $|G| \geq 34$ in the unrestricted-group theorem, or classify its exceptions. The vector-space proof uses the ability to extend a homomorphism from the constant-derivative subgroup; that extension can fail for general finite abelian groups. Understanding this obstruction may be as important as refining numerical constants.

[write] **6 October 2026; sources 11–14.** Remark W2 records that the cutoff cannot be removed for general groups ($\mathbb{Z}/12\mathbb{Z} \rightarrow \mathbb{Z}/2\mathbb{Z}$: 1296 against 1288) and the small exceptions found by exhaustive search. A possible lowering of the cutoff to 30 through source 12’s majority lemma is a marked question in item II.21.

Research question V.47.5 (Separate budgets for erasures and corrupted values). The partial-domain theorem treats holes through completion and a coarse cardinality inequality. Determine a sharp two-parameter envelope when a prescribed proportion of inputs is absent and a prescribed proportion of the remaining values is corrupted. Deleting a point and changing its value have different second-order energy costs, so one parameter cannot capture all the available information.

Research question V.47.6 (Efficient certified recovery). Can the canonical affine map be recovered using nearly linear time in the input-table length, with an a posteriori certificate matching the cubic bound? Randomized derivative sampling may reduce the anchor cost, but uniform recovery of the modal homomorphism must be justified, and the rare-error regime requires explicit sample-complexity accounting.

Research question V.47.7 (Higher-order respected arrangements). Develop analogues for the multilinear arrangement counts used later in Gowers’s paper. The key issue is not merely whether a higher-order defect is small: the pattern of repeated coordinates and the torsion-dependent cancellations must be tracked well enough to identify the true extremal error geometry. A naive replacement of 4 by the number of cube vertices would not settle the equality problem.

Research question V.47.8 (Can a high-energy endpoint be reached inside the general proof?). The present refinement is strongest when the respected-quadruple density is near one, whereas the initial inverse step generally gives much less. Is there a localization or amplification procedure that reaches this endpoint without losing more quantitative information than it gains? A useful answer must provide the size of the retained domain and the energy normalization together; replacing N^3 by a small-set cube without an extension argument would not suffice.

Research question V.47.9 (A machine-checked extremal layer). Implement the support-pattern counting and color-comparison layer as a reusable Mathlib development, then connect it to the existing ProveIt Section 6 statements. The finite certificates included here are useful regression tests, but a kernel-checked proof should make the two-torsion split and every normalization explicit.

V.48 Conclusion

Source 11, delivered Section 14.

The exact-additivity endpoint in Gowers’s Section 6 admits a precise quantitative theory. The principal mechanism is an error-value comparison: for sparse enough errors, replacing the nonzero values by one suitable value can only increase graph energy. Exact support-pattern counts then produce a cubic, and the equality case of set energy identifies subgroup cosets. Majority correction turns this local statement into a high-energy inverse theorem. The integer spacing of Hamming distance yields an exact non-affine energy gap; a quotient-by-affine-directions argument handles all prime-field vector-space sizes.

The results also delimit what this approach has not accomplished. They do not improve the small-correlation exponent in Proposition 6.1, do not supply a new global Szemerédi bound, and are not yet Lean-verified. What is supplied is a self-contained collection of sharp finite statements, explicit torsion corrections, equality classifications, reproducible checks, and a concrete route for extending the formalized Section 6 interface.

V.49 Reproduction and provenance

Source 11, delivered Appendix A.

The package contains the article source and compiled PDF, the exact verification program and its recorded output, a build script, and a short formalization interface note. A local reproduction requires a standard LaTeX installation with the packages used in the preamble and Python 3. From the package directory run

```
python3 checks/verify.py --output checks/verification_results.json
pdflatex -interaction=nonstopmode -halt-on-error article.tex
pdflatex -interaction=nonstopmode -halt-on-error article.tex
```

A third LaTeX pass can be used if cross-reference warnings remain after a source edit. The verification program uses only the Python standard library and deliberately avoids floating-point inequality tests.

The repository reads were limited to the cited paper interface and relevant Lean statement/proof excerpts. They are not a repo-wide audit. The bibliography records the source locations used for context and comparison. Original source PDFs and third-party font files are not redistributed in this package.

V.50 Formalization interfaces and verification

Source 12, delivered Section 10.

V.50.1 Where the new statements fit

The relevant definitions in the repository are `bohr`, `FreimanHom`, `Section10Setup`, and `HasBohrDifferenceModel`. The first uses centred modular absolute values and closed inequalities; the second is based on Mathlib’s additive Freiman-homomorphism predicate. The last two package the quantitative input and the local output of Section 10 [64].

New interface	Existing source and implementation role
Finite translation-loss and tree-intersection lemmas	Generalize the counting helpers in <code>Proofs10Bohr.lean</code> ; need only finite-set cardinalities and translation bijections.
Canonical difference and sharp extension	Replace the four-translate witness used for <code>corollary_10_11_holds</code> by a three-vertex argument and an induced value on $C + C$.
Finite radius selection	Add a covering lemma and a product-of-ratios argument; no differentiation, integration, or full regularity theorem is needed.
Fourth-moment smoothing	Reuse Parseval and the fibre cap in <code>Proofs10Main.lean</code> ; avoid the separate cardinality bound on the large-spectrum fourth-power sum.
General synchronization	Parameterize the overlap constant in <code>Proofs10Induced.lean</code> ; retain the nonempty-fibre hypothesis.
Parameterized local-model theorem	Separate <code>theorem_10_13_holds</code> from its fixed density schedule, choose B before the component, and retain the exact $\varrho^2\alpha$ slice fraction.

Table V.50.1: Proposed interfaces. These are a formalization plan, not declarations already checked by Lean. All named files are in the repository’s `GowersSzemerédi` directory.

An economical order is to formalize lemmas II.34.3 and II.39.1 and theorems II.35.2, II.37.2 and II.38.1 independently, then assemble theorem II.40.2. In particular, the extension lemma should not be tied to Bohr sets. This permits it to serve approximate groups, finite intervals, and other approximately translation-invariant domains.

The numerical schedule should be a separate theorem whose conclusion is the conjunction of (II.40.3)–(II.40.4), the rank bound, and the final radius comparison. This makes a change in

constants locally reviewable and prevents a lost ceiling or missing density hypothesis from being concealed in a large proof.

V.50.2 Independent finite checks

The accompanying scripts provide reproducible consistency checks. They supplement the proofs and do not certify arbitrary groups or constitute Lean verification.

Check	Cases	Arithmetic and scope
Three-translate lower bound	560,760	Exact integers; all nested $S \subseteq B$ and ordered directions in cyclic groups of orders at most 8.
Sharp-boundary construction	90	Exact fractions; $1 \leq m \leq 12$ and every $0 \leq t \leq m$.
Selected Bohr radius	7,900	Exact rational radii in 12 cyclic and product groups.
Overlap of the selected set	16,932	Exact set counts, including nonzero shifts which cross a nonempty boundary.
Fourier smoothing estimates	17,970	Direct finite convolutions and numerical Fourier transforms; maximum fourth-moment identity discrepancy $3.33 \cdot 10^{-16}$.
Directional repair examples	4	Exact pass/fail inequalities, including missing points and corrupted values in cyclic groups of orders 31, 47, and 101.

Table V.50.2: Executed checks included in the archive. The numerical Fourier tolerance is not used in any mathematical proof.

For example, the full-group repair test on $\mathbb{Z}/31\mathbb{Z}$ changes one value of an affine map. Its largest directional collision defect is 118/961. The majority map recovers the original slope, and the repaired affine map agrees at 30/31 of the points. A second test deletes three points and changes two values; the exact collision criterion still guarantees the recovered model, which agrees on 13/14 of the remaining set. The local interval test deliberately makes no global-affine claim.

V.50.3 Status of the deliverable

The archive contains the complete $\text{\LaTeX}$ source, compiled PDF, the figure and its generating source, both verification scripts, their executed reports, and a short build/readme file. The article's propositions and proofs are mathematical derivations; the supplied code checks finite instances. The inspected repository is identified by an immutable commit, and no change to that repository is part of this deliverable.

V.51 Further research questions and topics

Source 12, delivered Section 11.

The questions below are proposed research directions arising from the proved results. Except where an external theorem is cited, they are formulations for further investigation, not assertions that the exact wording is a previously published open problem. They are ordered roughly from local structural questions to the full quantitative program.

Question V.51.1 (Classify extremizers for the sharp overlap tradeoff). *For which B, S, C, ϕ does extension fail with $3\varepsilon + 2\kappa = 1$? Are irreducible equality examples governed by a three-part quotient, as in theorem II.35.3, or are there fundamentally different configurations?*

The proof indicates a concrete approach: equality requires the missing translates and the two boundary losses in a failed triangle to exhaust the ambient set without waste. Classifying these equality cases would be more informative than adjusting a numerical constant.

Question V.51.2 (Stability near the failure boundary). *If extension fails and $3\varepsilon + 2\kappa \leq 1 + u$ with small $u > 0$, what structural approximation to an extremal example follows under natural nondegeneracy assumptions?*

The assumptions matter: one can add unused components or directions to destroy a naive classification. A useful statement should specify how much of B and of the direction set participates in failed relations, then control the symmetric-difference distance to a model configuration.

Question V.51.3 (Prime cyclic groups and the same target). *Determine the optimal deterministic density-overlap region when $G = H = \mathbb{Z}/p\mathbb{Z}$, especially when B and C are Bohr sets with the same spectrum. How much does this narrower class improve on the universal $3\varepsilon + 2\kappa < 1$ guarantee?*

The construction proving universal sharpness does not settle this case. A study should first compare existing dense-set rectification and critical-pair results, then use finite linear algebra to identify the smallest prime-field obstructions. The distinction between a theorem for all abelian targets and one for a fixed target is essential.

Question V.51.4 (Optimal constants for finite radius selection). *For $2/3 < a \leq 1$, what is the best universal $c(a)$ such that some $r \in [\rho/2, \rho]$ supports extension from every a -dense subset of $\mathcal{B}(\Gamma, r)$ to $\mathcal{B}(\Gamma, c(a)\rho/d)$?*

The present argument gives $c(7/8) = 1/8$. It passes through the covering factor 4^d and through an inner-set lower bound for the overlap. Direct overlap estimates can be stronger than the inner-set count. Product examples show the $1/d$ scale is natural, but leave the constant unresolved.

Question V.51.5 (Measured growth in place of nominal rank). *Can a later stage of Gowers's argument preserve and use the actual growth ratio $|\mathcal{B}(\Gamma, \rho)|/|\mathcal{B}(\Gamma, \rho/2)|$, instead of replacing it by 4^d ?*

Theorem II.37.2 already gives the corresponding local improvement. The next issue is whether the rank or growth data can be carried through simultaneous families of spectra without losing the relations that motivated Section 10.

Question V.51.6 (Anisotropic spectral neighbourhoods). *Can separate radii for different characters exploit the weights $|\widehat{g}(\gamma)|^4$ while retaining the structural compatibility required later in the proof?*

The large-spectrum error before taking a common radius is bounded by

$$\frac{2\pi}{N} \sum_{\gamma \in \Gamma} \rho_\gamma |\widehat{g}(\gamma)|^4.$$

This suggests a constrained optimization problem for the radii. Any gain must pay for the resulting volume and for the cost of common refinements; maximizing the volume of one isolated box is not sufficient.

Question V.51.7 (From average error to uniform directional repair). *Under what additional overlap or representation hypotheses does a small global proportion of bad additive quadruples force the collision hypothesis of theorem II.36.2 on a useful Bohr neighbourhood?*

An answer could shorten the component-extraction part of Section 10. The challenge is to control directions with few representations. The weighted budget after theorem II.36.2 suggests retaining actual edge counts rather than discarding all information through a uniform worst-case bound.

Question V.51.8 (Sharp robust correction bounds). *Determine the best repair region in $(\varepsilon, \kappa, \eta)$, and the optimal affine-agreement conclusion in the global case. Is the nested bound $1 - \chi(\chi(\eta))$ attained subject to compatibility between all directional distributions?*

Each separate collision-to-majority inequality is sharp, but their simultaneous attainability in one group-valued function is an additional constraint. The factor 3 in the error budget also comes from a union bound which may not be extremal for compatible increments.

Question V.51.9 (Higher-order local relations). *Is $3\varepsilon + r\kappa < 1$ the correct universal scale for forcing an order- r Freiman map on C from an order-two map on S ? Which spanning-tree or relation-complex parameters replace r for a prescribed finite family of additive identities?*

The canonical difference map allows long relations to be checked through short triangles, so the density loss need not grow with the number of summands. More efficient decompositions of the prescribed relations may improve the boundary term.

Question V.51.10 (Reassemble Sections 13 and 16 with explicit new budgets). *Reprove the later local-model inputs using theorem II.40.2, retaining both the polynomial radius and the exact slice fraction $(1 - q)\varrho^2\alpha/16$.*

This is the most direct continuation of the present article. It requires a dependency-by-dependency calculation, including spectra indexed by other variables, common progressions, multilinear compatibility, and each minimum-width condition. The current repository's unresolved Corollary 16.11 estimate should be resolved on its own terms before a global numerical conclusion is drawn [66].

Question V.51.11 (A verified parameter calculus for the whole proof). *Can the local theorems expose monotone, composable bounds on rank, radius, retained density, and minimum ambient size so that the final iteration is a separately verified calculation?*

The parameterized theorem here is a useful first interface. A complete implementation should distinguish a mathematical hypothesis from a bound introduced merely for convenience, and should retain exact cardinality factors until the final simplification. This would make future improvements easier to assess and prevent local gains from being lost invisibly.

Question V.51.12 (Measure and infinite-group analogues). *Extend the translation-loss and synchronization arguments to finite-measure subsets of locally compact abelian groups, with Haar measure replacing cardinality and appropriate measurability assumptions on the maps.*

The finite intersection inequalities are measure inequalities, so much of the algebra survives. The points requiring care are representative selection, almost-everywhere versus everywhere identities, continuity of an induced homomorphism, and the meaning of a positive-measure family of witnesses. These should be stated explicitly rather than inferred from the finite case.

V.52 Parameter ledger and reproducibility

Source 12, delivered Appendix B.

The following ledger lists the fixed-spectrum specialization without dropping a density factor.

Symbol	Value or invariant
η	2^{-43} , error in the order-eight hypothesis.
θ, q	$10\eta^{1/5}$ and $\sqrt{\theta}$, with $\theta < 1/36$, $q < 1/6$.
α	$ X /(MN)$, with $0 < \alpha \leq 1/6$ in the fixed-spectrum specialization.
ϱ	$\alpha^2/32$, used for component selection, not a Bohr radius.
σ	$2^{-72}\alpha^9$, relative invariance error for fourfold fibres.
λ	$2^{-37}\alpha^{11/2}$, unchanged spectral threshold.
d	Actual cardinality of Γ ; $1 \leq d \leq 2^{74}\alpha^{-10}$.
ρ	$2^{-74}\alpha^9/\pi$, outer Bohr radius furnished by the fourth moment.
r_0	One of $3d$ selected radii in $(\rho/2, \rho]$, chosen before S and W .
κ	$1 - 4^{-1/3} < 3/8$, guaranteed translation loss on the selected B .
L	$M X ^3$, the fourfold-domain fibre cap.
$ \Omega $	$ X ^4 = \alpha LN$; the effective density is still α .
$ W $	At least $\varrho^2\alpha^2LN/16$.
$ W_1 / \Omega $	At least $(1 - q)\varrho^2\alpha/16$.
$ Y / X $	The same fraction after fixing three coordinates; at least $\alpha^5/20000$.
ζ	$\rho/(6d)$, at least $\alpha^{19}/(3\pi 2^{149})$.

The source snapshot was inspected through the GitHub connection. The source texts are cited by immutable commit in the bibliography. The final verification reports in the archive are produced by:

```
python3 verify_extension.py
python3 verify_bohr_fourier.py
python3 make_figure.py
pdflatex -interaction=nonstopmode -halt-on-error gowers_bohr_extension.tex
pdflatex -interaction=nonstopmode -halt-on-error gowers_bohr_extension.tex
```

The first verification uses the Python standard library. The second and the figure generator use NumPy and Matplotlib as indicated in the readme. The article does not require external bibliography software or network access to compile.

V.53 Finite examples, verification, and formalization

Source 13, delivered Section 10.

V.53.1 A complete partition beside a sharp obstruction

Take $N = 1009$, $r = 1000$, and the two modular phases

$$\phi_1(n) = 92n, \quad \phi_2(n) = 868n \pmod{1009}, \quad \varepsilon_1 = \varepsilon_2 = \frac{1}{4}.$$

The longest simultaneous good progression has exactly seven elements. For length eight, a candidate common difference is at most $\lfloor 999/7 \rfloor = 142$. The no-wrap criterion would require both centered steps to be at most $1009/28$. Checking all 142 possible differences shows that none qualifies. Length seven is attained with difference 143: its centered phase steps are 39 and 17, and the two spans are 234 and 102, both at most $1009/4$.

The same interval nevertheless has a complete common-difference partition into 330 cells of lengths three or four, with difference 22, produced by theorem I.26.8. This example illustrates why complete coverage and one long progression have related but distinct finite optimization problems. Its data, including the complete partition construction and all difference checks, are reproduced by `verification/verify_partitions.py`. The finite union-bound certificate also holds: its left-side count in (I.26.3) is 756718, below $1009^2 = 1018081$.

Figure V.53.1: The exponent comparison for two phases. The flexible boundary is optimal in the growing-cell sense proved in corollary I.26.6. The prescribed-length line is the sufficient boundary from the conductor argument; its optimality is not asserted. The line $b = 2a$ is the simultaneous length/diameter comparison used for Lemma 5.9.

V.53.2 What the executable checks establish

The accompanying scripts are deterministic and use no network. They address fragile parts of the derivations—normalization, integer rounding, orbit counts, Fourier signs, and equality cases. They support reproducibility; the mathematical proofs above establish the general theorems.

Script	Checked instances	Main checks
<code>verify_partitions.py</code>	3,437 partitions; 579,417 points; 410 composite-modulus cases	Exact coverage, disjointness, declared lengths, modular diameters, conductor thresholds; an explicit seven-point obstruction example
<code>verify_density.py</code>	50,000 seeded mixtures; five equality constructions; 440 parameter cases	Cell envelope, aggregate envelope, joint frontier, exceptional mass, Fourier-increment endpoints and rounding
<code>verify_cubes.py</code>	All 256 subsets over $\mathbb{Q}$ and $\mathbb{F}_p$, $p = 3, 5, 7, 11, 13$; 15 function cases	Rational cancellation and orbit identities; complete centered expansion; face-square identities; Fourier formulas and sign examples
<code>verify_fourier_counting.py</code>	8,146 intervals; 132 AP families; 186 spectral cases	Finite interval constant, exact dual equality, telescoping, endpoint uniformity bounds, a negative control, spectral-deficit equality

The partition tests use exact integers and rational arithmetic. Cube combinatorial and physical-space identities use exact rational arithmetic; Fourier evaluations use floating point, with maximum observed discrepancy about $3.5 \cdot 10^{-18}$ in that suite. The interval dual equality error was below $7 \cdot 10^{-16}$, and the telescoping identity error below $9 \cdot 10^{-17}$. The random density tests allow 10^{-12} tolerance, explicitly recorded in their output. Counts, seeds, versions, examples, and errors are stored in the accompanying JSON files. These tolerance checks are not described as exact arithmetic proofs.

V.53.3 How to fit the results into the Lean development

The existing source distinguishes proposition-valued numbered statements from companion theorems proving them. A robust extension should preserve those named interfaces and add stronger reusable lemmas underneath. The following table gives concrete attachment points in the inspected snapshot [68, 69].

Inspected interface	Suggested stronger helper	Main formal work
<code>Section05.lean</code> , <code>lemma_5_9</code>	Simultaneous affine partition with explicit target lengths	Rectangular finite pigeonhole; residue chains; consecutive-length decomposition; diameter transport
<code>Section05.lean</code> , <code>lemma_5_15</code>	Weighted high-average mass and discarded-mass bounds	Positive/negative parts; finite weighted sums; denominator positivity; extremal construction
<code>Proofs05</code> <code>Downstream.lean</code> , local phase refinements	Squared real-phase envelope and joint secant bound	Complex real-part inequality; endpoint envelope; convex norm of an affine map
<code>Sections01_03.lean</code> , <code>corollary_2_5</code>	Density-sensitive Fourier increment	Compose the new one-phase partition, phase removal, and weighted maximum-average lemma

Inspected interface	Suggested stronger helper	Main formal work
<code>Proofs03CubeUpper.lean</code> , <code>lemma_3_10_holds</code>	Coloop cancellation and exact centered expansion	Finite field linear algebra; measure-preserving translations; subset enumeration; normalized cube forms
<code>Proofs03Interval.lean</code> , <code>lemma_3_5_holds</code>	Length-sensitive interval spectral bound	Retain the minimum of length and decay; finite/integral comparison; normalize Fourier coefficients
<code>Proofs03</code> <code>ProgressionCount.lean</code> , <code>corollary_3_3_holds</code>	Telescoping count with density weights	Algebraic telescope; exact two-form factorization; reuse endpoint generalized von Neumann

The recommended initial formalization target is theorem I.27.1: it uses only finite weighted real sums and exposes a useful generic API. Next come the two finite integer partition decompositions and the one-phase Fourier corollary. The full three-cube identity is longer but has a finite, auditable structure: certify the coefficient-matrix kernels, prove the orbit identifications, and rewrite the resulting sums.

Three distinctions should remain explicit in any implementation. First, the article’s norms are normalized while the source `gowersNorm` is not. Second, cardinality-equals-length is not the same as an integer nonwrapping lift. Third, an axiom audit validates the dependency boundary of compiled theorems, but does not discharge hypotheses of conditional theorems or verify the correspondence between a proposition and its intended paper statement. The repository’s audit comments make this distinction themselves. No new Lean source with an unverified compilation claim is included in this package.

V.54 Further research questions and concrete next steps

Source 13, delivered Section 11.

The following questions are suggested by the proved results. Their status here is deliberately local: the report does not claim that each formulation has never appeared or been resolved elsewhere. Before treating one as a historical open problem, its exact formulation should receive a dedicated literature check.

V.54.1 Complete partitions with prescribed lengths

Research question V.54.1. Can a complete partition into lengths $v - 1$ or v achieve the flexible exponent frontier $(q + 1)a + qb = 1$, or is there a genuine arithmetic obstruction between that frontier and the proved sufficient region $(q + 2)a + qb \leq 1$?

[write] **6 October 2026; sources 21–27.** *Answered by source 23:* there is a genuine arithmetic obstruction. The prescribed-length frontier is $(q + 2)a + qb = 1$, even with cell-dependent differences (Proposition I.38.1), and the threshold is $L^{q+2} / \prod_i \varepsilon_i (1 + o(1))$ for lengths $L, L + 1$ (Corollary I.37.1); the lower example is realizable on a prime cyclic group. With an exceptional set the cost is quantified by its Theorem I.39.1 and Corollary I.39.4.

The present proof uses one common difference and requires every residue chain to pass the conductor $(v-1)(v-2)$. A useful first step is to formulate three separate minimax problems: one common difference, cell-dependent differences, and an exceptional set of mass $o(1)$. The last problem already has the flexible exponent by the discarded-remainder construction. Either a matching obstruction for the first problem or a way to rearrange the remainders in the second would resolve a precise limitation of the proof.

Research question V.54.2. What are the best leading constants in the flexible partition theorem for a fixed q and anisotropic tolerances?

The universal gap is less than four between the constructive and probabilistic constants. Geometry of numbers may improve the rectangular approximation step, while more careful distribution of chain remainders may improve the partition constant. The exact finite obstruction certificate provides a practical benchmark for small moduli.

V.54.2 Genuinely simultaneous polynomial recurrence

Research question V.54.3. For degree $k \geq 2$, which hypotheses permit simultaneous partition exponents polynomial in the number of phases, in place of repeatedly taking K th roots as in Lemma 5.9?

The linear proof cannot simply be reused by approximating all polynomial coefficients: after restricting to an arithmetic progression, the degree- j term contains d^j , and translation generates coupled lower-degree coefficients. A focused first case is a family of quadratics sharing a leading coefficient or lying in a bounded-height coefficient span. One should seek a joint recurrence statement tailored to those dependencies and then prove the same complete-partition interface. Success only for generic independent quadratics would still be valuable, but must be distinguished from a uniform all-coefficient theorem.

Research question V.54.4. Can a bounded-height generating family be chosen efficiently so that (I.26.6) is close to optimal for a given collection of modular phases?

The present theorem takes a representation matrix as input. Finding a better representation resembles an integer basis problem, with the analytic objective depending on both dimension and coefficient size. It is not ordinary vector-space rank. A useful output would be a certified generator matrix together with optimized positive budgets t_j , so every numerical gain is accompanied by a verifiable inequality.

V.54.3 Extremal density selection with additional information

Research question V.54.5. What is the exact largest guaranteed high-average *cell size* for a fixed number of cells, rather than the high-average mass solved by theorems I.27.1 and I.28.3?

Dividing mass by $M-1$ is useful, but it ignores how many cells are needed for negative mass and for the threshold cell in an extremizer. This is a finite constrained optimization problem. The natural first cases are $M=2, 3, 4$, followed by a piecewise formula in M . It may produce an improvement directly compatible with Lemma 5.15 without changing any analytic input.

[write] **6 October 2026; sources 11–14.** *Answered in the weighted model* by source 06's Theorem I.21.1: with M fixed and the cell masses free, the exact optimum is $\min\{P_+/(b(M-1)), S/(M-2)\}$ with explicit extremizers. Integer cardinalities and prescribed cell sizes remain open (item I.6).

Research question V.54.6. Can the joint frontier retain the entire list of phase radii s_j , cell weights, and a measured value of $V = \mathbb{E}|f|$, rather than a common radius and the endpoint upper envelope?

The affine aggregate inequality retains V exactly, while the sharp joint theorem optimizes over all functions in $[-a, b]$. Neither necessarily dominates the other after additional measurements are fixed. A dual optimization using a family of supporting lines to the distinct functions h_{s_j} is a concrete approach. An equality classification would show which measurements are actually useful.

Research question V.54.7. Which extremizers for theorem I.28.3 are ruled out when z is a polynomial phase on arithmetic progression cells?

The abstract extremizer places positive and negative function values at two phase endpoints. Algebraic phase constraints may prevent that configuration from occurring on many large cells simultaneously. Quantifying this obstruction would improve an application using genuinely new structural information, rather than attempting to strengthen an already sharp abstract inequality.

V.54.4 Cube geometry and higher-order cancellation

Research question V.54.8. Can the coloopless-subset polynomial $\sum_j c_{d,p}(j)z^j$ be evaluated or bounded effectively as d grows, with all characteristic dependencies explicit?

The quartic coefficient has the closed form (III.31.2), and dimension three is completely enumerated. Higher coefficients are a finite matroid problem. Complementation identifies coloopless sets with complements of flats of the dual matroid, suggesting a way to organize enumeration without examining every subset independently. Characteristic-dependent exceptional minors must remain visible. Even usable coefficient upper bounds could improve the crude binomial majorant.

Research question V.54.9. For fixed $\delta, \rho, \eta, \sigma$, what is the best possible upper value of $\mathcal{Q}_3(\delta + f)$, and which combinations of T_5, B_1, B_2, B_3, T_7 are jointly realizable?

The exact identity exposes the variables that were hidden by the norm triangle inequality. The separate estimates are not a full solution of their joint feasible region. The spectral deficit is attained by flat nonzero spectra, whereas the negative B_3 example uses a very different spectrum. Understanding that incompatibility is a plausible route to stronger bounds. A first target is to classify equality in $|B_2| \leq B_1$ simultaneously with $|T_7| \leq \eta^4 \sqrt{B_1}$.

Research question V.54.10. How far can the low-order terms in higher cube expansions be expressed using lower uniformity norms and a small list of spectral moments?

The three-cube calculation isolates an ordinary Fourier contribution at order four, a doubled-frequency moment at order five, and three six-point moments. For dimension four, one could first classify five- and six-circuits and ask which are controlled by U^2 rather than U^4 . This connects an explicit finite expansion with the theory of true complexity [29]; an effective inequality needs both the algebraic classification and quantitative analytic control.

V.54.5 A full quantitative and formal audit

Research question V.54.11. After replacing only the genuinely linear and real-valued local steps, what is the best complete bound obtainable by the existing Gowers proof architecture?

A valid answer requires a dependency-by-dependency parameter audit. Track the density at every iteration; the phase correlation before each partition; the number, dimension, and coefficient sizes of the phases; all exceptional masses; the actual new cell length; and the final transfer from modular to integer progressions. The improved telescoping count can relax a uniformity threshold, while the density-sensitive Fourier increment can improve local length. The higher-degree inverse step may nevertheless dominate the final asymptotic. Until that audit is complete, the correct output is a set of proved local improvements, as given here.

Research question V.54.12. Can the finite sharp statements and their extremizers be formalized as reusable Lean lemmas, with exact source normalization and an auditable numerical ledger?

This is a concrete implementation project. Begin with weighted real selection, then integer partition construction, then the normalized Fourier wrapper. For the cube identity, separate finite linear algebra from Fourier summation. Export the resulting constants and use the existing source ledger to distinguish completed companion statements from conditional consequences. The goal is a small set of stronger, reusable mathematical interfaces whose application to the larger proof is explicit.

V.55 Reproduction and source provenance

Source 13, delivered Appendix A.

The package contains the complete L^AT_EX source, compiled PDF, two standalone vector figures and their rendering script, four verification scripts, and their JSON outputs. Build the article from the package root using

```
python make_figures.py
pdflatex -interaction=nonstopmode -halt-on-error gowers_local_refinements.tex
pdflatex -interaction=nonstopmode -halt-on-error gowers_local_refinements.tex
```

The supplied figures are already rendered, so the first command is needed only to regenerate them. The density and partition scripts use the Python standard library. The cube and Fourier/counting scripts also use NumPy. The figure script uses NumPy and Matplotlib. The accompanying README gives the four verification commands. No original journal PDF or full third-party paper source is redistributed in the package.

The source snapshot was inspected through the user-selected GitHub connection. Its adapted paper has blob SHA 41085a0efde8c1932e86e80c791984f52841c22e; the status ledger has blob SHA feb6d45ba9e4a01092b8cf68083e1fbb99a1bf45. The accompanying provenance file records the pinned commit, relevant file paths, and hashes of the deliverable files. The article’s source comparisons refer to that snapshot. The mathematical proofs themselves are independent of future repository edits.

V.56 The Lean source map and a concrete formalization route

Source 14, delivered Section 8.

V.56.1 The inspected revision

The supplied repository [70] was inspected at commit

9ea383e9b28d885a936d5d681cd5584fffd2cb29.

The paper source and selected Lean files are recorded in the accompanying `source_manifest.json`, including upstream paths, byte sizes, and Git blob identifiers. The paper source matches blob 41085a0efde8c1932e86e80c791984f52841c22e. The source map below specifies where each refinement connects to the development.

Source location or declaration	Connection to this report
Definitions.lean, cubeCount, uniformity and cube-form definitions	Normalization bridge: divide the three-cube count by N^4 , use $f = 1_A - \delta$, and identify the uniformity budget with $\ f\ _{U^3}^8 \leq \alpha$.
Sections01_03.lean, lemma_3_10	The comparison point for Equation (F.19.1). A strengthened declaration must explicitly add the real centered and coprime-order assumptions, and its small-uniformity range.
Sections12_13.lean, DArrangement, arrangementCount	The two-coordinate arrangement model motivates the common-sidelength moment count. The present notation separates cube dimension from the number of cubes in an arrangement.
Sections14_15.lean, respectedCubePairCount, respectedGeneralArrangementCount	Direct counterparts of the collision count and the R_j family when all coordinate, index, and value groups specialize to $\mathbb{Z}_N$. The source's alternating-sign convention differs by a global sign, which preserves equality of label sums.
Sections14_15.lean, lemma_14_7	The $j = 8$ specialization of the moment step. Retaining $S = \sum_r B_r ^3$, and then $S - \Xi$ or S_{card} , provides a sharper local denominator.
Proofs09Moments.lean, Proofs12Parallelograms.lean, Proofs14Arrangements.lean	Existing moment and arrangement proof infrastructure to inspect when implementing the scalar interpolation and count identities. Our new stability and equality results are not already certified by merely referring to these files.
Sections08_09.lean, HasMonochromaticAP, corollary_8_3 [write: <i>HasMonochromaticAP is at Definitions.lean, line 113; corollary_8_3 is at Sections08_09.lean, line 52, and is open at HEAD e1db00e99</i>]	These encode monochromatic integer progressions. The polynomial supersaturation result requires a new finite-field reflection predicate and should not be presented as the same assertion.

Source location or declaration	Connection to this report
<code>Audit.lean</code>	The source audits theorem axiom dependencies against <code>propext</code> , <code>Classical.choice</code> , and <code>Quot.sound</code> , and counts exact companions for 120 numbered catalogue definitions. Its own comments distinguish this check from discharging conditional hypotheses or validating correspondence with the paper.

The repository also explicitly adjusts the printed exponent in Corollary 14.6 and propagates that adjustment to Lemma 14.8. The new moment denominator should be composed with the inspected statements and their hypotheses; it should not silently restore a printed exponent that the development has already corrected.

No Lean executable was available in the execution environment for this report. We inspected the source, but did not run the project build or the axiom audit, and did not add new Lean proofs. The article’s proof status is therefore conventional mathematics with reproducible finite diagnostics. This distinction is essential: a proposed theorem statement, an audited dependency boundary, and a complete kernel-checked proof are three different artifacts.

V.56.2 Recommended implementation order

The most direct first formalization target is the energy stability theorem. It requires finite sets, translations, counting, subgroup cosets, and rational inequalities, and does not depend on asymptotic notation or analytic Fourier transforms. A useful decomposition is:

1. Prove the overlap identity and the three-halves difference-set lemma for finite subsets of an additive commutative group.
2. Formalize the extraction of B and $H = B - B$, keeping $9/10$, $4/5$, and $5/4$ as rational constants.
3. Establish the two disjoint failed-triple counts in Equation (II.43.5). This is the essential combinatorial step and deserves its own reusable declaration.
4. Prove the polynomial defect inequality before introducing the square root. One can first state the conclusion as $d(1 - d) \leq \varepsilon$ with $0 \leq d < 1/3$, then derive the τ formulation separately.
5. Add the coordinate-corner homomorphism argument. Its image and fiber cardinalities force $e_i H \subseteq H$ without a dimension-dependent estimate.
6. Formalize the exact labeling classification using finite differences and inclusion–exclusion anchored at the origin.

The second target is the finite moment equality theorem. The scalar convexity argument can be separated from Fourier orthogonality. After obtaining the zero-or-common-modulus Fourier criterion, nonnegativity and equality in the triangle inequality recover constant weights on cosets. The combined geometric classification then follows through the zero sidelength and graph supports.

The cube expansion is naturally divided into a finite support classification, the Fourier identity, a finite inequality for S, D, ρ, b , and a real-variable optimization lemma. The asymptotic theorem

should be a final wrapper around these exact statements. This avoids encoding a long argument entirely in little-oh notation.

For polynomial colorings, begin with the reflection-coefficient equivalence and its Vandermonde hypothesis $p > k$. The minimum-support lemma, equality slicing, and norm construction are reusable finite-field results in their own right. Definitions should keep the palette $\mathbb{F}_q^r$, its coordinate degree bounds, ordered parametrizations, and the zero direction explicit.

V.57 A focused research program

Source 14, delivered Section 9.

The following priorities identify concrete next results and the information each would add. These are proposed research questions; they are not asserted to be established open problems with an exhaustive priority history.

1. **The optimal exponent-five coefficient.** For nontrivial exponent-five groups, determine whether a universal coefficient C_5 gives

$$M_{\delta,G}(u) = \delta^8 + 6\sqrt{2}\delta^4 u^4 + C_5 \delta^2 u^6 + o_\delta(u^6),$$

and whether $C_5 = 2^{3/4}/3$. The proof supplies the sharp exponent and a candidate model, but arbitrary small Fourier tails and their phases must be controlled before identifying the coefficient. Dependence on the rank of G is itself part of the question.

[write] **6 October 2026; sources 21–27.** *Answered by sources 21 and 23:* the universal coefficient exists and $C_5 = 2^{3/4}/3$, with an absolute $O(u^8)$ remainder independent of the rank (source 21's Theorem F.26.1, source 23's Theorem III.58.1); it is attained on every fixed group (source 21's Corollary III.55.2). Item III.23.

2. **The next term outside exponent five.** Determine the first term after $C_* \delta^{8/3} u^{16/3}$. The order-seven computation already warns that the next answer can depend on torsion. A plausible initial project is to compare fixed groups with minimum nontrivial character order at least eleven against order-seven groups, retaining every Fourier resonance at the first unresolved scale.
3. **Effective secondary rigidity.** Replace the sequential conclusion of Theorem III.34.3 by an explicit estimate in terms of the normalized deficit and u/δ . The final scalar optimization has a nondegenerate maximum. This should convert the proof into quantitative control of amplitude, phase, and unused Fourier fourth mass. A separate question is what additional hypothesis permits an L^2 approximation.
4. **The largest range of the energy envelope.** Determine the best universal range of ε for $|A\Delta C| \leq \tau(\varepsilon)|A|$, and separately the range forcing the nearest coset to split by coordinates. The current $1/100$ is a safe explicit range of the extraction argument. Classifying every exact envelope example would sharpen the present infinite-family sharpness statement.
5. **Quantitative repair of labels.** Once the domain is close to a product coset, turn the collision defect into a Hamming-distance estimate for $M + \sum_{U \subseteq [k]} f_U$. Dependence on the number of coordinates, the target group, and degenerate coordinate factors should be stated explicitly. A useful first case is a full $\mathbb{F}_p^2$ domain with labels in $\mathbb{F}_p$.

6. **Stability of simultaneous arrangement equality.** Find hypotheses under which near equality in the profile-moment bound yields a common coordinate subgroup, an approximately coset-supported family of section indices, and approximately $(k + 1)$ -additive top interactions. The spectral variance estimate controls weighted Fourier mass, but does not alone provide this joint spatial description.
7. **Dimension thresholds above the reflection budget.** Resolve the scalar degree-five, symmetric four-term problem, beginning with dimension five. The present bounds are $4 \leq d_{\max} \leq 8$ for the specified model and characteristic range. The Artin–Schreier example rules out one tempting norm construction in characteristic five; it does not rule out other quintic maps.
8. **Classification of exact polynomial extremizers.** Describe all cubic maps at the threshold in dimension four and all possible center-dependent subspaces $S_z(Q)$ above it. The equality geometry of the zero set is settled; compatibility as the center varies is the missing global condition. The example $x + y^2$ excludes a universal fixed-kernel answer.
9. **Second-minimum direction counts.** Determine the next attainable value of $|S_z(Q)|$ in dimensions $d \geq B + 2$, and over nonprime fields in dimension $B + 1$. The zero sets come from homogeneous odd coefficients of a single polynomial map, which may impose more restrictions than an arbitrary bounded-degree system.
10. **Palette size and redundant coordinates.** Replace the prescribed degree-vector budget by a useful invariant of the polynomial map’s actual image. The current theorem counts coordinates with degree bounds, even when some color information is redundant. Any improvement should separate algebraic redundancy from arbitrary relabeling of the palette.
11. **Higher-dimensional centered cube extremals.** Identify the first surviving centered correlations for U^d with $d \geq 4$, determine the sharp real mean-zero comparison with lower uniformity norms where one exists, and study the torsion-dependent extremizers. A successful method must control how different support types compete, not merely bound each one separately.
12. **A complete parameter ledger for the global argument.** Insert the profile and geometric denominators into an entire arrangement-extraction and density-increment chain. Track the densities, multiplicities, degeneracies, and threshold choices symbolically. The relevant output is a proved end-to-end parameter improvement; a better isolated local constant is not enough to infer it.

The energy stability theorem and the finite equality classifications are suitable near-term formalization projects. The order-five coefficient and the quintic coloring problem are compact research problems with explicit candidate constructions and obstructions. The higher-cube and global-density questions require additional ideas beyond the local proofs developed here.

V.58 Reproducibility, diagnostics, and proof status

Source 14, delivered Appendix B.

V.58.1 Contents of the source package

The package contains one complete article source, `gowers_extremal_refinements.tex`, its compiled PDF, the PDF figure and figure-generation script, two verification scripts and their recorded JSON results, the pinned source manifest, and a short build guide. The external paper and the Lean repository are referenced, rather than redistributed. The bibliography is embedded in the article source, so no BibTeX run or separate bibliography database is needed.

The article compiles with a standard pdfLaTeX installation:

```
pdflatex -halt-on-error gowers_extremal_refinements.tex
pdflatex -halt-on-error gowers_extremal_refinements.tex
```

The existing figure is included, so Python is not needed to build the PDF. To regenerate the computational records and the figure, use:

```
python3 verify_results.py
python3 verify_certificates.py
python3 make_figures.py
```

The first script requires NumPy, the certificate script uses only the standard library, and the figure script requires Matplotlib. All files are addressed relative to the scripts.

V.58.2 Checks performed

Check	Scope and result
Sparse Fourier identity	All $5^8 = 390\,625$ assignments of frequencies in $\{-2, -1, 0, 1, 2\}$ were tested against the four integer orthogonality constraints. Exactly 225 survive, in the eight histogram rows of the model table.
Centered support certificate	All 255 nonempty subsets of the cube vertices were classified with exact rational arithmetic. The quartic and quintic surviving counts are 12 and 8.
Small-torsion certificates	Every Fourier slot in groups of orders 5 and 7 was checked as an exact polynomial, including the phase cancellations in order five. All table entries and cube polynomials match.
Fourier inequality diagnostics	144 real spectra were tested on cyclic groups of orders 5, 7, 11, 13, 17, 25, including concentrated spectra and an order-five dominant character inside a larger group. The direct cube and Fourier formulas agree with maximum normalized numerical discrepancy below $2.5 \cdot 10^{-16}$. All tested norm inequalities pass the stated tolerances.
Energy and algebra	All 2036 nonempty subsets of cyclic groups of orders 1 through 10 were checked for the energy upper bound and coset equality. The defect-polynomial identity and nonnegativity were checked in 35 300 rational cases. Five larger prime examples verify exact sharpness.

Check	Scope and result
Coordinate geometry and labels	All 511 nonempty subsets of $\mathbb{F}_3^2$ were checked: exactly 16 attain the cube-collision maximum, precisely the coordinate cosets. Among all 19 683 labels of the full domain into $\mathbb{F}_3$, exactly 729 attain equality, matching $axy + u(x) + v(y)$.
Polynomial norm coloring	The norm associated with the irreducible polynomial $T^3 + T + 1$ over $\mathbb{F}_5$ was checked on all 125 inputs. For its cubic four-coordinate coloring, all 625 centers and all 625 directions per center were checked. Only the zero direction survives at every center.
Asymptotic arithmetic	The exact two-harmonic norm and cube formulas were evaluated at $u = 10^{-1}, \dots, 10^{-9}$ with 90-digit decimal arithmetic, verifying the norm constraint and convergence of the secondary residual to C_* .

The randomized diagnostic seed is 20261006. Numerical tolerances are recorded in `verification_results.json`; the exact tables are in `certificate_results.json`. Finite enumeration can detect normalization errors and missed torsion cases, but it does not establish the all-group inequalities, uniqueness statements, or asymptotic uniformity. Those claims are established by the proofs in the main text.

The principal arguments were also reviewed independently within the preparation process. The review led to explicit handling of order-five coincidences, the phase-error term in secondary rigidity, the small-field boundaries in the minimum-support proof, and the distinction between geometric support repair and label repair. This is internal review, not external peer review or formal verification.

V.59 Reproducible computations and Lean integration

Source 15, delivered Section 13.

V.59.1 Finite checks supplied with the manuscript

The accompanying `verify.py` uses only the Python standard library and a fixed random seed, 20261006. It computes arrangement counts by convolution, not by enumerating all sixteen cubes of an eight-arrangement. For each h , let m_h^{*d} be the d -fold additive convolution on $T \times V$. The exact identity

$$R_d(h) = \sum_{z \in T \times V} (m_h^{*d}(z))^2 \quad (\text{V.59.1})$$

is simply the count of two ordered d -tuples with the same sum. For the tested integer and rational measures, this uses exact arithmetic.

The executed checks include all 1,036 nonempty subsets of $(\mathbb{Z}/2\mathbb{Z})^2$, $(\mathbb{Z}/3\mathbb{Z})^2$, $(\mathbb{Z}/2\mathbb{Z})^3$, and $\mathbb{Z}/4\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$. They verify the cubic cap and the equivalence between its equality cases and Cartesian cosets. Most stability hypotheses in these very small groups occur only at exact equality. Two additional nonzero-deficit examples, in $\mathbb{Z}/101\mathbb{Z}$ and $\mathbb{Z}/101\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$, have deficit 99/10000 and produce the asserted coset certificates.

The joint normal form is checked against the count equalities for all 6,560 nonempty partial binary labellings on $(\mathbb{Z}/2\mathbb{Z})^2 \times \mathbb{Z}/2\mathbb{Z}$, and for 180 further ternary cases. Other tests cover random indicator domains, rational vertex weights, sharp subgroup examples, exact label decompositions, the polynomial stability identity, and all displayed exponent comparisons over a finite range. The weak parameter $q^{-1/8}$ in Lemma II.49.2 supplies a valid product property for the nonconstant random labels; the coupled inequalities are checked with its powers represented exactly as rational numbers.

Thirteen Fourier cross-checks use complex floating-point arithmetic with relative tolerance 10^{-9} . They are deliberately distinguished from the integer and rational count tests. The exact counts and all inequalities are not certified by those floating-point computations. The complete executed inventory is in `verification_results.json`, with a readable log in `verification.txt`. Every assertion passed in the supplied run. Finite examples supplement the proofs and do not establish a universal statement by themselves.

V.59.2 An explicit constructive certificate for the stability theorem

Given the finite set A , compute $r(t)$ and $P = \{t : 8r(t) > 7|A|\}$. Form $H = P - P$ and choose a coset of H maximizing its intersection with A . Under the theorem’s hypothesis this construction returns the asserted Cartesian coset. A verifier can check subgroup closure, coordinate-projection invariance, the two cardinality bounds in (II.52.1), and the final symmetric difference directly. The supplied script implements this construction. After the correlations are available, subgroup and coset construction require at most quadratic group-table work, with a separate coordinate-invariance check. Computing the input cube count naively has a 2^k vertex cost.

V.59.3 Repository interfaces that would support the new results

The inspected proof of Lemma 14.7 already has a general even-moment identity and the interpolation infrastructure, but the relevant helpers are private [80]. The shortest development path is therefore not to [6 *October 2026; sources 15–20; checked at HEAD 0b4890a1c*] *Precision*: the general even-moment identity is the private `cor147_moment_eq_count` (`Proofs14HigherArrangements.lean`, line 484, general d); the interpolation helpers `cor147_interpolation` and `cor147_moment_interpolation` (lines 653, 701) are hard-wired to $d = 8$. The unweakened Corollary 14.6 exponent is already kernel-checked as the private `cor146_direct_lower` (note in Section F.20).

formalize an unrelated Fourier theory anew. It is to expose an appropriate public interface and retain the intermediate count.

A practical module sequence is as follows.

1. **Public moment identity.** Export a general- d version of the moment–arrangement correspondence. Define the collision parameter using `respectedGeneralArrangementCount 1 B phi`, avoiding an unnecessary second notion of the same count.
2. **Division-free interpolation.** Prove $R_2^{d-1} \leq R_1^{d-2} R_d$ over real casts. Treat $R_1 = 0$ before introducing normalized quotients. The case $d = 2$ should be separated from strict-convexity arguments.
3. **Fibre cap.** Formalize the injection $(h, y, z) \mapsto (y, y + h, z)$ and then the label-forgetting injection. Only finite group arithmetic and cardinalities are required.

4. **Collision-parametrized product step.** Refactor the reference-cube argument in `Proofs14Arrangements.lean` to conclude $R_2 \geq \gamma^{u_k} C^4 / (nM^7)$ before inserting the density lower bound. Its documentation already makes clear that the reference base has to be retained in an injection or accounted for by averaging [81].
5. **Coupled exponent arithmetic.** Combine the previous two public results and only then substitute the collision lower bound. Introduce a new stronger theorem and recover the existing corrected statement as a corollary, rather than silently changing the meaning of an existing name.
6. **Independent stability modules.** The small-difference lemma, energy-deficit argument, coordinate-mixing argument, and exact joint normal form can be developed separately from the analytic proof chain. They should have their own statements and checks rather than being counted as completed source lemmas.

The source checkpoint reports a successful build and axiom audit of its existing development [83]. That report was read, not reproduced here. This package contains no newly kernel-checked Lean theorem and makes no claim to close later open stages in the repository. The accompanying `integration.md` records proposed interfaces and the same limitations. In particular, a mathematically proved enhancement is not already a Lean enhancement merely because its intended dependencies exist.

V.60 Relation to existing work and remaining research

Source 15, delivered Section 14.

V.60.1 Literature position

The basic moment conversion is Gowers’s mechanism, and the near-maximal energy part of the Cartesian proof belongs to the familiar almost-period approach in additive combinatorics. Our proof adds an explicit coordinate mixing argument because an arbitrary subgroup need not split into coordinate subgroups, as Example II.53.4 demonstrates.

Near-extremizers for ordinary Gowers–Host–Kra seminorms are studied by Eisner and Tao [7]. Kovač and Rogers’s September 2026 preprint studies sharp bounds, near-extremizers, and degree-lowering inequalities for L^p norms of multiple autocorrelations [71]. These are relevant surrounding theories, but the present functional counts *coordinate-restricted axis cubes with a shared side vector*; it is not being identified with the usual unrestricted Gowers norm. In particular, results whose hypotheses exclude compact open subgroups cannot simply be applied to finite groups to improve a constant that is attained by the subgroup examples above. This manuscript claims neither to supersede that literature nor to settle its already resolved questions.

The investigations below are concrete follow-on questions generated by the proved results. They are not represented as a list of historically recognized open problems. Some may admit a reformulation using existing stability or property-testing results.

Question V.60.1 (Best Cartesian stability constant). *What is the smallest uniform function $\delta(\varepsilon)$ for which $Q(A) \geq (1 - \varepsilon)|A|^3$ forces a Cartesian coset within $\delta(\varepsilon)|A|$ points?*

Theorem II.52.2 gives $\delta(\varepsilon) \leq 18\varepsilon$ up to $1/100$, while Example II.52.3 gives $\liminf_{\varepsilon \rightarrow 0} \delta(\varepsilon)/\varepsilon \geq 1$ along an admissible sequence. Determining the leading constant and the largest valid near-extremal range is a finite, explicit extremal problem.

[write] **6 October 2026; sources 15–20.** *Leading constant answered by source 14: its Theorem II.43.3 gives $\delta(\varepsilon) \leq \tau(\varepsilon) = \varepsilon + O(\varepsilon^2)$ up to $1/100$, and Example II.52.3 (= source 14's Proposition II.43.4) attains it, so the leading constant is 1, not 18. The largest valid range is source 14's Question 4 and stays open (item II.31).*

Question V.60.2 (Quantitative repair of labels). *Suppose the respected cube-pair count is at least $(1 - \varepsilon)|A|^3$. After passing to the nearby Cartesian coset, can the labels be altered on $O_k(\varepsilon)|A|$ points, with appropriate treatment of missing points, to obtain the exact form (II.51.1)? Can the dependence on k be removed?*

The allowed correction class must include all coordinate-omitting functions and must work in arbitrary finite abelian value groups. Requiring only an ordinary polynomial would miss the exact examples already classified. The denominator measuring errors should be specified before attempting a property-testing argument on sparse fibres.

Question V.60.3 (Robust joint normal forms). *If both $1 - C/\Gamma$ and $R_8 C^6/R_2^7 - 1$ are small, is there a quantitative analogue of Theorem II.54.2 in which most fibres share one horizontal subgroup and the top mixed values are close to a $(k + 1)$ -multiadditive model?*

The spectral theorem supplies weighted closeness to a common magnitude; the geometric theorem supplies separate fibre cosets. Their combination still requires coherence across fibres. A robust conclusion must retain arbitrary fibre translates and coordinate-omitting terms, and must state whether the approximation is in point mass, collision mass, or cubic mass.

Question V.60.4 (Preserving the coupled gain in the later proof). *How much of the improvement in (II.50.4) survives the selection and density-increase arguments in Sections 15–17, and the quantitative iteration in Section 18?*

A useful first deliverable is a symbolic parameter ledger carrying $(\beta, \gamma, \chi, \rho_3)$ through each extraction. Replacing these by single worst-case density parameters too early could erase the gain. Only a complete ledger with verified hypotheses could justify a statement about a final Szemerédi bound. The present article does not provide that last step.

Question V.60.5 (Optimal product-property amplification). *Are the powers $3d - 2$ of χ and the associated exponents in (II.49.7) optimal under PP_γ alone, or can the reference-cube averaging exploit further compatibility between side vectors?*

The constants in raw moment amplification are sharp, but its simultaneous combination with the configuration lower bound may have incompatible extremizers. Establishing a genuinely stronger theorem would require examining that compatibility, not just optimizing an isolated application of Jensen. The side-vector profile in Proposition II.53.3 is an explicit place to begin.

Question V.60.6 (Balanced extraction versus density cost). *When can one pass to a substantial subdomain with nearly equal fibre densities while retaining enough respected arrangements to benefit from ρ_3^{-6} or the precise profile bounds?*

An answer should optimize the retained arrangement mass against the loss in β and the number of occupied fibres. Example II.48.4 shows why a balance assumption cannot simply be inserted without a cost.

Question V.60.7 (Weighted near-extremizers). *Can near equality in the weighted cubic cap be converted into a useful rounding theorem for f , under natural lower-density or nonconcentration hypotheses?*

The exact argument in Section II.56 proves only that exact saturation forces zero–one weights. Controlling the total mass of fractional weights from a global cubic deficit is a separate issue. Its resolution would connect the weighted coupling theorem to geometric stability without imposing an indicator-domain reduction at the outset.

Question V.60.8 (Nondegenerate and anisotropic variants). *What error term is necessary when arrangements are required to have distinct vertices, or when the allowed side vectors come from a prescribed anisotropic family?*

A fixed side restriction preserves the moment identity, whereas excluding cross-cube coincidences need not. A satisfactory theorem should distinguish these cases and quantify the exceptional counts, especially when the ambient groups have small torsion. Prime cyclic asymptotics should not be used to justify a statement for arbitrary finite groups.

Question V.60.9 (Certificates and formal interfaces). *Can the public moment identity, collision cap, and reference-cube bound be assembled into short checked Lean proofs of the stronger statements, with an automated exponent ledger and executable finite certificates?*

The immediate target is the division-free all- d inequality followed by the collision-parametrized product step. The structural stability results can then be checked independently. This separation would make the distinction between analytic improvements, combinatorial models, and final iteration obligations explicit in the proof status.

[write] **6 October 2026; sources 15–20.** *Cross-answers.* The second and third questions above are source 14’s Questions 5 and 6 (item II.24); the fourth restates source 14’s Question 12 and source 04’s Question 7 (items V.1, II.3), and the sixth is a variant of source 04’s Question 7. The others are new in this report; all are merged in Section V.2.

V.60.2 A proposed order of work

The highest-leverage next step is the collision-parametrized Lean interface, because its proof ingredients are already present and it records the main quantitative saving. In parallel, the elementary Cartesian stability proof is a contained formalization project. A parameter ledger through later sections and a robust version of the joint normal form are the more substantial research tasks. Neither should be replaced by a claim that the local gains automatically constitute a global breakthrough.

V.61 Conclusion

Source 15, delivered Section 15.

The arrangement argument loses information at two different places: in replacing the collision count by an ambient second-moment cap, and in eliminating that collision parameter before combining the product-property step with interpolation. Keeping it produces sharp density-sensitive amplification and the stronger coupled bound

$$a_8 \geq \beta^{22 \cdot 4^k} \gamma^{44k4^k + 56 \cdot 2^k}.$$

The same parameter also has a geometric meaning. Its cubic cap has exact Cartesian extremizers, its near-extremizers satisfy a dimension-free linear-error theorem, and simultaneous moment and cubic equality have the complete fibrewise multiadditive normal form in Theorem II.54.2. These conclusions are proved independently of the uncompleted later stages of the supplied formalization.

V.62 Notation and verification inventory

Source 15, delivered Appendix A.

Symbol	Meaning
X, M	Horizontal product group and its cardinality.
T, n	Vertical group and its cardinality.
V, q	Value group and its cardinality.
B_x, b_x, β_x	Horizontal fibre, its size (or mass), and its normalized density.
β, ρ_3	Mean fibre density and mean cubed fibre density.
$R_d, R_d(h)$	Respected d -arrangements, globally and at a fixed side vector.
C, C_h, C_x	R_1 and its side-vector and vertical-fibre decompositions.
Γ	Cubic cap $\sum_x b_x^3$.
a_d, χ	Counts normalized by $M^{2d+1}n^{2d-1}$ and M^3n .
$Q(A)$	Unlabelled parallel axis-cube-pair count in A .
e_k, u_k	$2k4^k$ and $8 \cdot 2^k$, the two product-property exponents.
$\mathcal{D}_d$	Relative defect $R_d C^{d-2} / R_2^{d-1} - 1$.

Table V.62.2: Executed finite checks. Counts refer to cases, not to individual assertions within a case.

Family	Cases
Exhaustive nonempty horizontal subsets	1,036
Additional positive-deficit stability certificates	2
Random indicator arrangement domains	48
Constant-label coupling tests	48
Rational vertex-weight domains	12
Sharp subgroup moment model	1
Exhaustive binary label maps on $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/3\mathbb{Z}$	64
Additional random label maps	48
Multiadditive composite-modulus label models	4
Exhaustive partial-domain joint-extremizer cases	6,560
Additional ternary joint-extremizer cases	180
Exact rational spectral-stability cases	320
Integer exponent comparisons	84
Floating-point Fourier identity cross-checks	13

The script also checks the unbalanced-fibre counterexample and the diagonal subgroup counterexample. All random choices are deterministic from the recorded seed. No external mathematical package or network service is required to reproduce the checks.

V.63 Source pin and proof-status boundaries

Source 15, delivered Appendix B.

The repository was inspected at the immutable commit

9ea383e9b28d885a936d5d681cd5584fffd2cb29.

The supplied paper TeX has blob identifier

41085a0efde8c1932e86e80c791984f52841c22e.

The consulted original PDF has printed Lemma 14.7 and Lemma 14.8 on page 560; the arrangement definition appears on page 559. The repository’s Section 14 definition file was inspected separately because its repaired exponents differ from the printed statements. The exact URLs, blob identifiers available for the inspected files, and access date are recorded in `provenance.json`.

The package contains a mathematical manuscript, compiled PDF, executable finite verification, and an integration plan. It does not contain a new compiled Lean proof, a patch pushed to the repository, or a proof of any new global bound for progression-free sets. Its universal conclusions rest on the written proofs, not on the finite tests or on an unperformed build.

V.64 How the refinements enter the larger argument

Source 16, delivered Section 9.

The three improvements affect different interfaces, and their quantitative information should be kept separate until an actual composition is justified.

V.64.1 From a local phase to a smaller cyclic model

For a cell Q of upper size U , a lower bound

$$\mathcal{C}_{k+1}(\mathbf{1}_Q g) \geq \beta U^{k+2}$$

translates, under a cube-preserving identification with a subset of a new cyclic group of order p' , into

$$\|g_Q\|_{U^{k+1}}^{2^{k+1}} \geq \beta (U/p')^{k+2}. \quad (9.1)$$

This formula is only a normalization identity once the identification preserves all cubes being counted. The existence of a suitable identification and the avoidance of wraparound must be proved for the chosen interval model.

Theorem F.21.1 supplies larger cells than the short-cell implementation in the source proof. Their maximum remains a controlled multiple $3km$, so the scale change is explicit. Whether a later step benefits from the improved factor requires substitution of this upper size into (9.1) and into all polynomial partition thresholds. The active-pattern theorem, Proposition IV.14.2, provides an alternative when exact preservation of the earlier scale is more important.

V.64.2 From affine spectra to local linearity

The moving-frequency condition $|(a_i h + b_i) d_Q|_N \leq \delta N$ places the actual progression step in the corresponding Bohr constraints. The certificate theorem constructs that condition directly. It can therefore be inserted at an interface which requires small frequencies times the step, without first converting a quadratic diameter statement.

The uniform recurrence threshold in (6.5) must still be discharged after the number q of affine pieces has been chosen. In the source, q can itself be a very large function of the density parameter. An improvement from exponential to quadratic dependence on q in the local exponent is substantial, but it is not a calculation of the complete final bound.

V.64.3 From exact cube coefficients to inverse information

The low-order cube formulas identify which small vertex configurations create the first terms of a balanced perturbation. They allow precise bookkeeping of low-dimensional Fourier structure inside a higher cube. They also show where torsion enters: order two already affects the fourth term, and order three adds new fifth-order configurations from dimension four onward.

Turning this information into an improved inverse theorem requires control of the remainder and a mechanism extracting useful structure from the relevant Fourier expressions. The coefficient identities alone do not provide that mechanism. They do provide exact targets against which a proposed inequality or a formal expansion can be checked.

V.65 Source fidelity and a formalization plan

Source 16, delivered Section 10.

V.65.1 What was actually inspected

The repository snapshot identified in Section F.21 reports 98 exact companion proofs and 22 open catalogue statements, with a separate axiom audit [84]. *[6 October 2026; sources 15–20] Stale since the pin:* at HEAD 0b4890a1c the ledger records 101 exact companions and 19 open statements (lemma_16_9, lemma_13_8 and lemma_13_7 have closed since dca9f0638), and FORMALIZATION_ST ATUS.txt reports 233 modules and 2,138 audited public theorems (169 and 1,658 at the pin). Those are the repository’s recorded checkpoint results; this report does not claim to have rerun that Lean build. The status file also distinguishes repaired signatures and conditional implications from full source-fidelity claims.

The following files are particularly relevant to the new work:

- `Sections17_18.lean` gives the explicit partition uniformity normalization and the statement of Proposition 17.7.
- `Proofs17Phase.lean` contains the polarization and phase-twisting infrastructure.
- `Proofs17LocalizedPhaseRemoval.lean` contains the existing carry-pattern implementation of the local step. *[6 October 2026; sources 15–20]* It is the proof of `proposition_17_7_holds` (line 2900), an exact companion at the pin and at HEAD (note in Section F.21); its small

branch is the private `prop177_small_branch` (line 1283), the argument of this source’s small case. The polarization (3.2) is the private `powersetDifference_pow` and the phase (3.1) the private `polarizationPhase` (`Proofs17Phase.lean`, lines 142 and 217), used by `lemma_17_1_holds` (line 374).

- `Proofs13QuadraticRecurrence.lean` isolates the Section 13 transport and weighted selection interface, including documented scale and endpoint issues.

These source observations motivated the exact $l + 1$ normalization, the properness conditions, and the explicit separation of finite certificates from external existence thresholds.

V.65.2 Suggested theorem boundaries

A formalization can be divided into reusable finite statements.

1. **Cyclic window geometry.** Construct the sets S_t in the enlarged cyclic group, prove their two possible cardinalities, prove the exact coverage count (4.4), and prove that each family of equally spaced centers gives a partition. No Fourier analysis is needed here.
2. **Phase-independent localization.** State Theorem IV.13.2 for arbitrary functions f_ϵ and an explicitly supplied polarization identity. This avoids coupling the geometric theorem to a factorial argument.
3. **Polynomial synthesis.** Prove (3.1) and the formal coefficient criterion. Over $\mathbb{Z}/N\mathbb{Z}$, keep factorial divisibility as a named hypothesis instead of hiding it in simplification.
4. **The exact certificate algorithm.** Formalize Theorem I.30.2 from a supplied s . The required operations are residue partitions, interval chunks, rectangular pigeonhole, and a triangle inequality in $\mathbb{R}/\mathbb{Z}$. The recurrence theorem can then be attached as a separate imported interface.
5. **Small cube configurations.** Represent cube vertices as Boolean functions, classify four- and five-element supports, and combine finite Fourier orthogonality with the integer relation modules described in Section III.39.

Kernel checking would certify these local implications. It would not automatically certify that a new final Szemerédi exponent follows from the existing higher-dimensional structural chain. The latter needs a separate theorem with all numerical hypotheses and model changes visible in its type.

V.66 Reproducible computations and their role

Source 16, delivered Section 11.

The archive contains three verification programs and their recorded output. They use small cases to challenge the algebra and geometry; the proofs in the preceding sections establish the general results.

Program	What is checked
<code>verify_localization.py</code>	Finite cyclic support containment, cyclic partitions, phase signs, exact interval cube counts, and direct localization inequalities.
<code>verify_partitions.py</code>	An exact rational recurrence certificate, full coverage by the constructed cells, cell lengths, and every resulting step inequality.
<code>verify_cube_coefficients.py</code>	Enumeration of small binary supports and exact rational cube-polynomial coefficients in several cyclic groups.

The localization energy calculation uses floating-point complex arithmetic, with recorded numerical tolerances; its combinatorial support checks use integer arithmetic. The partition and cube coefficient checks use exact arithmetic in their stated finite examples. None of these programs is a substitute for a proof of the cited recurrence theorem, a Lean check, or an exhaustive literature search.

V.67 Further research questions and priorities

Source 16, delivered Section 12.

V.67.1 Local phase removal

1. **Determine the best retention factor at controlled cell size.** Fix $C \geq 3$, an upper size Ckm , and a lower size $m/(3k)$, and ask for the largest coefficient $c_k(C)$ for which a statement of the form Theorem F.21.1 holds. The sliding construction and the local-scale ceiling determine the leading $k \log k$ loss. Close the remaining factor exponential in k , or find a sharper obstruction.
2. **Retain cells of size $O(m)$.** Can one obtain a factor $2^{-O(k \log k)}$ while also forcing every cell to have upper size Cm for an absolute C ? The active-pattern theorem preserves the short-cell scale, but still contains a global pattern count.
3. **Optimize nonuniform windows.** The present partitions use equal real widths. Input increments with unequal side lengths suggest anisotropic displacement budgets, and input energy concentrated away from extreme increments may permit smaller windows. A useful theorem would retain all weights through the localization step.
4. **Extend the polarization interface.** Theorems IV.12.2 and IV.12.4 settle the formal coefficient test and the classical prime-field functional test. Investigate corresponding localization theorems for nonclassical torsion-valued phases, stating their target groups and degree conventions explicitly.

V.67.2 Partitions controlling their own steps

5. **Close the dimension gap.** For equal powers, the sufficient exponent is of order q^{-2} , whereas Theorem I.31.1 permits at most order q^{-1} . Can a universal partition theorem attain c/q ?

6. **Determine the anisotropic feasible region.** Is the strict interior of $(q + 1)a + 2 \sum_i b_i \leq 1$ sufficient, perhaps with logarithmic losses? The present work proves necessity and a smaller sufficient region, not equivalence.
7. **Use the weight during construction.** A weighted extraction of one useful progression might beat the full-partition obstruction. Develop a direct weighted theorem suited to the arrangement counts in Lemma 13.5.
8. **Measure the effective spectrum dimension.** Find structural hypotheses ensuring that the moving slopes lie in a low-dimensional bounded-height integer span. Combine such a result with Corollary I.30.8.
9. **Make thresholds numerical.** Track the constants in a simultaneous recurrence theorem well enough to replace $X_0(C, q)$ by an explicit computable bound. Alternatively, formalize a certificate-producing finite algorithm and compare its actual performance with the worst-case existence theorem.

V.67.3 Cubes and the full quantitative induction

10. **Classify sixth-order supports.** Determine the relevant primitive relation modules for six Boolean vertices in arbitrary dimension. The fourth- and fifth-order calculations suggest a systematic classification by small integer matrices and their torsion quotients.
11. **Control the higher-dimensional remainder sharply.** The remainder estimates supplied by repeated Gowers–Cauchy–Schwarz are uniform but rarely optimal. Determine sharp dependence on lower Gowers norms, the density, and the torsion profile.
12. **Find extremizers and stability statements.** The coefficient formulas identify equality mechanisms at low order. Which functions nearly maximize the complete higher-dimensional cube polynomial under fixed lower-order norm constraints?
13. **Propagate the local gains through the complete proof.** Substitute the new partition scale and recurrence thresholds into the structural, localization, remodeling, and density-increment steps. Prove the resulting numerical recurrence before claiming an improvement to the final Szemerédi bound.
14. **Build a kernel-checked local refinement package.** Start with the finite certificate theorem and sliding-window geometry. They have explicit finite statements and avoid the currently open global dependencies. Then add the exact cube coefficients and a separate source-fidelity audit.

V.68 Conventions for reproducibility and citation

Source 16, delivered Appendix A.

The article is self-contained at the level of its new finite proofs. The mixed cube inequality is the standard Gowers–Cauchy–Schwarz inequality; the modern simultaneous recurrence theorem is cited as an external result. The supplied code records finite checks and can be rerun independently.

The files in the archive are:

- this article in L^AT_EX and PDF;
- the three verification programs and their output;
- the plot source, its formula-based comparison table, and the figure;
- a README with build and verification commands.

The source repository is referenced at a fixed commit so that a later change to its formalization status or statement repairs does not silently change the meaning of this report.

V.69 Relationship with the inspected Lean development

Source 17, delivered Section 9.

V.69.1 Snapshot and relevant interfaces

The repository inspection was anchored to commit

dca9f06383ccdfc2ed208ccb7c9882214fdb09ac.

The relevant directory is

Combinatorics/Ramsey/Lean/GowersSzemerédi.

The statements in `Sections08_09.lean` use `phiAdditiveTupleCount`, `additiveTupleCount`, `GammaAdditive`, and `GammaHomOfOrder` [85]. The inspected `Proofs09Moments.lean` proves the graph Fourier-moment identity and then Lemma 9.2 [86]. The restriction module imports `Proofs15Restriction` and presents Lemma 9.3 through the height-zero arrangement interface [87]. These are source observations, not claims that the entire repository was rebuilt during preparation of this note.

V.69.2 A particularly small first change

The existing proof of `section9_second_moment_1e` first obtains

$$\sum_{u,r} |\hat{f}_u(r)|^2 = N^2 |B|$$

and only then uses $|B| \leq N$. [6 October 2026; sources 15–20] `section9_second_moment_1e` is a private lemma (`Proofs09Moments.lean`, line 480); the equality $N^2 |B|$ is a step inside its proof, and the fourth and sixteenth moment identities exist only inside `lemma_9_2_holds` (line 527). The first formalization task is to expose the equality as its own reusable lemma. Combining it with the existing fourth- and sixteenth-moment identities should give the division-free target

$$G_{16}(B, \phi) |B|^6 \geq G_4(B, \phi)^7. \quad (\text{V.69.1})$$

The division-free form also behaves cleanly for $B = \emptyset$. For nonempty B , it is exactly the $r = 8$ case of Proposition II.59.1.

V.69.3 The all-moduli interface is a real difference

In the inspected statement, `lemma_9_3` quantifies over $N : \text{Nat}$ with `[NeZero N]`, without a primality assumption. The new cyclic theorem is for prime N . It is a quantitative strengthening in the paper’s prime setting, but not a proof of the repository proposition with only its numeric bound changed. A safe addition is a separate prime-modulus theorem with an explicit characteristic and size interface. The old theorem need not be overwritten.

V.69.4 A staged formalization plan

A useful dependency order is as follows.

1. Expose the exact graph second moment and prove (V.69.1); then generalize the moment inequality in finite abelian groups.
2. Define the finite Fourier coefficients of K_L , prove their nonnegativity, establish $0 \leq K_L \leq 1$, and prove the finite coefficient identity and the bound on $S_{m,L}$.
3. Define bounded affine degeneracy, prove the rank-two fiber count, and derive pairwise distinctness of generic tuples.
4. Formalize conditional product sampling only for distinct points, then prove the exact good/bad probabilities.
5. Prove the signed-expectation extraction lemma independently of Fourier analysis and instantiate it with the exceptional-set bound.
6. Separately formalize the augmented-column rank calculation and the fixed-characteristic system theorem.

No uncompiled proof script is presented as a certified theorem in this package. In particular, the current package contains no Lean module with an implicit or explicit admission disguised as a completed proof.

V.70 Finite audits and reproducibility

Source 17, delivered Section 10.

The package includes `verify.py` and its generated `verification_results.json`. The exact tests use integer arithmetic and rational numbers; NumPy, when available, supplies an additional independent numerical phase-average check. The random seed is 20261006.

The direct phase checks had maximum absolute discrepancy less than 2.1×10^{-17} from the exact rational answers. In the full enumeration of additive quadruples in $\mathbb{F}_2^2$, there were 64 tuples, of which 40 were affine-degenerate; the projective union bound was 48. The repeated-point example in Section II.64 is also checked exactly.

The graph tests include all nonempty partial maps from $\mathbb{F}_3$ to $\mathbb{F}_3$, deterministic random partial maps over $\mathbb{F}_5$ and $\mathbb{F}_7$, and explicit affine equality cases. Higher energies are computed by iterating exact convolution of the graph counting measure and summing squares of the resulting representation counts. This is independent of the Fourier-interpolation proof.

Check performed	Number
Exact Fejér signal lower and upper bounds	1016
Finite graphs inspected	587
Exact graph moment inequalities, orders 2 through 8	4109
Exact equality classifications, orders 3 through 8	3522
Exact generic good/bad Fourier survival identities	48
Independent direct averages over all phase parameters	16
Exhaustive scalar-linear-functional rank checks	96

Table V.70.1: Audits completed for this manuscript. Counts are script outputs.

These finite computations test normalizations, powers, equality cases, rank formulas, and collision handling. They do not certify the large parameter theorem, whose proof is the preceding sequence of lemmas. The general weighted theorem and arbitrary-system rank-gap corollary are supported by their written proofs, not by a claim of exhaustive computational verification over their infinite parameter ranges.

To reproduce the computations and build the document:

```
python3 verify.py
pdflatex -interaction=nonstopmode -halt-on-error article.tex
pdflatex -interaction=nonstopmode -halt-on-error article.tex
```

A third LaTeX pass can be used if the local installation requests an additional cross-reference update. The supplied `build.sh` performs three passes.

V.71 Further research questions and proposed directions

Source 17, delivered Section 11.

1. The actual extremal restriction exponents. For prime cyclic groups, determine the largest guaranteed size of a subset on which $1 - \eta$ of the m -term relations are respected, as a function of the absolute relation parameter α . Does one need losses of order $\alpha^m \eta^{m-1}$ in tuple count? Proposition II.62.2 settles only a scalar proof template. A matching extremal construction, or a stronger unrestricted theorem, would distinguish the method's cost from the phenomenon itself.

2. Reducing the ambient-size threshold. The union bound pays for every bounded affine degeneracy as though it survived with probability one. A rank- or multiplicity-stratified estimate of its actual survival should be tested. Can the degree $2m - 1$ in $(\alpha\eta)^{-1}$ in (F.22.5) be reduced while preserving the retention powers? This would make the present theorem substantially less asymptotic.

3. An extremal filter problem. For a prescribed mean q and degree D , maximize $\sum_n |\hat{h}(n)|^m$ among $0 \leq h \leq 1$. The Fejér filter gives a transparent feasible point, while Lemma II.62.1 gives a universal ceiling. Identifying exact or asymptotically optimal filters could improve the constants and the degree needed before controlling exceptional tuples.

4. Composite cyclic moduli. Develop a replacement for bounded affine genericity that records the Smith normal form or the relevant greatest common divisors of coefficient minors. The goal is a theorem with explicit dependence on torsion, not an unjustified carry-over of field fiber counts. Such a theorem would match the all-moduli Lean interface more directly.

5. The higher arrangements of Sections 12 and 15. Compute the complete short-relation lattice for the configurations used in the later stages of Gowers’s proof, then evaluate a Fejér-type filter on that lattice. A successful extension must control every additional relation class, not only a distinguished balanced relation. This is the specific missing step before the present local improvement can be propagated through the main induction.

6. Preserve chosen spectral information while restricting. Impose auxiliary lower bounds on selected Fourier coefficients, or on Fourier energy over a prescribed set of characters, during extraction. The signed objective could be augmented by Lagrange multipliers, but one must show that its expected margin remains positive. This targets the compatibility issue that motivates the transition from Section 9 to the more delicate later arguments.

7. From approximate relations to exact structure. Under the new retention bounds, determine when a further restriction can be made an exact Freiman homomorphism of the same order without losing the prescribed spectral data. A comparison should separate the cost of obtaining a high respected proportion from the cost of making it exact. Ordinary energy extraction alone does not preserve every additional constraint needed downstream.

8. Exploit the entire error-rank distribution. The certificate (II.63.8) is a polynomial in q whose coefficients are the rank profile. Study inputs where most, but not all, unrespected tuples have high error rank. A useful theorem might combine a small exceptional low-rank tail with the improved exponents in Theorem II.63.5, rather than assuming a uniform rank gap.

9. Efficient certification and extraction. Find algorithms for estimating the signed objective and the exceptional mass without enumerating all tuples. Convolution and fast Fourier transforms can evaluate several unweighted counts, but repeated entries, conditional Bernoulli choices, and vector-valued graph data must be handled correctly. The desired output is a runtime theorem as well as an existence theorem.

10. Certified optimization in Lean. After formalizing the exact-data certificate, allow L to be chosen by a verified finite search using exact rational values of $S_{m,L}$. This would avoid freezing the convenient but nonoptimal choice $L = \lceil (m+1)/(\alpha\eta) \rceil$ in every application. The certificate is a suitable interface between computation and the structural mathematical proof.

V.72 Conclusion

Source 17, delivered Section 12.

A high-degree positive Fourier filter can replace the tiny distinguishing advantage of repeated degree-one filters. For the single balanced relation, this yields a fully explicit restriction theorem with

losses $\alpha^m \eta^{m-1}$, including all repeated and degenerate tuples in the final count. Exact second-moment bookkeeping independently removes an unnecessary density factor from the input obtained from additive energy.

The fixed-characteristic analogue reveals the more general organizing quantity: the increase in rank when the graph coordinates are appended to a configuration. Its full rank-profile certificate and rank-gap corollary provide a systematic extension beyond a single equation. The remaining work is concrete: improve the treatment of exceptional tuples, understand optimal filters, and analyze the actual relation lattices of the higher configurations before making any global claim.

V.73 A compact proof-dependency map

Source 17, delivered Appendix A.

The proof of the prime-cyclic estimate depends on the following chain:

The moment inequality is independent of this chain and supplies a stronger input. The finite-field systems theorem uses the same signed objective but replaces Fourier coefficients by the rank of augmented columns. Neither proof imports a later section of Gowers’s argument.

V.74 Source provenance and claim ledger

Source 17, delivered Appendix B.

Item	Status and source
Printed target	Gowers, Lemmas 9.1–9.3 and Corollary 9.4, pp. 515–518. The original PDF pages were visually inspected; the repository’s TeX transcription was also read.
Repository snapshot	Commit <code>dca9f06383ccdffc2ed208ccb7c9882214fdb09ac</code> . The relevant statement and moment-proof source ranges were inspected. No whole-repository build was performed.
Moment inequality	Standard interpolation argument, reproved with exact mass and its unweighted equality classification. Not claimed as a new general principle.
Fejér restriction	Quantitative refinement established in this note by the displayed proof. Bibliographic priority is not established.

Item	Status and source
Weighted extension	Included in the main theorem and its proof. Its hypotheses concern weighted initial tuple counts; its conclusion is an ordinary subset.
Finite-field systems	Written proof via augmented-column rank, with explicit genericity, threshold, and error-rank hypotheses.
Method limitation	An upper bound on the scalar signed-expectation certificate only; not an impossibility theorem for general extraction.
Computations	Exact finite audits and a separate numerical phase check. No inference of universal validity solely from experiments.
Formal verification	Not performed for the new results. A dependency-level integration plan is given instead of an unverified claim of completion.
Global bounds	No new global Szemerédi bound claimed. Later arrangement analysis and a complete quantitative induction remain separate tasks.

V.75 Quantitative consequences and limits of substitution

Source 18, delivered Section 6.

The preceding results improve different numerical quantities. Keeping those quantities separate makes their mathematical significance easier to assess. Table V.75.1 records the direct consequence of each part.

Source component	Proven replacement	Direct effect
Lemma 15.4	Exact leading coefficient $k+C_d$, with explicit second-order error	A sharp asymptotic and a smaller finite exceptional-set bound
Lemma 15.5	$\lambda p \geq k + 2\,585\,445$ suffices in the stated parameter range	A smaller ambient-prime threshold; the retention exponent stays fixed
Lemma 3.10	Complete degree-four and degree-five cube coefficients	A tighter cube-count upper estimate, with all small-torsion contributions visible
Lemma 5.9	Simultaneous induction in degree through a recurrence radius	Polynomial dependence on the number of phases in the exponent, using the cited modern input
Quadratic specialization	Shared leading frequency, arbitrary lower slopes	Linear dependence on q in the reciprocal exponent, using the source’s scalar recurrence

Table V.75.1: The scope of the local improvements. Every replacement has its own hypotheses, as stated in the corresponding theorem.

V.75.1 Interpreting the polynomial exponents

The degree-two comparison is particularly transparent. For oscillation r^{-2a} , the old reciprocal exponent is 2^{11q+1} , the new general quadratic reciprocal exponent approaches $126q^2 + 129q + 2$, and the shared-leading-coefficient specialization gives $99q + 98$. The obstruction for unrestricted quadratic phases is $7q + 1$. These numbers are not four theorems with identical hypotheses: the shared frequency

restricts the input class, and the obstruction is a necessary condition, not a construction. The strict inequalities in the sufficient asymptotic statements absorb coefficient-independent constants.

q	Old reciprocal	General quadratic	Shared leading term	Obstruction
1	2^{12}	257	197	8
2	2^{23}	764	296	15
4	2^{45}	2534	494	29
8	2^{89}	9098	890	57

Table V.75.2: Reciprocal exponents at oscillation r^{-2a} . The middle two columns are strict asymptotic sufficient bounds, and the last column is a necessary upper limit on a for the unrestricted class.

Figure V.75.1: Comparison of the exponents in Table V.75.2 on a logarithmic vertical scale. Larger a gives longer progressions. The figure compares exponents, not the finite input sizes at which the asymptotic statements become effective.

The main analytic reason for the improvement is visible in the recurrence $E_j = (1 + js_j)E_{j-1} + 2s_j$. For fixed degree, a recurrence cost $s_j = O_j(q)$ is paid only once at each degree. The original repeated refinement pays a degree-dependent exponent once for each polynomial. This explains the change from exponential to polynomial dependence on q . It also explains the remaining gap: a direct induction multiplies the dimension cost at successive degrees, while the necessary frontier suggests that a more simultaneous treatment might avoid some of those products.

V.75.2 Why the cube estimate is a genuine upper-bound improvement

For $\delta, \varepsilon \geq 0$, the upper bound in Corollary III.40.9 is never larger than $(\delta + \varepsilon)^m$. The degree-one through degree-three terms have been removed; $B_d \leq \binom{m}{4}$ and $Q_d + S_d \leq \binom{m}{5}$, because their terms

count disjoint classes of vertex subsets; the remaining binomial terms are the same. At fixed positive density, the first possible error is of fourth order. In the source’s uniformity parameter $\alpha = \varepsilon^{2^d}$, it is of order $\alpha^{4/2^d}$.

The sharpness theorem concerns the bound over all finite abelian groups. Its extremizing sequence lives on increasingly large elementary abelian two-groups. It does not settle the best coefficient after excluding two-torsion, nor does it classify all nearly extremizing sets. The exact formula, which separates E_2 from the ordinary fourth Fourier moment, provides information that can be used to investigate those sharper questions.

The fifth coefficient has no fixed sign. Treating it as an error requires an absolute value or a bound on its magnitude. Its explicit spectral form can be more useful when the Fourier support is known: absence of doubling relations can suppress T_5 , and absence of order-three characters removes E_3 . The remainder bound remains valid without either simplification.

V.75.3 What a full quantitative propagation would require

A new global quantitative theorem would require a closed parameter audit through the later structural and phase-removal steps. In particular, one would have to track how a changed ambient-size threshold affects every recursive call, how a new simultaneous polynomial partition is invoked inside common-difference boxes, and how the resulting widths and retained densities survive the final density iteration. An exponent improvement in one partition lemma cannot be inserted into an unchanged downstream formula without checking those dependencies.

The arrangement improvement has a particularly clean local interface: the Riesz-product proof uses the exceptional-set estimate only to absorb degenerate arrangements. Section II.66 redoes that absorption explicitly. The cube expansion is also independent of any inverse theorem. These two components can therefore be reused immediately as standalone lemmas. The polynomial transfer has an explicit analytic interface, but the general numerical exponent quoted from Lau’s preprint remains dependent on that input [73].

V.76 Relation to the Lean development

Source 18, delivered Section 7.

The repository inspection was pinned to commit

`dca9f06383ccdfc2ed208ccb7c9882214fdb09ac`.

The selected Lean files read during this work have matching blob identifiers in that commit. [6 October 2026; sources 15–20] The degeneracy predicate is `GeneralArrangement.IsDegenerate` (`Sections14_15.lean`, line 354, at HEAD `0b4890a1c`); `lemma_15_4` and `lemma_15_5` (lines 402 and 414) have exact companions (notes after Theorem II.66.8 and Corollary II.66.9); `lemma_5_9` (`Section05.lean`, line 261) and `lemma_3_10` (`Sections01_03.lean`, line 340) also have exact companions. None of this source’s statements is formalized. The paper source was read as blob `41085a0efde8c1932e86e80c791984f52841c22e`. The accompanying provenance file records the exact paths and identifiers. No repository changes were made as part of preparing this report.

The arrangement refinement uses the existing definitions. `GeneralArrangement` stores the shared side vector, cube bases, and cross-sections. Its degeneracy predicate quantifies over all coordinate

monomials, which is precisely the stronger definition used here. Thus the new proof does not need a change to the meaning of degeneracy. It needs a stronger counting theorem for that predicate.

Inspected component	Role in a possible implementation
<code>Sections14_15.lean</code>	Supplies <code>GeneralArrangement</code> , <code>arrangementMoment</code> , the full degeneracy predicate, and the current statements of Lemmas 15.4 and 15.5.
<code>Proofs15DegenerateArrangements.lean</code>	The current proof separates zero sides from coefficient cases. The refined proof would replace its single-polynomial fibre estimate with the paired affine-rank bound.
<code>Proofs15Walsh.lean</code>	A starting point for the Boolean moment transform and the characterization of parity by vanishing proper moments.
<code>Proofs15LevelSets.lean</code>	Proves the general multilinear level-set estimate. The refined arrangement argument bypasses this estimate for nonparity certificates by exhibiting explicit affine minors.
<code>Sections01_03.lean</code>	Records the uniformity and cube-count statements whose normalizations must be respected.
<code>Proofs03CubeUpper.lean</code>	The current Lemma 3.10 proof uses Minkowski's inequality. The new expansion would be a separate stronger theorem proved from finite sums, Fourier orthogonality, and cube Cauchy–Schwarz.
<code>Section05.lean</code>	Contains the polynomial-partition statements. A recurrence-radius premise provides a clean interface for checking the elementary degree-descent argument independently of its analytic input.

For cube norms, the article uses normalized averages. The source's unnormalized quantity differs by the factor $|G|^{(d+1)/2^d}$. Equivalently, the 2^d -th power of the source norm is $|G|^{d+1}$ times the normalized cube moment. Recording that equality once would prevent repeated normalization errors in later statements.

An economical implementation order is: first the Boolean moment inversion and the two affine-rank counting lemmas; then the single-certificate bound; then certificate equivalence and its finite class count; finally the sharp hyperplane count and the absorption corollary. A simpler finite theorem with a larger coefficient could be checked before the exact combinatorial count C_d is implemented. In the cube part, the universal finite Fourier kernel identity should precede the classification of small matrices. For partitions, the two elementary integer decomposition lemmas and the degree-descent transfer can be formalized with recurrence as a named hypothesis.

The new theorems in this report are mathematical proofs, not newly checked Lean declarations. The inspected source establishes the integration points; it does not certify the results written here. No Lean compilation of these additions is claimed.

V.77 Exact finite verification and reproducibility

Source 18, delivered Section 8.

The accompanying `verify_refinements.py` uses only the Python standard library. It checks finite consequences of the proofs with exact integer and rational arithmetic. The program is

corroborating evidence and a reproducible way to inspect the constants; the general arguments above remain the proofs.

The following checks passed:

1. All $\binom{16}{4} + \binom{16}{5} = 6188$ four- and five-vertex subsets of the four-dimensional cube were classified by rank over suitable finite fields. The counts were 100 ordinary rectangles, 40 extra binary planes, 160 ordinary five-circuits, and 16 extra ternary configurations.
2. Fourth and fifth coefficients were computed directly by expanding the product over every cube, for dimensions three and four on cyclic groups of orders 2, 3, 4, 5, 6, 7. All twelve test cases agreed with the formula, including groups with two-torsion, three-torsion, both, and neither.
3. Pure-parity hyperplanes were enumerated independently for $d = 2$ at $p = 5, 7$, for $d = 3$ at $p = 7, 11$, and for $d = 4$ at $p = 11, 101$. The resulting counts were $C_2 = 4$, $C_3 = 51$, and $C_4 = 484$, as predicted.
4. Ternary certificate classes modulo affine equivalence were enumerated at sizes 2, 4, 6, 8, giving 1, 25, 301, 3025. These agree with $(3^n - 2^{n+1} + 1)/2$.
5. The exceptional-diagonal probability for the sharp nonparity certificate was computed exactly for $d = 2$ and $p = 5, 7, 11$. The values $29/625$, $55/2401$, and $131/14641$ agree with $p^{-2} + (p - 1)p^{-4}$.
6. Every binary square matrix of sizes two, three, and four was enumerated. The maximum absolute determinants were 1, 2, 3, consistent with the independent Hadamard-bound proof.

As a concrete check of the order-three correction, on $\mathbb{Z}/3\mathbb{Z}$ take $f = (2, -1, -1)$ and cube dimension four. The fourth coefficient is 200 and the fifth is 352. Omitting the sixteen ternary configurations would give a fifth coefficient of 320, so this test detects a real failure of the torsion-free formula in characteristic three.

To reproduce the checks, run

```
python3 verify_refinements.py --output verification_results.json
```

To rebuild the article, run `pdflatex` twice on the supplied main `.tex` file, keeping `partition_exponents.pdf` beside it. The supplied source is self-contained apart from that included figure and standard L^AT_EX packages; its bibliography is embedded.

V.78 Further research questions and proposed next steps

Source 18, delivered Section 9.

The following questions arise directly from the proofs. They distinguish well-defined improvements to these local statements from the much larger task of improving global Szemerédi bounds.

1. **The second degeneracy coefficient.** Determine the coefficient of p^{-2} in the count of degenerate d -arrangements, initially for $d = 2$ and small k . The first-order proof shows what must be included: intersections of the leading hyperplanes and the nonparity loci of codimension two. A

satisfactory answer should identify any exceptional primes, rather than fitting a polynomial to a few counts.

[write] **6 October 2026; sources 21–27.** *Answered for $d = 2$ by source 27’s Theorem F.32.3: $(k^2 + 21k - 6)/2$ for characteristic $p > 4 \cdot 2^k$, with the exact count for $k = 1$ in characteristic at least 11 (exceptional characteristics 2, 3, 5, 7); general d is reduced to the statistic $b_{2,d,p}$ (its Corollary II.99.2). Item II.38.*

- 2. Distinct nonparity loci.** The coefficient $A_{2d2k} - A_{2d}$ counts certificate classes, including many with impossible or identical solution sets. Classify the simplest additional equivalences between the resulting algebraic loci. Even a systematic bound for the certificates of lowest moment order $k - 1$ would improve the explicit second-order error.
- 3. The full moment-order distribution.** Use the parameter $t = k - m$ in Lemma II.66.2 instead of replacing all costs by their $t = 1$ upper bound. This requires counting ternary functions with specified vanishing Boolean moments. A first milestone is an exact enumeration for $k \leq 4$, followed by a structural inequality valid for general k .
- 4. The balanced-subset hyperplane arrangement.** Determine its intersection lattice and characteristic polynomial. The number of hyperplanes is already C_d ; understanding their intersections would give the exact pure-parity degeneracy probability for all sufficiently large primes and would contribute to the preceding second-order problem.
- 5. Small primes and one-arrangements.** Treat $p \leq 2d$ by counting balanced ternary vectors modulo p , and treat $d = 1$ separately. The diagonal cross-section event then has different size, so the p^{-2} conclusion for nonparity certificates cannot simply be retained. In characteristic three, affine symmetries of the ternary alphabet also change the quotient count.

[write] **6 October 2026; sources 21–27.** *Partly answered.* For $d = 1$ the leading coefficient is $(k^2 + 3k)/p$ (source 22’s Theorem II.85.1); the first-order count for small p is source 27’s Theorem II.96.3, with $L_{d,p}$ from its Theorem II.95.1, including characteristic three. Item II.38.
- 6. Sixth and higher cube coefficients.** Extend the small-matrix classification to six vertices. New affine dependence dimensions and new integer invariant factors must be tracked; a list of rational circuits alone will not suffice over all finite groups. The desired output is an exact formula with a remainder bound, not only a numerical enumeration of one cube dimension.
- 7. Sharp coefficients on odd-order groups.** Determine the best fourth-order coefficient when order-two characters are absent, especially in dimension four. The universal B_d sharpness construction does not answer this question. A likely useful subproblem is an optimal comparison between a real mean-zero function’s U^2 and U^d norms under the relevant group restrictions.
- 8. Stability of cube-count sharpness.** If a sequence nearly attains B_d , what must its low-order Fourier spectrum look like? The separate nonnegative terms V_4 and E_2 make this a more structured problem than the corresponding triangle-inequality equality case. Distinguish weighted functions from indicator sets in any stability statement.
- 9. The general quadratic partition gap.** Can the sufficient reciprocal exponent be reduced from order q^2 to order q ? The obstruction is $7q + 1$ at error exponent $2a$. One should first decide whether flexible lengths and the stronger $v - 1, v$ requirement have the same asymptotic frontier.

10. **Eliminate several degrees in one step.** The transfer handles the leading coefficients simultaneously, but then repeats the process for lower degrees. Find a recurrence formulation that also controls the coefficients created by translation. The shared-leading quadratic corollary supplies a useful test family in which the number of genuinely independent top frequencies is much smaller than the number of polynomials.
11. **Coefficient-rank profiles and explicit constants.** Develop a theorem in which each degree has its own bounded integer span of frequencies, and compute the resulting sequence of recurrence costs. In parallel, extract fully numerical recurrence constants where possible. An exponent with an uncontrolled starting threshold is valuable asymptotically but insufficient for concrete finite comparisons.
12. **A complete formal and quantitative substitution.** Implement the elementary lemmas in Lean, then trace their use through the remaining proof with explicit parameter interfaces. The first deliverable should be a checked replacement for the Lemma 15.5 threshold and a checked conditional polynomial-partition transfer. A global quantitative claim should follow only after every later width, density, and ambient-size condition has been verified.

V.79 Source record and attribution

Source 18, delivered Appendix A.

The research request identified two paths in <https://github.com/VladimirReshetnikov/ProveIt>:

```
Combinatorics/Ramsey/Papers/sz-thm-gowers-proof
Combinatorics/Ramsey/Lean/GowersSzemerédi
```

The published PDF was also consulted through the University of Maryland mirror listed in the bibliography. The paper reconstruction is useful for searching and for seeing explicit source corrections; the article does not silently identify all edited formulations with the printed 2001 text.

The core derivations were cross-reviewed independently within this task. The analytic inputs are credited where used, and the computational files record only finite checks. This division is deliberate: a numerical experiment cannot prove the general rank theorem, and an uncompiled Lean sketch would not constitute kernel verification.

V.80 Source audit and the boundary of the Lean integration

Source 19, delivered Section 7.

The mathematical improvements in this article concern a finite sampling and interpolation step in the proof of Gowers’s Lemma 16.10. The following audit distinguishes the original published paper, the edited transcription in the repository, the propositions currently stated in Lean, and their available proofs. The repository snapshot is commit `dca9f06383ccd2ed208ccb7c9882214fdb09ac`. The source checks below are read-only inspections at that commit; a new Lean build was not run for this article.

V.80.1 Published argument versus the edited transcription

In the original paper, Lemma 16.10 and its proof occupy printed pages 574–575. The relevant finite step starts with, in each fibre, at most q classes on which the function is affine in the last coordinate. The proof uses $r = \lceil q\sigma^{-2} \rceil$ random coordinates and seeks two distinct sampled points in each retained class [1]. The edited repository transcription places Lemma 16.10 at line 3459 and retains this sampling step, while adding warnings about the closing parameter comparison [89].

There is a precise distinction between two sample hits and two distinct sampled coordinates. For independent sampling with replacement from an n -point set, a class of size s has fewer than two distinct sampled coordinates with probability

$$s \left(1 - \frac{s-1}{n}\right)^r - (s-1) \left(1 - \frac{s}{n}\right)^r, \quad s \geq 1. \quad (\text{V.80.1})$$

Indeed, the event consists of no hit, together with the disjoint events that the unique sampled member of the class is each of its s possible points. In contrast, the binomial expression $(1-u)^r + ru(1-u)^{r-1}$ bounds fewer than two hits counted with multiplicity. It does not, without another argument, bound the event in (V.80.1). A singleton class always fails the requirement of two distinct points, regardless of the sample size.

For a uniformly chosen r -element subset, where $0 \leq r \leq n$, the corresponding probability is instead

$$\frac{\binom{n-s}{r} + s \binom{n-s}{r-1}}{\binom{n}{r}}. \quad (\text{V.80.2})$$

The conventions are that an out-of-range binomial coefficient is zero and that the population has $n \geq 1$ points. The sampling theorem of the present article uses this finite-population model and the more general recovery condition $|R \cap C| \geq \min(d, |C|)$. The latter allows a fully sampled small class to be represented by a lower-degree interpolant. Thus neither repeated coordinates nor singleton classes are silently treated as a pair of distinct interpolation nodes.

V.80.2 The closing graph budget: two different source formulas

It is essential to retain a dimensional distinction between the two versions of the argument. Put

$$A_j = 2^{2^{j+8}}, \quad \mathcal{Q}(t, \gamma, j) = (\gamma t)^{-A_j}.$$

These are the graph-count controls used in the repository’s `multipleC` and `multipleQ`, and agree with the displayed controls on printed page 567 of the original paper [1, 90]. Write

$$\sigma = \rho/4, \quad R = \gamma^{-2} s(2^{-(k+2)} \theta, \gamma, k), \quad p = 4r^2 R,$$

where r is the number of sampled coordinates. The original published comparison on page 575 is

$$\mathcal{Q}(\sigma/p, \gamma, k)^p \leq \mathcal{Q}(\rho, \gamma, k+1). \quad (\text{V.80.3})$$

The edited repository transcription instead uses dimension $k+1$ on the left-hand side as well [89]. These are different inequalities and should not be quoted interchangeably. [6 October 2026; sources 15–20] The printed page was not checked at the write; this is the source’s reading of the 2001 paper. The transcription carries an editorial note at Lemma 16.10 that the displayed closing comparison does not justify the lemma.

Both versions have an explicit algebraic obstruction with the displayed controls. Assume $k \geq 1$, $r \geq 1$, and $0 < \theta, \gamma, \rho \leq 1$, and set $a = \log(1/(\gamma\rho)) \geq 0$. Since $A_{k+1} = A_k^2$, taking logarithms shows that (V.80.3) is equivalent to

$$p(a + \log(4p)) \leq A_k a. \quad (\text{V.80.4})$$

In particular it fails whenever $p \geq A_k$. The displayed auxiliary parameter already exceeds that range. Indeed, with $B_k = 2^{2^{k+6}}$, the definition of s gives

$$R = \gamma^{-2} \left(\frac{2^{k+3}}{\theta\gamma} \right)^{B_k} \geq 2^{(k+3)B_k} > 2^{2^{k+8}} = A_k.$$

For the last strict inequality it suffices to observe that $B_k > 2^{k+8}$ for $k \geq 1$. Therefore $p = 4r^2 R > A_k$, and (V.80.4) fails throughout this range. This calculation concerns the stated numerical comparison, not the truth or falsity of Lemma 16.10 as a mathematical assertion.

The same-dimension comparison in the edited transcription fails even more directly: for $p \geq 1$,

$$\mathcal{Q}(\sigma/p, \gamma, k+1)^p = \left(\frac{4p}{\gamma\rho} \right)^{A_{k+1}p} > \left(\frac{1}{\gamma\rho} \right)^{A_{k+1}} = \mathcal{Q}(\rho, \gamma, k+1).$$

[write] **6 October 2026; sources 15–20.** *Certified formally since the pin:* `section16_same_dimension_closing_comparison_fails` (Proofs16ClosingComparison.lean, line 25, HEAD 0b4890a1c) proves $\text{multipleQ}(\rho, \gamma, k) < \text{multipleQ}(\rho/(4p), \gamma, k)^p$ for $p \geq 1$ and $0 < \gamma, \rho \leq 1$, this display in the Lean indexing; like this source, it is an obstruction to the displayed proof step, not a counterexample to Lemma 16.10.

Consequently, reducing the number of anchors gives a real local improvement but does not by itself justify either displayed closing comparison. One must also redesign the quantitative closure, preserve the dependence on the outer parameter, or replace the relevant structural input. The present article does not infer an improved global Szemerédi bound from the sampling improvement.

V.80.3 What the pinned Lean development establishes

At the pinned commit the machine-readable ledger contains all 120 numbered catalogue entries and records 98 exact companion proofs and 22 open statements. The repository checkpoint reports that its 169 reachable modules compiled and that its axiom audit checked 1,658 public theorems, allowing only `propext`, `Classical.choice`, and `Quot.sound` [91, 92]. [6 October 2026; sources 15–20] *Stale since the pin:* at HEAD 0b4890a1c the ledger records 101 exact companions and 19 open statements and `FORMALIZATION_STATUS.txt` 233 modules and 2,138 audited public theorems; `lemma_16_9`, `lemma_13_8` and `lemma_13_7` have closed since dca9f0638. These are the results reported by that checkpoint; they are not a new build result of this article. The audit itself explicitly distinguishes an axiom check of a conditional implication from a proof of its hypotheses.

The relevant part of the catalogue is as follows.

Statement	Status at the pinned commit
Lemma 16.3, the one-dimensional base case	Exact companion
Lemmas 16.5 and 16.6	Exact companions
Lemma 16.8, with repaired parameters	Exact companion
Theorem 16.2 and Lemma 16.4	Open
Lemmas 16.9 and 16.10	Open
Corollary 16.11	Open
Theorems 18.1 and 18.2	Open

[write] 6 October 2026; sources 15–20. *Stale row.* Lemma 16.9 is now an exact companion: `lemma_16_9` (`Section16.lean`, line 749) is proved by `lemma_16_9_holds` (`Proofs16Lemma9.lean`, line 158), added in 16bbbe5ad at 14:31 on 6 October 2026, after this source’s pin (14:17). Lemma 16.10 is still open (`lemma_16_10`, line 851), still with no related theorem in the ledger, although proved partial results exist (note after Corollary II.70.8).

In particular, `lemma_16_10` has no exact companion or related theorem in the ledger. Its two substantive inputs are stated as `FinalCoordinateSectionsMultiplyLinear` and `Section16AllBoxLineCovers` [90]. The first gives multiple multilinearity of each section at a fixed final coordinate, with iteration parameter

$$\gamma^{-2}s(2^{-(k+2)}\theta, \gamma, k).$$

The second packages the line covers and width bounds intended to come from Lemma 16.9.

Several interface facts matter for an implementation. `Section16LineCover` stores at most a natural number `qGamma` of affine functions in each fibre. The separate natural number `qDelta` controls the recurrence-width loss. They have different bounds and cannot be identified without a proof. The migrated `MultiplyLinear` predicate requires proper input and output boxes and a loss parameter in $(0, 1]$. In contrast, the current `Section16AllBoxLineCovers` interface still quantifies over arbitrary boxes and does not yet carry the corresponding properness clauses. [6 October 2026; sources 15–20] *Stale:* at HEAD 0b4890a1c `Section16AllBoxLineCovers` (`Section16.lean`, line 824) requires `P.IsProper`; the older unrestricted form is kept as `Section16AllBoxLineCovers_unrestricted_box_encoding` (line 806). The current signature of `lemma_16_10` also assumes only a nonzero modulus. Distinct interpolation nodes in an arbitrary `ZMod N` need not have invertible differences. A field hypothesis, a prime modulus, or explicit pairwise unit-difference hypotheses are therefore needed in the algebraic interpolation layer.

V.80.4 A practical formalization route

The finite sampling theorem should first be formalized independently of the Section 16 induction. Its natural data are a finite population, a finite family of rows, at most q disjoint classes in each row, and the uniform family of r -element population subsets. Counting pairs consisting of a sample and a class gives the hypergeometric expectation. Finite averaging then supplies an actual sample with the claimed lost mass. This stage needs finite sums and binomial coefficients; it does not need a probability-space formalization or a prime modulus.

The next layer constructs the Lagrange interpolant for each nonempty anchor subset of size at most d over a field. For a recovered large class, agreement at d nodes implies agreement with its degree at most $d - 1$ polynomial. For a smaller recovered class, all its points are nodes, which is sufficient for agreement on that class. The interpolation statement should expose both conclusions rather than assert uniqueness of the original polynomial on a singleton.

Finally, the sampled fixed-coordinate sections must be placed on a common proper refinement, and their covering functions substituted into the interpolation formula. The existing public helpers `BaseCase.properMultiplyLinear_finsetUnion` and `BaseCase.properMultiplyLinear_fin_sum` provide proved finite-family closure for iteration parameters at least one; `IsMultilinear.mul_new_coordinate` supplies the elementary multilinear lift used in the affine case. General degree in the final variable requires an additional mixed-degree predicate and its closure lemmas. Domain restriction also matters: a sampled section is only certified where that section’s partial domain is present.

The resulting local theorem can be connected to `Section16LineCover`. It should retain explicit sample, graph-count, width, and exceptional-mass bounds. Declaring `lemma_16_10_holds` would require the additional geometric and quantitative closure obligations described above. No such full Lean companion, and no completion of Theorems 18.1–18.2, is claimed here.

V.81 Verification and reproducibility

Source 19, delivered Section 9.

The package contains a standalone L^AT_EX source with an embedded bibliography, the compiled PDF, the figure used in the article, the source audit, and executable diagnostics. The mathematical proofs do not depend on a numerical search finding the claimed objects. Computation is used to check exact finite identities, normalization, endpoint conventions, and illustrative values.

V.81.1 Exact finite checks

The script `verification/verify_sampling.py` uses only Python’s standard library and exact rational arithmetic. Its recorded run checks the following.

- 1,136 comparisons between the hypergeometric formula and explicit enumeration of subsets, for populations of size at most eight and interpolation orders at most four.
- 1,664 instances of the universal loss bound, including the finite dynamic program and the full-population endpoint.
- All 64 subsets of a six-point population in the symmetric extremal-family construction, grouped by their sample sizes. The loss is independent of the particular anchor subset and equals the exact minimax value.
- A deterministic conditional-expectation selection example with 25 partial rows on 12 columns. Its five selected columns are 2, 5, 9, 10, 11, with zero-based column indices. The expected unnormalized loss decreases from 21047/198 to an actual loss of 78 out of 300 ambient row-column points.
- 243 finite-field interpolation evaluations, including small classes and functions with independent affine degree bounds in two horizontal variables.

The file `verification/sampling_results.json` records the results and the exact profiles in table II.68.1.

The script `verification/verify_polynomial.py` checks the determinants, the finite Newton-lift identities, and the modular counterexample described in section I.34. Its exhaustive quadratic tests examine 20,402 coefficient tuples, and its determinant checks cover 40 degree-spacing pairs. Results are in `verification/polynomial_results.json`.

The figure script `verification/make_figures.py` evaluates the unique-root equations for the occupancy constants with high-precision decimal arithmetic and draws the figure using Matplotlib. The displayed decimals are numerical evaluations, not a replacement for the exact formulas and uniqueness proof.

V.81.2 Build and source provenance

From the unpacked directory, the PDF can be rebuilt with

```
latexmk -pdf -interaction=nonstopmode -halt-on-error \  
gowers_interpolation.tex
```

The supplied PDF figure is sufficient for compilation; regenerating it is optional. The file `README.txt` gives the short commands for rerunning the diagnostics.

The source manifest records the exact repository commit and file hashes used for comparison. The full paper and Lean development were read through the selected GitHub integration. The relevant published formulas were also checked against the original PDF, including its displayed Section 16 controls and final graph comparison. The source audit deliberately records the original and edited formulas separately.

All principal new claims received a written-proof review independent of their initial derivation. This is a description of the checks performed for the report. It is not external peer review, and no new Lean build or kernel verification was run.

V.82 Further research questions and proposed projects

Source 19, delivered Section 10.

The questions below are proposed follow-up problems arising from the proved results. Unless an external source is cited, they are questions formulated here, not assertions that a particular problem is already recognized as open throughout the literature.

V.82.1 Exact sampling and interpolation

Research question V.82.1 (Structure of finite extremal profiles). Can the maximizers in (II.68.1) be classified without dynamic programming? In the numerical examples, equal small classes often maximize the loss, but the small-sample regime also uses unequal sizes forced by the total-size constraint. Determine how many distinct positive class sizes a maximizer ever needs, and locate the transitions as r/n varies.

The exact integer optimization makes this a finite mathematical question with certificates. A useful first result would be a uniform bound, depending only on d , on the number of distinct sizes in an optimizing vector. Such a result would turn the extremal value into a substantially smaller optimization.

Research question V.82.2 (Rates in the sharp sampling law). Give explicit upper and lower error bounds for $r\mathcal{M}_{n,q,d}(r)/q - C_d$ in terms of $1/r$, r/n , and q/r , with a stated range of validity. Can these bounds replace the simple factor d in the finite sample budget by a nearly optimal constant at a practically verifiable population size?

The proof of theorem II.69.4 already separates compact Poisson approximation from an exponentially controlled tail. The remaining work is quantitative uniformity and the lattice rounding of the maximizing class size.

Research question V.82.3 (Selecting cheap and informative slices). Suppose different columns have different structural refinement costs. Can the anchor selection minimize a combination of lost mass and the elementary-symmetric graph count, rather than the lost mass alone? What is the correct replacement for uniform sampling in that problem?

Here a column should be assessed by both the classes it helps recover and the complexity of its slice cover. The heterogeneous formula in remark II.70.4 supplies a precise objective; the conditional-expectation algorithm supplies a starting point when that objective has a computable expectation.

Research question V.82.4 (Going beyond the common-anchor certificate). Can algebraic relations among the row polynomials reduce the number of required sampled slices below the q/σ scale? For example, what changes when many affine pieces share a slope, or when all slice functions belong to a low-dimensional common function space?

The minimax lower bound does not forbid such an improvement: its rows deliberately have no structure beyond the specified class partitions. A theorem using additional shared algebraic information would address a different, stronger input model.

Research question V.82.5 (Robust polynomial lifting). Develop an analogue when each row is approximately polynomial or each sampled slice has errors in its values. Which node separation, agreement-density, or norm hypotheses permit a quantitative repair without losing the linear number of slice refinements?

Over the reals or complex numbers, the norms of Lagrange basis polynomials must be controlled. Over finite fields, an agreement-based formulation may be more appropriate. These are different problems and should have separate hypotheses.

V.82.2 Geometry and polynomial recurrence

Research question V.82.6 (Proper modular boxes without inherited coordinates). Replace the additional inherited-coordinate hypothesis in corollary II.70.8 by the precise proper-box predicates used in the live Lean development. Prove a synchronization theorem with an explicit width loss, or produce an obstruction showing what additional information is necessary.

This is the most immediate geometric integration task. The algebraic interpolation theorem is already independent of it. A proof should explicitly control subprogression steps and wrapping, rather than infer integer containment from injectivity of a modular parameterization.

Research question V.82.7 (The nonlinear exponent gap). For fixed $k \geq 2$, can the sufficient partition bound be improved from a denominator of order q^k to a smaller power of q ? Is the necessary region

$$\left(1 + \sum_j j q_j\right) a + \left(\sum_j q_j\right) b \leq 1$$

attainable, even for quadratic phases?

An intermediate improvement by one power of q would already require a different way of handling lower coefficients created by translation. The present proof repeatedly solves a new lower-degree recurrence problem; retaining correlations between those problems is a plausible place to seek a gain.

Research question V.82.8 (Prescribed lengths without the square loss). Can a complete partition into cells of two consecutive prescribed lengths achieve the flexible-length exponent range without the generic square-length requirement in lemma I.34.4? What is the optimal tradeoff among minimum length, allowed length variation, and phase diameter for nonlinear phases?

Research question V.82.9 (Numerical recurrence thresholds). Make the coefficient-uniform constants $U_{j,m}$ in the recurrence input numerical, at least for small degrees and moderate dimension. Track them through (I.34.9) before attempting any fully numerical global density-increment estimate.

The numerical exponent specialization from Lau does not by itself supply numerical values for every threshold. A complete parameter audit must account for both.

V.82.3 Closing the structural induction

Research question V.82.10 (A consistent family of structural controls). Design control functions for the induction that retain the outer parameter dependence and absorb the actual output of the shared-slice theorem. Can one prove a closure statement using those controls and then quantify the resulting final density increment?

The logarithmic obstruction in section V.80.2 provides an immediate test for any proposed repair. A revised definition must be stable under the operations actually used: restriction, union, sums, adding an unused coordinate, choosing slices, and interpolation. Passing one numerical comparison is not enough if a later operation violates the same control family.

Research question V.82.11 (Formal certificates for the finite ingredients). Formalize, in order, the hypergeometric counting identity, the marked-sample bound, the finite minimax construction, and the common-refinement interpolation theorem. Can the exact dynamic-programming profiles be exported as small certificates checked independently of the search program?

These tasks have clear finite statements and relatively modest dependencies. They can be completed before the full Section 16 induction is repaired. The higher-degree phase-partition transfer can likewise be formalized against an explicit recurrence hypothesis, keeping the imported theorem separate from the new transfer argument.

Research question V.82.12 (A complete local-to-global parameter audit). After the geometric and structural closure tasks are complete, propagate all changed constants through the remaining inverse, phase-removal, density-selection, and iteration steps. Which local savings survive in the final function of density and progression length?

This last task is the necessary route from the improvements in this article to any claim about a global Szemerédi bound. The present report supplies exact local theorems, sharpness certificates for a natural sampling problem, and explicit interfaces for carrying out that audit.

V.83 Formalization and reproducibility

Source 20, delivered Section 9.

V.83.1 Connection with the inspected Lean interfaces

The inspected `Sections01_03.lean` defines `progressionAverage`, `theorem_3_2`, `corollary_3_3`, `lemma_3_8`, and `lemma_3_9` [94]. The progression average there is an unnormalized sum on $\mathbb{Z}/N\mathbb{Z}$. Its Theorem 3.2 specification assumes prime modulus and $k \leq N$ [6 October 2026; sources 15–20; *HEAD 0b4890a1c*] (`theorem_3_2`, `Sections01_03.lean`, line 258, and `corollary_3_3`, line 276, with exact companions `theorem_3_2_holds` and `corollary_3_3_holds`, `Proofs03ProgressionAverage.lean`, line 381, `Proofs03ProgressionCount.lean`, line 349; none of this source’s results is formal); the new cyclic statement can instead use (III.44.4), or impose the exact coprimality condition to make all costs one. The inspected `Proofs01_03.lean` contains the finite Fourier identities underlying this normalization [95]. These are source observations, not a claim that the repository already formalizes the theorems in this article.

A useful implementation order is as follows. First formalize uniform fiber averaging for a surjective homomorphism, including the equal-fiber cardinality proof. Next formalize the joint-image subgroup and its two quotient maps from Lemma III.43.1. Then define directional cube powers as normalized finite sums and establish positivity without real fractional powers. The kernel-elimination theorem should first be proved in its powered form (III.43.6); the final roots are a separate real-analysis wrapper. The finite-index comparison can similarly be proved as an inequality between 2^s -th powers using character orthogonality and the existing cube Cauchy–Schwarz interface.

The second-order telescoping identity is independent of groups and analysis. It is a finite polynomial identity over a commutative ring, with the first two selected indices providing a natural induction or finite-set partition proof. Separating it from the analytic bound should make both developments reusable. The Gauss construction requires a separate finite-field exponential-sum development and should not block formalization of the main counting theorem.

No Lean executable was available in the working environment used for this package. No Lean source is presented as compiled or kernel checked, and the repository was not modified. The supplied verification program uses exact rational arithmetic for finite tests, not proof-assistant certification of the general statements.

V.83.2 Executed verification

The accompanying `verify.py` uses the Python standard library for its exact tests. It computes directional cube powers by derivative recursion. For the two-function theorem it compares rational quantities in the powered inequality

$$|\Lambda|^{2^{k-1}} \leq D_i(f_i)^{2^{k-1}} D_j(f_j)^{2^{k-1}} (\mathbb{E}|f_\ell|^2)^{2^{k-2}} \prod_{r \notin \{i,j,\ell\}} \|f_r\|_\infty^{2^{k-1}}. \quad (\text{V.83.1})$$

No floating-point root is needed. This tests the actual L^2 gain, including non-coprime and repeated slopes.

An optional NumPy check, also executed, directly averages the weighted three-term example on $\mathbb{F}_{29}^2$. It gives

$$\Lambda_3(f) = 0.00003419510332526960,$$

with discrepancy less than 1.4×10^{-20} from the evaluated exact formula. Its computed U^2 fourth power is approximately $7.85288905 \times 10^{-7}$, below the proved bound $4.64476813 \times 10^{-6}$. These are floating-point checks and are labeled separately in `verification_report.json`. Neither the Gaussian computation nor the finite rational tests replace the proofs.

Exact test family	Number
Exhaustive two-function/ L^2 inequalities on $\mathbb{Z}/2\mathbb{Z}$	6,561
Random rational two-function/ L^2 inequalities, orders 3–5	1,710
Finite-index norm comparisons	252
Exact equalities for coset-supported functions	252
First-two-residual polynomial identities	700
Exhaustive three-term indicator bounds on odd cyclic groups	680
Higher-order rational quadratic counting bounds	105
Quadratic-phase matrix rank cases	64
Exact pair-quotient averaging identities	65
Total	10,389

Table V.83.1: Executed exact arithmetic tests. All passed. Random tests use the fixed seed 20261006; “exhaustive” refers only to the specified finite families, not to all functions or groups.

To reproduce the exact checks, run

```
python3 -S verify.py --output verification_report.json
```

To include the optional NumPy calculation, omit `-S` and add `-gauss`. The manuscript is self-contained as a TeX source with an inline bibliography and no external figures. Three runs of `pdflatex` resolve the contents and cross-references.

V.84 Further research questions and topics

Source 20, delivered Section 10.

The questions below are a proposed program arising from the proved bounds. Except for the explicit local extremal questions formulated here, they are research directions rather than assertions that a literature-wide open status has been established.

Question V.84.1 (Optimal exponent for longer symmetric counts). *For fixed $k \geq 4$ and density bounded away from zero and one, determine the largest θ for which an estimate $|\Lambda_k(1_A) - \delta^k| \leq C_{k,\delta} U^{k-1} (1_A - \delta)^\theta$ holds uniformly over admissible finite abelian groups. The present article proves $\theta \geq 2$ and settles optimality only for $k = 3$. Can higher-degree phase rank degeneracies furnish matching examples?*

Question V.84.2 (Sharp three-term density coefficient). *Determine the best coefficient multiplying u^2 in the small- u three-term problem, separately for weights and indicator sets. Is the upper coefficient $\sqrt{\delta(1-\delta)}$ attainable asymptotically under the indicator constraint? The rounding proof preserves a positive coefficient, but is far from an optimal-constant calculation.*

Question V.84.3 (Prime-cyclic sharpness). *Construct a quantitatively controlled prime-cyclic analogue of Theorem III.48.3, or identify an obstruction that improves the available exponent or coefficient in that restricted family. A transfer argument must preserve the count excess relative to the square of the norm, rather than merely preserve positivity.*

Question V.84.4 (The best multilinear torsion constant). *For fixed L and marked positions i, j, ℓ , determine the operator norm in (III.43.5) after replacing both directional seminorms by global ones. The product $\kappa_i \kappa_j$ is explicit, but sharp individual norm conversion does not settle simultaneous sharpness of the full counting estimate.*

Question V.84.5 (Equality and stability of the two-function argument). *Classify equality in Theorem III.43.3 beyond constant functions, and obtain a stability statement for near equality. The proof suggests compatibility conditions between almost constant fiber magnitudes and almost proportional quotient-conditional derivatives. Formulating the correct quantitative metric is part of the problem.*

Question V.84.6 (Optimized unequal-density elimination). *Develop an exact finite optimization procedure for second-order elimination using the full profiles $\|b_i\|_{U^s}$, densities, L^2 norms, and subgroup costs. The existing first-order dynamic program in the repository is not automatically optimal for this two-marked problem. Can one obtain a useful polynomial-time approximation without enumerating all position orders and tail decompositions?*

Question V.84.7 (More than one ordinary norm gain). *Which systems admit an improvement retaining two uniformity norms and several L^p factors? Ordinary iteration tends to change the power of a later density gain. A sharp mixed-norm region, stated as a finite polytope of exponents when possible, would clarify the best sparse-set bounds obtainable from this method.*

Question V.84.8 (A quotient-adapted counting baseline). *Replace the product of means by a baseline determined by conditional expectations on the torsion quotients, with (III.46.3) as its first correction. Can a systematic expansion remove large κ costs while retaining global uniformity control on the remaining genuinely transverse directions?*

Question V.84.9 (Localization preserving two uniform factors). *Find a no-wrap or interval-localization mechanism that retains two small balanced norms in every error term. This would connect the quadratic modular threshold to integer density-increment arguments without assuming that multiplication by an arbitrary interval indicator preserves uniformity.*

Question V.84.10 (Effect on a complete quantitative iteration). *Insert the improved counting threshold into a fully specified inverse theorem and density-increment scheme, and propagate every parameter. Which exponent in the final bound changes, and which loss remains dominant? This is the required calculation before any global-bound improvement can be claimed.*

Question V.84.11 (General coefficient modules). *For systems of integer matrix forms on finite modules, express the subgroups $L_i(\ker L_j)$ through Smith normal forms or determinantal ideals. An exact arithmetic interface could turn the abstract theorem into a computable torsion-sensitive bound for higher-dimensional configurations, including systems with several parameter directions.*

Question V.84.12 (Kernel-checked proof certificates). *Formalize the two-function theorem, the sharp finite-index comparison, and the second-order telescoping identity as independent reusable components. An especially useful first milestone is a powered, root-free theorem over finite sums, with an automatically checked certificate for every coefficient index in (III.44.4).*

V.85 Conclusion

Source 20, delivered Section 11.

The decisive local change is to keep two functions at the last Cauchy–Schwarz stage. That produces a bilinear dependence on their uniformity norms, with one additional L^2 factor. An exact second-order expansion then converts the analytic estimate into quadratic symmetric counting error. Torsion is neither ignored nor excluded: the kernel-image directions identify it, a sharp

index comparison quantifies it, and explicit collapsed-pair examples show why some dependence is necessary.

The three-term construction also supplies a boundary to this line of improvement. Over admissible growing-dimensional groups, even genuine sets can have count excess proportional to the square of a small balanced U^2 norm. Thus further progress must exploit extra structure, a sharper coefficient, a different norm, a restricted ambient family, or information unavailable in the present symmetric estimate.

V.86 Source audit and package scope

Source 20, delivered Appendix A.

The source inspection took place on 6 October 2026. A repository branch checkpoint observed during the work was

1bd57e91c76800c175c311fd1f37b2a10f07b9db.

The repository was active during inspection. The earlier research comparison is therefore identified by its actual inspected blob, not silently treated as the complete state of every later commit.

Source	Inspected identifier or range
Original paper TeX in the Ramsey paper directory	41085a0efde8c1932e86e80c791984f52841c22e. Paper Theorem 3.2, Corollary 3.3 and uniformity normalization were also checked against the original PDF, including rendered pages.
Existing local-refinements article	45b408f6d970a6d997973189663395670b5f3e6e. Introduction, cube/sharpness discussion, and the density-weighted progression section, especially source lines 1840–2025.
Sections01_03.lean	[write] Source 04’s delivered manuscript; the first write replaced <code>article.tex</code> at 14:34, after this inspection. f9fcd166af0ea5a8e8c674576c1e47f3705485cd, inspected at the checkpoint above, including definitions on lines 250–340.
Proofs01_03.lean	e72f7bd53a23d5880cbddbfebd0664d529e47c10, Fourier-identity infrastructure inspected near the start of the file.

The source manifest records these identifiers and the primary external references. The archive includes the article source and PDF, verification program and report, build instructions, and this manifest. It does not redistribute Gowers’s paper, the repository, or third-party font files. No repository write, external submission, or new formalization claim is part of the package.

V.87 Repository interface and verification

Source 21, delivered Section 10.

V.87.1 What was inspected

The source audit used the GitHub connection to inspect `VladimirReshetnikov/ProveIt` at commit `43306653afaaaaa0b58a7ca71e4067c245594867`. The inspected directory was `Combinatorics/Ramsey`. The principal comparison files were the Gowers transcription, the existing research compilation, the Section 3 statements and definitions, the cube upper-bound proof, and the proof-status ledger. The frozen commit is used in the source manifest so later edits of the moving branch cannot change the object being compared.

Source or declaration	Role in the comparison
Gowers, Lemma 3.8	Cube Cauchy–Schwarz, the standard analytic input
Gowers, Lemma 3.9	Triangle inequality; the projection consequence quantifies a related equality defect
Gowers, Lemma 3.10	The general cube upper bound strengthened in the real centered characteristic-five setting
<code>Sections01_03.lean</code> , <code>lemma_3_10</code>	The formal statement of the original cube upper bound
<code>Proofs03CubeUpper.lean</code> , <code>lemma_3_10_holds</code>	An existing exact companion declaration, as also recorded in the ledger
<code>Definitions.lean</code>	Conventions for <code>UniformOfDegree</code> , <code>gowersNorm</code> , and <code>cubeCount</code>
Earlier extremal manuscript, Section 3	The specifically unresolved characteristic-five coefficient question

The ledger’s status for `lemma_3_10` is `exact_companion`. This is a report of the inspected source and ledger, not a fresh build certification. The new inequalities in this article are written mathematical proofs; no new Lean theorem is claimed, and the repository was not modified by this task.

[write] **6 October 2026; sources 21–27.** *Checked at HEAD `2dfe46f44`.* `lemma_3_10` is at `Sections01_03.lean`, line 340, and its exact companion `lemma_3_10_holds` at `Proofs03CubeUpper.lean`, line 82; the ledger still records `lemma_3_10` as an exact companion. The seven repository files this source cites have the same blobs at HEAD as at its pin, so its comparison is current. No characteristic-five or cube-expansion declaration exists.

V.87.2 A concrete formalization route

The shortest route to formalizing the new material is to separate finite combinatorics from real optimization.

1. Prove the Fourier sum-of-squares identity on a finite abelian group and specialize to real centered functions. Establish the axis identity as a finite-sum equality.
2. Formalize the three opposite-pair families and the eight extra order-five tuples as disjoint weighted finite sets. This gives (III.52.2) without analytic asymptotics.
3. Prove the three six-vertex identities and the derivative identity for C_7 algebraically. The displayed profile inequalities then use finite-sum Cauchy–Schwarz and Hölder.

4. State the finite profile theorem (III.52.4) with explicit nonnegative real parameters. Keep this usable theorem independent of asymptotic notation.
5. Prove the scalar localization and absorption lemmas, and then the two-variable quadratic optimization. This isolates the absolute smallness threshold and remainder constant.
6. Treat the five-point polynomial as a finite certificate, followed by a separate real analytic optimization theorem. A formal proof of its exact coefficients is substantially easier than a formal proof of the analytic maximizing branches.

The general exponent-five group requires a finite abelian-group interface or a vector-space model over $\mathbb{F}_5$; a statement only on $\mathbf{ZMod}\ N$ does not automatically represent $\mathbb{F}_5^n$. Normalization also matters. In this article the cube average is N^{-4} times the count and the centered uniformity budget is u^8 . Any implementation should verify these factors at the interface, rather than transfer theorem names alone.

V.87.3 Computational checks supplied with the article

The archive contains two standard-library Python verifiers. Their role is to test finite algebra and catch transcription errors; the proofs above establish the general results.

- `verify_order5.py` enumerates all 625 Fourier cube assignments on $\mathbb{F}_5$, obtaining 34 monomials. It compares physical-space cube averages, the full Fourier formula, the six-row table, and the expanded phase polynomial. It checks the rational series coefficients and $20/9$ exactly.
- `verify_profiles.py` checks the three sextic support identities and the septic derivative by exact monomial dictionaries on $\mathbb{F}_5$. It also checks the finite profile and energy inequalities on deterministic examples in $\mathbb{F}_5$ and $\mathbb{F}_5^2$, including direct physical-space cube averages.

The supplied run records report all checks passing. The largest normalized floating-point discrepancy in the two independent runs was below $2 \cdot 10^{-13}$. This small numerical discrepancy is consistent with rounding; the exact dictionary and rational checks use integer or rational arithmetic. The general asymptotic claims are not inferred from finite sampling.

V.88 Further research questions

Source 21, delivered Section 11.

The questions below distinguish a natural next calculation from a larger structural problem. None is asserted to be a previously published open problem without a separate source establishing that status.

Question V.88.1 (The universal eighth-order coefficient). *For fixed $0 < \delta < 1$, let*

$$M_\delta^{(5)}(u) = \sup_{\substack{G \neq 0 \text{ finite abelian, } 5G=0 \\ W: G \rightarrow [0,1], \mathbb{E}W=\delta \\ \|W-\delta\|_{U^3} \leq u}} Q_3(W).$$

Does the limit

$$\lim_{u \downarrow 0} \frac{M_\delta^{(5)}(u) - \delta^8 - 6\sqrt{2}\delta^4 u^4 - C_5 \delta^2 u^6}{u^8}$$

exist, and is it 20/9? Theorem F.26.1 gives a finite upper limsup, while Corollary III.55.2 gives lower liminf at least 20/9. The missing step is a sharp treatment of frequencies outside the dominant five-point quotient.

Question V.88.2 (Fixed higher dimensions). For $G = \mathbb{F}_5^n$ with fixed $n \geq 2$, is the eighth-order coefficient always 20/9? Can an extremizing family be proved to depend on one linear functional for all sufficiently small norms? The projection estimate (III.57.1) supplies approximation, but not exact attainment after norm rescaling.

Question V.88.3 (A quantitative eighth-order stability theorem). If the objective is within $O(u^8)$ of the displayed sharp sixth-order expansion, what is the best bound for the Fourier mass outside $\{\pm\xi, \pm 2\xi\}$? Determine whether a U^2 error of order u^2 is the correct uniform scale and identify the additional phase and amplitude losses.

Question V.88.4 (Further terms on the five-point group). The analytic maximizing branches in Theorem III.55.1 permit recursive calculation of higher coefficients. Determine the exact u^{10} and u^{12} terms and the first nonzero displacement of the phases. At order u^{12} , the phase perturbation can affect the value, so a computation confined to the limiting phases is insufficient.

Question V.88.5 (Exact finite-norm maximizers). For fixed $0 < \delta < 1$, how far can the analytic maximizing branches be continued before a weight reaches 0 or 1 or a different branch takes over? The six-row formula reduces the question on $\mathbb{F}_5$ to a compact, explicit constrained problem. Certified interval arithmetic or elimination could locate its transition values.

Question V.88.6 (Other torsion classes). Determine the comparable near-constant expansion on exponent-three groups, where the centered low-degree cancellations and pure-pair norm differ. For mixed odd torsion, classify the secondary behavior according to the order of the largest Fourier character, taking care that competitors of several character orders may coexist.

Question V.88.7 (Higher-dimensional additive cubes). For $d \geq 4$, determine the sharp leading real-centered coefficient in $Q_d(\delta + f)$ at fixed $U^d(f)$, and classify the first torsion-dependent correction. The three-cube Fourier sum-of-squares representation is unusually simple; higher dimensions require a larger incidence-kernel analysis.

Question V.88.8 (Optimal profile inequalities). The estimates $|C_6| \leq 28H$ and $H \leq 3\sqrt{DE(\lambda)}$ are adequate for the sharp sixth-order theorem, but their constants and simultaneous equality cases have not been optimized here. Determine which profiles can actually approach equality in all the needed estimates.

Question V.88.9 (Quantitative conversion from weights to sets). The probabilistic argument allows the ambient dimension to be made arbitrarily large. What is the least dimension needed to approximate the model through a specified order, or to realize a specified density with an explicit cube-count error? Deterministic rounding would provide a useful constructive complement.

Question V.88.10 (Machine-checked finite certificates). Can the 34-monomial five-point certificate and the sextic support identities be checked by a small trusted Lean evaluator, followed by a proof of the scalar profile theorem? This is a concrete entry point that does not require formalizing the entire analytic maximization argument at once.

Question V.88.11 (Where local gains affect larger arguments). *Which finite-field density or counting arguments genuinely use this sharper cube count with its characteristic-five structure? Identify an explicit downstream theorem before claiming a quantitative improvement. The absence of long proper progressions in exponent-five groups prevents a direct extrapolation to integer Szemerédi bounds.*

The most focused next target is the first question: the proofs already isolate a finite eighth-order gap, and the model supplies the exact candidate 20/9. A resolution would require a sharper geometric analysis of the off-line Fourier tail, rather than another optimization of the two-harmonic phases.

V.89 Finite incidence certificates and reproducibility

Source 21, delivered Appendix A.

V.89.1 Centered support census

Associate to each cube vertex ω the column $(1, \omega_1, \omega_2, \omega_3)^\top$ over $\mathbb{F}_5$. The expectation of a product of centered functions on a support is the sum of Fourier monomials whose frequencies lie in the kernel of the corresponding column matrix. A zero forced coordinate makes the monomial vanish. The relevant small census is

Support size	Number	Classification relevant to the expansion
1	8	Independent; centered expectation zero
2	28	Independent; centered expectation zero
3	56	Independent; centered expectation zero
4	70	12 rank-three parallelograms; 58 rank four
5	56	8 full-support circuits; 48 with a forced zero
6	28	Omitted-pair distances 1, 2, 3: 12, 12, 4
7	8	One omitted vertex; the derivative formula applies
8	1	The full U^3 power

This census explains why the first three errors vanish and why the fourth and fifth terms have coefficients 12 and 8.

V.89.2 The full five-point polynomial certificate

Order the vertices as 000, 001, 010, 011, 100, 101, 110, 111. All 625 solutions of the four Fourier constraints on the full cube can be parameterized by $(s, t, v, w) \in \mathbb{F}_5^4$ as

$$(s + t + v + 2w, -s - t - w, -s - v - w, s, -t - v - w, t, v, w).$$

The four equations can be checked by substitution, and the last four chosen parameters are recovered directly from the labels at 011, 101, 110, 111, proving that the parameterization is bijective. Counting the multiplicities of the monomials $a_0^{e_0} \cdots a_4^{e_4}$ gives the accompanying CSV certificate. The multiplicities sum to 625, and every exponent vector has total degree eight.

This is independent of the six-slot sum-of-squares calculation: one certificate solves the physical cube’s orthogonality equations, while the other groups Fourier parallelograms into squared terms. Their agreement supplies a useful finite algebra check.

V.89.3 How to reproduce the supplied artifacts

From the extracted archive directory, run

```
python3 code/verify_order5.py
python3 code/verify_profiles.py --output data/profile_validation_results.json
make pdf
```

The verifiers need only Python’s standard library. The optional figure-generation program uses `matplotlib` with high-precision arithmetic from Python’s `decimal` module; the prebuilt PDF figure is included, so plotting packages are not needed to compile the article.

V.90 Source manifest and status of claims

Source 21, delivered Appendix B.

The machine-readable source manifest records the repository commit, paths, and Git blob hashes of the inspected files, together with the primary literature URLs. The earlier project report was read as a separate manuscript, not assumed to be part of the inspected repository snapshot.

Claim category	Status in this article
Gowers–Cauchy–Schwarz and norm property	Standard results of Gowers; used with their normalization stated explicitly
Quartic gap and earlier characteristic-five lower example	Prior project results, reproved or recovered from exact formulas
Uniform coefficient C_5 with $O(u^8)$	Proved in Theorem F.26.1, with matching examples
Phase envelope and necessary rigidity	Proved in Theorems III.53.2 and III.54.1
Five-point coefficient 20/9	Proved for the fixed group in Theorem III.55.1
Universal eighth-order coefficient	Undetermined; 20/9 is a lower bound and an explicit candidate
New Lean certification or new global Szemerédi bound	Not claimed
Bibliographic priority	Not established by the source search

The proof development and an independent mathematical audit agreed on the core inequalities and both asymptotic optimizations. The article incorporates the audit’s corrections concerning the zero norm case, the sign of a phase cosine, and consistent phase notation. The included review note records that mathematical review as an AI-assisted check; it is not external peer review.

V.91 Verification, attribution, and repository integration

Source 22, delivered Section 11.

V.91.1 Exact computational checks

The package contains four small Python programs, using only the standard library. They use exact integer, rational, and finite-field arithmetic. The results are recorded as JSON so that the numerical claims can be reproduced independently of the typeset manuscript.

Program	Verification performed
<code>verify_certificates.py</code>	Exhaustive moment–degree duality for all ternary slices in dimensions one through three over $\mathbb{F}_5$ and $\mathbb{F}_7$; affine slice counts; independent sparse Laurent convolution versus the joint-moment recurrence; the explicit $d = 2$ polynomial and a $d = 3$ binomial-basis polynomial; exact coefficient comparison tables.
<code>verify_two_cubes.py</code>	Direct enumeration of all ternary slices and normalized translations in the listed $k = 1, 2$ cases. It matches the full squarefree moment vectors and checks the stated finite interval for $\delta_{k,1}$, without using the stabilizer argument.
<code>verify_polynomial_patterns.py</code>	20 400 norm evaluations and all 74 norm-value pairs over $\mathbb{F}_5, \mathbb{F}_7$ certify the origin examples; 512 Vandermonde-budget cases include degrees exceeding characteristic; 3 476 quadratic maps and 2 051 540 center/direction evaluations check the quadratic classification; 444 extra-direction fibers at 72 centers check the cubic-core formula using 119 592 core directions.
<code>verify_norm_obstruction.py</code>	Irreducibility of the field moduli, all eligible ratios for $(q, p) = (3, 3), (5, 5), (9, 3)$, and an independent full start/direction enumeration in $\mathbb{F}_{27}$. The ratio counts are 6, 20, 18; the corresponding full- p progression counts are 156, 62 480, 13 104.

The factorized origin check for $N_3 + N_5$ is exact: every norm value has its verified fiber size, and every pair of norm values is tested against the two reflection equations. It therefore certifies a count over all q^8 directions without pretending to have explicitly iterated that many vectors. Likewise the value 7 810 000 is a proved lower bound for the global symmetric count, not a numerical estimate or an exact global count.

The two-cube checks found no extra degeneracy outside the listed hyperplanes in their tested cases. The theorem uses an explicit remainder and does not promote that observation to an all-prime statement. All general claims are proved in the body of the article. Independent internal review checked the degree filtration, the class quotients, the finite summation by parts, the zero-set rigidity, and the distinction between prime-field and extension-field quadratic functions.

V.91.2 How this fits the existing formalization

At the inspected repository snapshot, the arrangement definitions are in `Combinatorics/Ramsey/Lean/GowersSzemerédi/Sections14_15.lean`. They include `GeneralArrangement`, `arrangementMoment`, `GeneralArrangement.IsDegenerate`, and `degenerateGeneralArrangementCount`. The existing file `Proofs15DegenerateArrangements.lean` contains `lemma_15_4_holds` for the original-size estimate. The present arrangement results use the same full moment definition of degeneracy, not a weaker collision-only predicate.

A practical formalization order is as follows.

1. Define parity-normalized certificate degree by the finite Boolean interpolation coefficients, then prove Lemma II.82.2 as an identity of finite sums.
2. Prove the diagonal and paired-diagonal rank statements of Lemma II.82.3; an injective choice of the pivot variables gives the finite counting bound directly.
3. Formalize affine ternary slice classification and the affine-value equivalence relation. First use U_1 ; the slope-balanced constant-term refinement can then be added without changing the rank proof.
4. Prove the cumulative weighted-sum lemma once in a general ordered semiring or real setting. It is a reusable guard against invalid shell subtraction in other counting arguments.
5. Add the refined arrangement theorem under its explicit prime condition $p > 4d$, and retain the separate $d = 1$ theorem under $p > \max\{3, 2k + 1\}$.
6. Add polynomial equality patterns as a separate definition. A symmetric four-term pattern and a monochromatic four-term pattern have different predicates and different degree budgets. Their identifiers should make that distinction explicit.

This package contains mathematical proofs and executable finite checks, but no new Lean proof file. It has not rebuilt the repository or altered its proof-status catalogue. In particular, this document should not be used to mark a theorem as kernel-checked.

[write] 6 October 2026; sources 21–27. *Checked at HEAD 2dfe46f44.* Every name above exists (`Sections14_15.lean`: `GeneralArrangement`, line 192; `arrangementMoment`, line 346; `GeneralArrangement.IsDegenerate`, line 354; `degenerateGeneralArrangementCount`, line 364), and `lemma_15_4_holds` is at `Proofs15DegenerateArrangements.lean`, line 1131. The suggested separate directory was declined: the manuscript is printed in this report (Section F.4).

V.91.3 Suggested placement and reproducibility

The standalone source `gowers_degree_stratification.tex` has no external bibliography or figure dependency. It can be placed in a new subdirectory of `Combinatorics/Ramsey/Research/GowersSzemerédi/` along with the accompanying `code/` and `data/` directories. The supplied PDF is compiled from that source. The README records the build commands and a concise statement-level comparison with the earlier reports. The source ledger records the repository revision, source paths, and checksums used to ground the work.

The intended integration is additive: a new research article and its verification artifacts. The theorem numbering in Gowers’ paper is not renumbered, and the existing formal statements are

not silently replaced. Each quantitative substitution should cite the new theorem together with its stronger characteristic hypothesis.

V.92 Further research questions and proposed next steps

Source 22, delivered Section 12.

The following questions distinguish exact problems exposed by this article from broader research goals. None is asserted to be a recognized major open problem solely because it is listed here.

Research question V.92.1 (The actual second degeneracy coefficient). For fixed k and $d \geq 2$, determine the coefficient of p^{-2} in $\delta_{k,d}(p)$. The present theorem reduces the dominant nonparity search to slope-balanced affine Boolean slices. A solution must still identify coincident codimension-two loci and their intersections with the pure-parity hyperplanes. Counting certificate classes alone cannot give the answer.

Research question V.92.2 (Exactness in the two-cube case). Is $\delta_{k,1}(p) = L_k(p)$ for every sufficiently large prime p , or do some nonaffine translation loci contain points outside $t_i = 0, \pm 1$ and $t_i \pm t_j = 0$? The finite checks for $k = 1, 2$ suggest a concrete starting point. Either a containment theorem or a single exact counterexample would sharpen the structural picture.

Research question V.92.3 (Degree-two Boolean certificates). Count ternary-valued Boolean polynomials of degree at most two together with their necessary moment balances, up to affine value changes. The first target is an explicit cumulative bound much smaller than $A_{2d(1+k+\binom{k}{2})}$. A successful classification should feed directly into the p^{-3} term of the finite bound.

Research question V.92.4 (A feasible-class filtration in every degree). The current higher-degree profile counts many classes whose lowest moment constraints are inconsistent. Can one build cumulative bounds after imposing all necessary constraints, while retaining a valid summation-by-parts comparison? The exact degree-one endpoint shows why this is promising and also why differences of separate upper bounds must be treated carefully.

Research question V.92.5 (The balanced constant-term polynomials). Find a compact generating function in both k and d for $J_{k,d}$. The leading coefficient is an alternating-cycle count; the lower coefficients should admit a description using a finite collection of decorated incidence graphs. Such a description could provide efficient exact values for the eight-arrangement application.

Research question V.92.6 (Small characteristics). Extend the balanced count to primes $p \leq 4d$ by replacing integer constant terms with zero coefficients in a finite group algebra. Which additional modular balance types change the leading or second degeneracy coefficient? The Boolean degree/rank argument itself remains available, but the pattern-class and no-aliasing counts must be redone.

Research question V.92.7 (A fully propagated quantitative bound). Carry the improved exceptional-set function through the entire chain from respected arrangements to multilinear structure, phase removal, density increments, and iteration. The correct output is a checked parameter dependency graph with a closed final estimate. A local improvement alone does not establish a better global Szemerédi bound.

Research question V.92.8 (Global quintic avoidance beyond the cubic core). Determine the maximum dimension of a scalar polynomial of degree at most five, or six, avoiding symmetric

four-term progressions over fields of characteristic greater than four. The current range is four to eight. The exact pointwise theorem rules out improving eight by an argument that guarantees a nonzero direction at each independently prescribed center. The no-additive-extension theorem rules out the entire family $x_0 + N_3(u) + R(w)$ with added variables. Mixed dependence between the old and new coordinates is therefore a natural construction target.

Research question V.92.9 (Simultaneous sharpness for a general equality pattern). For which node partitions and degree caps is the minimum $q^{\max(n-B,0)}$ attained by one polynomial at every center? The low-degree monochromatic and symmetric patterns give positive examples. The high-degree norm example shows that pointwise sharpness alone supplies no answer.

Research question V.92.10 (Classifying general pointwise extremizers). Minimum support determines the geometry of the successful direction set, but not all polynomials producing it. Classify the maps that attain the pointwise minimum for a given evaluation matrix. The complete quadratic normal form is a first instance. A useful classification should account for centers at which the subspace changes.

Research question V.92.11 (Surjectivity beyond complete norm cores). Characterize polynomial cores whose reflection map is onto at every center. Such a characterization would identify a broad family for which independent additive extensions cannot improve avoidance. It is also natural to ask for lower bounds on every reflection fiber, not only surjectivity.

Research question V.92.12 (Higher-order extension defect formulas). The cubic-core formula expresses the exact global count in terms of the support of a third difference. For five or more odd norm layers, can one obtain an equally useful expression in a hierarchy of odd differences? The triangular norm construction supplies a recursion, but higher-block choices affect the targets of lower blocks.

Research question V.92.13 (Stability of the zero-defect classification). If the third difference of R vanishes on almost every pair, is R close to a prime-field quadratic function with a quantitatively sharp error bound? The exact cubic-core formula converts this directly into stability for the number of symmetric progressions in independent extensions. Connections with classical low-degree testing should be used explicitly rather than rediscovered without attribution.

Research question V.92.14 (Norm lines outside characteristic-divisible degrees). For general t , count ratios θ for which $N_t(\theta + j)$ is constant on $\mathbb{F}_p$, or merely satisfies the required reflection equalities. The exact degree- p answer uses a Frobenius orbit on an Artin-Schreier translate. Other degrees may require a more general description of the conjugate-root polynomial.

Research question V.92.15 (An initial Lean milestone). Formalize the exact formulas $J_{k,2}$ and $\delta_{1,1}(p)$, together with the abstract weighted cumulative-sum lemma and the evaluation-matrix minimum. These results have small interfaces and provide useful reusable components before the full degree-stratified arrangement theorem is attempted.

V.93 Verification record and repository integration

Source 23, delivered Section 9.

V.93.1 What the accompanying checks establish

The package includes three independent exact-arithmetic programs. They use Python’s standard library and make no network requests. Their purpose is to detect finite combinatorial, normalization, and transcription errors in the formulas used by the proofs. They do not replace the arguments establishing asymptotic uniformity or arbitrary-dimension inequalities.

Table V.93.1: Exact verification performed for this article.

Program	Verified content
<code>verify_prescribed_partitions.py</code>	1770 interval conductors; 20181 nonzero mixed-radix residues; 3122 rational phase vectors for the torus bound; four complete partitions; 5000 exact residue-packing formulas; 196 exceptional-mass gap calculations; and the prime obstruction with modulus 29269.
<code>check_fifth.py</code>	The entire centered cube polynomial, all six entries of the five-point Fourier-slot table, the exact norm and weighted-count polynomials, and the 12, 12, 4 sextic support multiplicities. Coefficients are integers in a formal phase ring with $z^{10} = -1$.
<code>verify_section16_gluings.py</code>	177103 localization instances, 88688 contained short progressions, 1099140 residue-transport instances, and 2361 sampling profiles and sample sizes, including the exact add-one identity.

The phase program verifies its full partitions by checking coverage, disjointness, allowed lengths and phase diameters, not just the chosen denominator. For the prime obstruction it enumerates every possible step allowed by the minimum cell length. In the cube program, the special phase is represented algebraically; floating-point cancellation is not used to certify the polynomial identities. The transport program checks both orientations of the integer step and the cardinality of every residue chain.

The included figure is generated from proved upper and lower formulas. Its shaded band bounds an unknown exact threshold. It is not the result of optimizing over all phase vectors numerically.

V.93.2 Suggested integration into the research collection

This article can be placed in a new research directory, for example

Combinatorics/Ramsey/Research/GowersSzemerédi/
sharp-thresholds-and-extrema/.

Keep the article as a separate unit before merging it into the large collection: its central contribution is the completion of specific sharpness questions, and this is easiest to review when the earlier sufficient bounds remain visibly attributed.

In the research-question ledger, the following updates are justified by the written proofs:

1. Mark the prescribed-length conductor-loss question as resolved for simultaneous affine phases with arc diameters below $1/2$, in the eventual universal-threshold sense. Record both the finite sandwich and the leading constant one. Keep separate any question about a particular interval length, an exact number of cells, or nonlinear phases.

2. Mark the characteristic-five secondary cube coefficient as determined: it is $2^{3/4}/3$ with an absolute $O(u^8)$ error. The result applies to real centered functions, gives the weighted supremum on every fixed nontrivial exponent-five group, and has indicator sharpness in growing dimension. Keep the tertiary coefficient open.
3. Record the common-base construction and full-width affine transport as proved conditional lemmas for the proper modular-box interface. Keep the final Section 16 control-function comparison and the ordinary-integer source-fidelity problem open.

The repository’s original paper transcription is an object of ongoing mathematical repair. The result here should be entered as an independent theorem and linked to the relevant numbered lemma; it should not silently replace the source’s statement or erase the history of a correction.

V.93.3 A feasible formalization sequence

The partition results have a particularly direct finite formalization route. Define the semigroup of permitted cardinalities, establish its conductor property, and prove the interval conductor formula. The mixed-radix obstruction needs only divisibility, centered modular distance, and counting residue classes. It would already certify the new sharpness conclusion without formalizing a measure-theoretic torus packing argument. The slightly weaker rectangular upper bound is entirely finite and has the same sharp asymptotic; the stronger finite packing constant can be added later.

For the cube theorem, a useful interface consists of the normalized Fourier identity (F3), the exact homogeneous expansion (F4), the concentration penalty (F8), and the incomplete-cube bounds (F9). The subsequent optimization is a real inequality with absolute small-parameter hypotheses. The five-point lower model can be checked by a finite algebraic certificate, but a proof assistant still needs an explicit bridge from that certificate to the Fourier definitions.

For geometric gluing, the natural order is Lemma II.103.3, Lemma II.103.4, Theorem II.103.6, and finally Theorem II.103.7. The existing modules `Proofs16RelativeSteps.lean`, `Proofs16CommonBase.lean`, `Proofs16Interpolation.lean`, and `Proofs16SampleSelection.lean` provide nearby interfaces [110]. The proofs must preserve the orientation of a negative integer lift and the exact cardinalities of proper progressions. No claim that these proposed declarations have been kernel-checked is made in this package.

[write] **6 October 2026; sources 21–27.** *Checked at HEAD 2dfe46f44.* The four modules named above exist; `lemma_16_10` (`Section16.lean`, line 851) is open, and the formal results compared with Section II.103 are in the notes there. The research-question updates proposed in this section are made in Section V.2 (items I.12, III.23 and II.40). The suggested separate directory was declined: the manuscript is printed in this report.

V.94 Further research questions and topics

Source 23, delivered Section 10.

The first two questions have the shortest path from the present proofs to additional quantitative results. The later questions address structural generalization and the unresolved global dependency chain.

1. **Determine the second asymptotic term of the prescribed-length threshold.** We now know $T_{\{L, L+1\}}(\epsilon) = L^{q+2} / \prod_i \epsilon_i (1 + O_q(L^{-1}))$. The lower and upper bounds differ at

the relative $1/L$ scale. Is there a universal next coefficient, or do rounding and arithmetic properties of the tolerances force oscillation? Begin with $q = 1$ and a fixed rational tolerance, where every relevant step can be inspected exactly on small intervals.

2. **Determine the tertiary cube coefficient in characteristic five.** The sharp secondary coefficient leaves an $O(u^8)$ error. At this order, additional Fourier modes can compete with the two selected harmonics. The exact five-point polynomial gives an explicit test family; a rigorous global optimum would need a sharper treatment of the tail terms than the union bound in (F9). A finite-dimensional variational reduction would be particularly useful.
3. **Obtain a quantitative stability theorem for the phase obstruction.** The mixed-radix construction realizes the sharp asymptotic threshold. Must nearly worst phase vectors resemble a sequence of nested rational quotients after a suitable change of coordinates on the phase torus? Specify a metric and a notion of near-extremality before attempting the classification; a threshold statement alone does not force such a structure.
4. **Find exact thresholds when the range of lengths is a fixed fraction of the minimum.** When $w = o(L)$ the leading constant is known. For $w \sim \theta L$, $0 < \theta \leq 1$, the conductor is explicit but the present upper and lower phase factors need not have the same leading constant. One can first optimize the upper construction over shorter prefixes of the permitted interval. A matching lower construction may require more information than the smallest allowed length.
5. **Classify optimal exceptional-set profiles.** Formula (I.39.1) is exact for the rigid examples, and (I.39.2) determines the joint limit $L \rightarrow \infty$, $\eta \rightarrow 0$ for one exact length. What is the leading constant for fixed $\eta \in (0, 1)$? How does the answer depend on a general numerical semigroup of allowed lengths? The gap function g_S supplies an explicit family of lower bounds.
6. **Extend the obstruction to polynomial phases with prescribed lengths.** A degree- d phase on a progression is controlled by several finite differences. Seek a higher-degree analogue of the mixed-radix construction that forces progression steps into a useful divisibility class while retaining the tiling obstruction. The goal is a matching necessity theorem for a carefully stated polynomial-partition bound, rather than only an upper recurrence estimate.
7. **Quantify the characteristic-five phase rigidity.** The proof forces harmonic alignment and $\cos(5\theta) \rightarrow 0$ at optimal secondary order. Turn the deficit below $2^{3/4}/3$ into explicit bounds for $|b/(\kappa\delta^{-1}u^2) - 1|$, the relative phase error, and the fourth-power Fourier tail. A bound in L^2 would require additional information and should not be inferred from these tail estimates.
8. **Analyze mixed torsion groups.** The norm penalty caused by order five is tied to the order of the dominant character. In an odd-order group supporting both order-five and larger-order characters, determine which spectral regime maximizes the local cube count under additional constraints. The unrestricted supremum and a supremum conditioned on the dominant character order are different problems.
9. **Improve common slice refinement through joint structure.** The exponent in Theorem II.103.6 is a product over all sampled slices. A structural theorem for the vector of slice values might avoid some of this repeated loss. The target should give one common partition directly, with explicit exceptional mass and list size, so that interpolation can use it without another refinement.

10. **Optimize localization when the child width is large.** The factor $1/3$ is sharp for the width-independent cap used here. The transport proof actually needs $tw \leq |J|$, where $t(u-1) \leq b-1$. When a large lower bound for w is already known, the worst width-two obstruction disappears. A width-dependent localization rule could improve the constant and perhaps the finite thresholds used in Section 16.
11. **Close the Section 16 parameter recurrence.** Substitute the actual affine-class count, anchor count, exceptional budgets, and slice profiles into the gluing theorem. Determine control functions that are closed under every step of the induction. The source’s displayed final comparison is not justified by the local construction alone. A useful deliverable would be a checked recurrence with explicit initial values and a proof of its solution, followed by a complete dependency audit.
12. **Formalize the sharp lower bounds first.** The numerical semigroup and mixed-radix arguments are finite, relatively short, and independent of the difficult structural steps in the original proof. They provide a realistic first kernel-checked addition. Then formalize the exact cube identities and the transport lemma. Maintaining a clear distinction between source statements, repaired statements, and new refinements will make later integration substantially easier.

V.95 Build instructions and package contents

Source 23, delivered Appendix B.

The ZIP contains one complete LaTeX source, its compiled PDF, the figure files, three exact verification programs, their recorded outputs, a figure-generation script, a source manifest and a Makefile. The article does not require access to the original papers or previous reports in order to compile. All mathematical sections are in the single file `gowers_sharp_thresholds.tex`.

With a standard TeX Live installation, run

```
pdflatex -interaction=nonstopmode -halt-on-error gowers_sharp_thresholds.tex
pdflatex -interaction=nonstopmode -halt-on-error gowers_sharp_thresholds.tex
pdflatex -interaction=nonstopmode -halt-on-error gowers_sharp_thresholds.tex
```

Alternatively, `makepdf` runs these three passes. The exact checks are reproduced by `makecheck`; they need Python 3 and no external packages. Regenerating the optional figure requires NumPy and Matplotlib, but the generated PDF figure is already included. The source manifest records the inspected repository revision and source URLs. No Lean source or compiled proof certificate is included.

V.96 Examples, boundary cases, and reproducible checks

Source 24, delivered Section 10.

V.96.1 Three structural examples

Example V.96.1 (An affine map has no vertical obstruction). If $\phi(x) = T(x) + a$ on B , where $T : G \rightarrow H$ is a group homomorphism, then $F_k = \{0\}$ for every k . Equal domain sums produce

equal output sums because both sides contain the same number of copies of a . The extraction theorem therefore returns all of B , without paying the generic factor kC^{2k+1} .

Example V.96.2 (A small nontrivial fibre with an active avoidance step). Let $p = 101$, $B = \{0, 1, 2\}$, $k = 2$, and $\phi(0) = \phi(1) = 0$, $\phi(2) = 1$. The only conflicting two-term domain sum is $0 + 2 = 1 + 1$, so

$$F_2 = \{0, 1, -1\}, \quad Q_2 = 3.$$

The avoidance length in (II.79.5) is $L = \lfloor 99/(2 \cdot 2) \rfloor = 24$. The choice $d = 2$ works: the multiples $2j$ with $1 \leq j \leq 48$ are neither 1 nor -1 modulo 101, and symmetry handles negative j . One colour fibre contains $\{0, 1\}$. This is an order-two Freiman restriction, while the entire map is not. The example exercises the nonconstant-output, nonzero-length part of the proof rather than merely the $L = 0$ pigeonhole case.

Example V.96.3 (Different objectives select different cores). Theorem II.74.1 is appropriate when the original threshold $\delta^2 m/2$ and the 90% conclusion must be preserved. For an additive application, the one-sample choice $\beta = p^2/16$ trades a smaller common-neighbour count for a larger core. The popular-mass cancellation then makes that trade profitable. There is no universal rule that more samples improve the final structural estimate.

V.96.2 Finite checks supplied with the article

The companion `verify.py` uses only Python’s standard library. All inequalities tested are evaluated with integers or exact rational numbers. The recorded run completed the following checks:

Check family	Cases
Cubic supporting-line inequalities on a rational grid	4,040
All incidence matrices with four indices and three ambient points	4,096
Weighted moment identities with deterministic random inputs	100
All nonempty symmetric four-vertex graphs, allowing loops	1,023
All nonempty subsets of $\mathbb{Z}/q\mathbb{Z}$, $q \in \{3, 5, 7, 11\}$	2,212
Graph maps for vertical-fibre and extraction checks	3,216

Table V.96.1: Exact finite regression checks. All passed. Among the graph-map checks, 60 exercised $Q_k > 1$ and $L > 0$ simultaneously.

For the incidence matrices, the program enumerates every ordered three-sample, verifies the exact expectation identity, and checks that the best score is at least $49u^3n^2/54$ with u equal to the actual mean codegree. For each small graph it verifies the one-sample score, the pruning inequality, and the common-intermediate walk bound. For each small additive set it checks both popular-mass estimates and all three rounded conclusions of Corollary II.77.2.

The fibre checks verify the injection into $(k + 1)\Gamma - k\Gamma$, the cardinality inequality, the existence of an allowed scalar, and the Freiman property of the constructed colour fibre. All full-domain maps $\mathbb{F}_p \rightarrow \mathbb{F}_p$ for $p \in \{2, 3, 5\}$ are tested at order two, together with 60 three-point-domain maps over $\mathbb{F}_{101}$ and $\mathbb{F}_{503}$. The latter are generated by a fixed random seed; the checks themselves remain exact.

These experiments can catch sign errors, threshold errors, and incorrect constants. They do not prove the theorems for arbitrary sets or all orders. In particular, the finite-field-vector hashing theorem is proved above but is not part of the supplied finite regression suite. The JSON report states the scope explicitly.

V.96.3 Constructive content and its limits

The core-selection proofs are finite algorithms. One can compute codegrees, score every allowed sample, choose a maximum-score sample, and prune its bad-degree vertices. In the one-sample argument there are only m candidate samples, once the neighbourhood table is known. The four-walk tuple injection proves the difference bound; an implementation need not enumerate D^4 to select the set.

The extraction step is also constructive after F_k is known: compute L , search the nonzero scalars for an allowed d , and take a largest colour fibre. Computing the exact defect fibre can itself be expensive as k grows. No claim of an efficient general-purpose algorithm for arbitrarily large k is implicit in these existence proofs.

V.97 Integration with the inspected Lean development

Source 24, delivered Section 11.

V.97.1 The inspected snapshot

Repository observations refer to commit

2e0553b0c8a6c9c93221156cc83e95d68ee8bb07.

The relevant directory is

Combinatorics/Ramsey/Lean/GowersSzemerédi.

The statement module `Sections06_07.lean` contains `HasDenseIntersectionCore`, `lemma_7_4`, `lemma_7_5`, and `corollary_7_6`, with the source bounds listed in Table F.29.1. Its `proposition_7_3` is stated for finite sets in an integer-vector group. The module explicitly records the primality and density hypotheses needed at the corresponding interfaces [113].

The proof file `Proofs07DRC.lean` uses `DRCIndex := Fin 5`. It defines a common-sample core, a bad-pair count, and a score equal to the square of the core cardinality minus ten times the bad-pair count. Its finite-counting lemmas express sums over samples as fifth powers of codegrees. These are the exact identities that should be parameterized, not discarded.

The file `Proofs07BalogSzemerédi.lean` uses popular *sums* instead of popular differences, while citing `lemma_7_4_holds` as its selection input. Its early auxiliary lemmas include representation-count bounds and an energy identity. The use of sums is compatible with the argument here, but requires a sign-adjusted walk identity; it should not be changed silently.

[write] **6 October 2026; sources 21–27.** *Checked at HEAD 2dfe46f44.* `HasDenseIntersectionCore`, `proposition_7_3`, `lemma_7_4`, `lemma_7_5` and `corollary_7_6` are at `Sections06_07.lean`, lines 156, 135, 167, 183 and 197; `DRCIndex` at `Proofs07DRC.lean`, line 21, and `lemma_7_4_holds` at line 536. All four files have the same blobs at HEAD as at this source’s pin. The form of `proposition_7_3` in every abelian group is formal as `proposition_7_3_group_holds` (`Proofs07BalogSzemerédi.lean`, line 854); see the note in Section F.29.

V.97.2 A minimal mathematical interface for the refactor

A parameterized DRC layer should expose the identity

$$\sum_{v \in V^t} |K_v|^2 = \sum_{i,j} |A_i \cap A_j|^t, \quad (\text{V.97.1})$$

together with its bad-pair analogue. Both identities are integer counting statements before normalization. A separate real-valued lemma can then turn a positive score average into an existential core. This separation avoids interleaving casts, sampling combinatorics, and nonlinear real inequalities.

For the cubic specialization, the main new arithmetic obligation is (II.74.4). A rational formulation can clear denominators and use the factorization

$$s^3 - 3b^2s + 2b^3 = (s - b)^2(s + 2b), \quad b = 7u/6.$$

The negative branch is handled by monotonicity on $[0, u/2]$ and the endpoint value $u^3/108$. The rational constant $49/54$ is preferable to the algebraic optimum for a first implementation.

A graph-certificate layer should take as inputs the exact values $|D|$, $|K|$, the bad-degree threshold, and the common-neighbour threshold. It should return the injection into four labelled edge values and the relative difference bound. Only the final numerical corollary should substitute $\tau = \kappa/2$ or replace p by a lower bound.

V.97.3 Retaining the repository's popular-sum convention

For the sum graph, an edge between a and b is labelled by $a + b$. A walk a, b, v, c, a' then gives

$$(a + b) - (b + v) + (v + c) - (c + a') = a - a'.$$

The four labels still recover the intermediate vertices from fixed endpoints, so the same fibre injection and cardinality estimates apply. The energy identity and the estimate $\tau m|D| \leq pm^2$ use popular sum representations instead. This provides a direct route to the existing module without a wholesale rewrite of its representation-count infrastructure.

V.97.4 The fibre layer and its formal obligations

The proposed fibre lemma should be stated for a graph in a product of abelian groups. Its proof requires only finite-set membership in an iterated sumset and injectivity of

$$(y, (x, \phi(x))) \mapsto (x, \phi(x) + y).$$

The nonempty-graph hypothesis must be retained when cancelling $|\Gamma|$. The growth estimate should then be imported in the exact form (II.78.3), with exponent $(k + 1) + k$.

The prime-cyclic avoidance layer should separately prove that $1 \leq j \leq kL < p$ implies invertibility in $\mathbb{F}_p$, count forbidden nonzero scalars, and establish the integer-division inequality $k(Q - 1)(L + 1) \geq p - 1$. The $Q = 1$ branch should bypass the division by $Q - 1$ entirely. Treating positive and negative multiples as unrelated would lose the improved constant in Theorem II.79.3.

Finally, graph energy must be identified with `phiAdditiveCount`. A new order- k theorem should be proved first, and the source's order-eight theorem recovered as a weakened corollary. This preserves existing downstream statements while making stronger constants available to later work.

V.97.5 What would constitute formal verification

The results in this article have not been added to the repository or checked by Lean. Source inspection establishes the existing interfaces, not successful compilation of a modified proof. A completed formalization would include the parameterized finite identities, all injection and threshold lemmas, the final order- k compiler, and a kernel-checked proof of the displayed order-eight bound, with no new axioms or admitted proof holes. The Python regression suite is not a substitute for any of these obligations.

V.98 Further research questions and concrete next steps

Source 24, delivered Section 12.

The questions below are proposed research targets. They are not presented as a list of established famous open problems, nor as claims that the literature has been exhausted. Each is tied to a specific loss or limitation exposed by the proofs.

Question V.98.1 (The actual dense-intersection extremal problem). *For fixed δ , determine the largest fraction $f(\delta)$ such that hypothesis (II.74.1) always supplies a core with 90% of its ordered pairs above threshold $\delta^2 m/2$ and size at least $f(\delta)n$. Is the power δ^3 an artefact of the sample-core construction? Seek matching incidence constructions or a stronger lower bound before making an optimality claim.*

The theorem here gives $f(\delta) \geq \sqrt{C_3}\delta^3$. The scalar sharpness proof does not supply an upper bound for f : its two-point laws may fail to arise from set intersections. A productive first step is to formulate the finite incidence optimization with the positive-semidefinite Gram constraints kept.

Question V.98.2 (Can codegree geometry rescue two samples?). *Does positive semidefiniteness, nonnegative incidence factorization, or control of diagonal entries force a positive two-sample score in a range where the scalar relaxation is negative? Alternatively, can actual incidence families approximate the scalar near-extremizers from Theorem II.75.1?*

A resolution would identify whether the obstruction in (II.75.5) is genuinely combinatorial or only an information-loss barrier. This is a sharper target than simply asking for “better dependent random choice.”

Question V.98.3 (Optimal profile-sensitive sampling). *Given an explicit codegree matrix, how much can one improve the certificate by choosing a nonuniform law ν , a different number of samples, or tuple-dependent thresholds? Can a useful optimization algorithm return a small exact certificate that a proof assistant can verify independently of the search procedure?*

The weighted identity in Theorem II.73.1 is already a correct verification interface. The remaining task is an effective and mathematically justified search strategy, not a new probabilistic existence principle.

Question V.98.4 (Higher-arity scalar envelopes). *For respected arrangements involving r indices, optimize the moment-defect bound in Corollary II.73.2, including the choice of sample number and defect penalty. Which choices minimize the eventual exponent after several structural reductions?*

A natural first case is $r = 3$ with two prescribed badness thresholds. The scalar objective becomes piecewise polynomial, suggesting a finite supporting-line or supporting-polynomial certificate. Its compatibility with actual higher-order intersection tensors remains a separate issue.

Question V.98.5 (The smallest possible vertical-fibre exponent). *Given $|\Gamma - \Gamma| \leq C|\Gamma|$, what is the best universal bound for $|\{y : (0, y) \in k\Gamma - k\Gamma\}|$? Can $2k + 1$ in (II.79.3) be reduced, perhaps under an additional hypothesis on the domain projection or the codomain?*

The first meaningful cases are $k \geq 2$; at $k = 1$ a graph has no nonzero vertical defect at all. Both upper bounds and examples must respect the graph condition. General small-doubling examples without injective first projection do not automatically answer this question.

Question V.98.6 (Sharper extraction from a given symmetric defect set). *For $F \subseteq \mathbb{F}_p$ symmetric and containing zero, what is the largest guaranteed size of a set $P \subseteq \mathbb{F}_p$ satisfying $(kP - kP) \cap F = \{0\}$? Can a nonprogression choice of P improve the extraction fraction beyond the interval-avoidance bound for structured defect sets?*

The proof of Theorem II.79.3 only needs such a set P : a translate of P captures an average fraction $|P|/p$ of the outputs. Its arithmetic-progression construction is explicit but need not be extremal for a particular F .

Question V.98.7 (Mixed-torsion codomains). *Extend the extraction theorem to general finite abelian codomains with quantitative dependence on their invariant factors. Can the prime-cyclic progression method and finite-field hashing be combined without multiplying all the losses from the primary components?*

The obstruction is concrete: the equations $jd = w$ need not have a unique solution when j is not invertible, and a random homomorphism need not send every nonzero defect uniformly to a common target. Any extension should state exactly which torsion parameters enter.

Question V.98.8 (End-to-end threshold optimization). *Optimize all structural parameters jointly along the Section 7 pipeline, using the actual energy spectrum rather than a single energy lower bound. How much is gained by combining the full profile certificate (II.76.3), the exact defect count Q_k , and a density-dependent popularity threshold?*

Equation (II.80.5) solves the one-parameter version with coarse energy information. The next version should produce an explicit certificate and compare actual retained sizes, not just formal powers of γ .

Question V.98.9 (Propagation into later sections). *Which later approximate-homomorphism and respected-arrangement lemmas remain valid with their hypotheses unchanged after replacing the Section 7 interfaces by the stronger ones here? After tracing every use, what fully explicit improvement results in the complete 2001 quantitative argument?*

This is a finite but nontrivial dependency-audit problem. Improving one intermediate exponent does not justify replacing every occurrence of a source constant mechanically. The intended outcome should be a complete theorem with all thresholds rechecked, not a heuristic extrapolation to a global record.

Question V.98.10 (A parameterized, kernel-checked structural library). *Can the DRC score identity, graph-walk injection, fibre compression, and quantitative compiler be implemented once over general finite sets and abelian groups, then instantiated both at the original constants and at the improved ones?*

A successful implementation would make future improvements local: new scalar inequalities or new energy inputs could be plugged into unchanged combinatorial proofs. It would also expose exactly which constants are consequences of counting identities and which are chosen for convenience.

V.99 Conclusion

Source 24, delivered Section 13.

The main methodological lesson is to postpone coarse substitution. Keeping the exact codegree distribution allows a cubic certificate that preserves the original dense-intersection threshold. Keeping the actual popular-edge mass cancels four otherwise costly density powers in a walk count. Keeping only the vertical obstruction to Freiman coherence reduces the sumset growth exponent from $4k$ to $2k + 1$, while its symmetry improves the extraction prefactor.

These refinements yield complete local theorems, including the explicit order-eight bound $2^{-295}\gamma^{103}|B_0|$ and the modern-input family (II.80.2). Their scope is precise: proved Section 7 improvements and generalizations, a sharp scalar optimization, and a concrete formalization programme. No unverified propagation through the full Szemerédi argument is needed for any of the conclusions stated here.

V.100 A compact proof and constant ledger

Source 24, delivered Appendix A.

The self-contained order-eight route uses the following exact chain:

$$\begin{aligned}
E(\Gamma_0) &\geq \gamma m^3, \\
\tau &= \gamma/2 \quad (\text{or use the actual energy first}), \\
p &\geq \gamma/(2 - \gamma) \geq \gamma/2, \\
|K| &\geq pm/\sqrt{2}, \\
|\Gamma_1| &\geq |K|/2 \geq 2^{-3}\gamma m, \\
C_1 := \frac{|\Gamma_1 - \Gamma_1|}{|\Gamma_1|} &\leq 2^{11}p^{-2}\tau^{-4} \leq 2^{17}\gamma^{-6}, \\
Q_8 &\leq C_1^{17}, \\
|B| &\geq \frac{|\Gamma_1|}{8Q_8} \geq \frac{2^{-3}\gamma m}{2^3(2^{17}\gamma^{-6})^{17}} \\
&= 2^{-295}\gamma^{103}m.
\end{aligned}$$

When the energy hypothesis is an inequality, either use $\kappa = E(\Gamma_0)/m^3$ throughout and weaken at the end, or retain γ as a lower bound in the popular-energy split. Both give the displayed chain.

For the cubic selector, the arithmetic certificate consists of

$$\begin{aligned}
L(s) &= 3(7u/6)^2s - 2(7u/6)^3, \\
s^3 - L(s) &= (s - 7u/6)^2(s + 7u/3), \\
-9(u/2)^3 - L(u/2) &= u^3/108, \\
L(u) &= 49u^3/54.
\end{aligned}$$

All constants in these two ledgers are rational except the harmless square root in the intermediate core-size bound. The supplied test program checks the final exponent identities separately from the finite combinatorial examples.

V.101 Package contents and rebuilding

Source 24, delivered Appendix B.

The package contains the article source and PDF, the exact `verify.py` regression program, its recorded `verification_results.json`, a README with scope and build instructions, and a source-provenance note. The article’s bibliography is embedded in this single `.tex` file; no external bibliography processor is required.

From the package directory, the PDF can be rebuilt with

```
pdflatex -interaction=nonstopmode -halt-on-error
gowers_section7_refinements.tex
```

Run the command three times to stabilize the table of contents and cross-references. The line break above is typographic: the command and filename belong on one shell line. The exact finite checks are reproduced with

```
python3 verify.py -output verification_results.json
```

No network access or third-party Python package is required by the test program. A conventional LaTeX installation with the packages listed in the preamble is sufficient for the article.

V.102 Repository integration and verification record

Source 25, delivered Section 9.

V.102.1 Interface crosswalk

A suitable standalone destination is

```
Combinatorics/Ramsey/Research/GowersSzemerédi/arrangement-degeneracy-codimension/.
```

This package does not modify the repository, its ledger, or existing formal proofs. It supplies a separately labelled research manuscript.

<code>arrangementMoment</code>	Theorem II.88.1	Split the minimal Walsh degree and the span of the vectors b_i .

Source interface	Result here	Integration point
<code>GeneralArrangement.IsD egenerate</code>	Theorems II.89.1 and II.90.1	Separate block-parity witnesses; preserve the modular-multiple condition exactly.
<code>degenerateGeneralArran gementCount, lemma_15_4</code>	Theorem F.30.1	Add a refined theorem with $d \geq 2$ and $N > 2d$ prime; retain the old statement for its wider parameter range.
<code>lemma_15_5, arrangemen tSelectionExponent</code>	Theorem II.92.1	Supply an explicit threshold and exact repetition count before deciding whether to weaken them to the existing statement.

For a first formalization, using $\mathbb{Z}/N\mathbb{Z}$ with N prime would minimize changes to the existing definitions. The extension to an abstract finite field can then be a generalization of the new result. The geometric codimension statement need not be formalized to obtain the finite counting bound: pivot-coordinate bijections and finite linear-map fibre cardinalities suffice.

The hyperplane enumeration should be a separate finite combinatorics lemma. In particular, the quotient by $a \sim \lambda a + \mu w$ must not be replaced by the simpler but incorrect quotient $a \sim -a$. The two-value classes have six representatives, not two. Likewise, the constant cross-section fibre in Theorem II.88.1 must not be omitted; it is the source of the exact $(q-1)q^{-2d}$ term.

No Lean source is included with placeholder proofs. This avoids giving unverified code the appearance of a checked formal result. A natural implementation order is Walsh expansion, pivot ranks, the two-row fibre count, projective classes, union bounds, and finally selection.

V.102.2 Exact computations supplied with the manuscript

The script `code/verify.py` uses only Python's standard library. Its saved output is `data/verification.json`. The executed checks are as follows.

- (1) Direct integer-projective and finite-field enumeration of the hyperplane classes for $d = 1, \dots, 5$, matching 0, 4, 51, 484, 4225; evaluation of the closed formula through $d = 9$.
- (2) An exact characteristic-5 check for $d = 3$, obtaining 57 rather than 51 hyperplanes.
- (3) 1550 instances of the Walsh moment identity, and 315 seeded minimal-layer rank tests, with cube dimensions up to six.
- (4) All 3240 non-block-parity ternary sign classes for $k = 1, d = 2$ over each of $\mathbb{F}_5$ and $\mathbb{F}_7$. For each class the full base-coordinate count is obtained from exact ranks of the two affine equations, over all cross-sections. The maximal probabilities are respectively 29/625 and 55/2401, exactly the bound of Theorem II.88.1.
- (5) Exact counts for the sharp witness with $(d, q) = (1, 5), (2, 5), (2, 7), (3, 7)$, and rational checks of the one-factor Riesz coefficients for $n = 8, 16, 32, 64$.

All these checks passed in the recorded run. They test finite cases, normalizations and algebraic identities; they do not replace the general proofs. In particular, the script does not enumerate every

full arrangement, does not simulate the selection theorem, and does not run Lean. The source audit and README in the archive repeat these boundaries for repository intake.

[write] 6 October 2026; sources 21–27. *Checked at HEAD 2dfe46f44.* Every name in the table exists in Sections14_15.lean: `walshCharacter` (line 310), `signedWalshMoment` (line 329), `arrangementMoment` (line 346), `GeneralArrangement.IsDegenerate` (line 354), `degenerateGeneralArrangementCount` (line 364), `lemma_15_4` (line 402), `arrangementSelectionExponent` (line 409) and `lemma_15_5` (line 414); the file has the same blob as at this source’s pin. The predicate requires all moments, including the empty monomial and the last coordinate, and excludes modular multiples, as the definition here does. The suggested separate directory was declined: the manuscript is printed in this report.

V.103 Further research questions

Source 25, delivered Section 10.

Question V.103.1 (The exact second-order term). *For fixed k, d , determine whether a field-independent coefficient $C_{k,d}$ exists such that*

$$Z_{k,d}(q) = (k + H_d)q^{D-1} + C_{k,d}q^{D-2} + o(q^{D-2})$$

over sufficiently large characteristics, and compute it in the first nontrivial cases. Theorem II.90.1 proves that non-parity witnesses already contribute at this order. Intersections of the known hyperplanes and overlaps among codimension-two witness loci must both be counted.

Question V.103.2 (Compressing the second-order constant). *Replace $U_{k,d} = (3^{2d2^k} - 3^{2d})/2$ by a substantially smaller explicit constant. Many ternary patterns have identical or nested moment loci. The minimal-layer rank $k - s$ suggests separating witnesses by Walsh support before applying the union bound, rather than assigning every remaining witness the same q^{-2} cost.*

Question V.103.3 (The full cross-section arrangement). *Determine the intersection lattice and characteristic polynomial of $\mathcal{H}_d$. For $d = 2$, the exact union count is (II.90.5); for larger d , a structural description would replace the Bonferroni estimate with an exact formula for $v_d(q)$. The classical finite-field method for hyperplane arrangements [98] is a natural framework, but a full analysis of this specific balanced ternary quotient is not supplied here.*

Question V.103.4 (Small-characteristic classification). *Find a closed formula for $|\mathcal{H}_d(\mathbb{F}_q)|$ when $3 < p \leq 2d$, and classify the additional components in characteristics 2 and 3. Example II.89.2 shows that replacing the characteristic assumption by “ q sufficiently large” is not valid. A satisfactory answer should identify the modular balancing terms and the altered affine orbits, rather than merely give numerical tables.*

Question V.103.5 (Efficient detection of degeneracy). *Given an arrangement, detect a nontrivial ternary moment relation without scanning 3^n patterns. The present classification supplies a cheap first-stage test using $k + H_d$ hyperplanes; a useful second stage would exploit the structured Walsh moment matrix and return a verifiable witness. The difficulty is ternary dependence, not ordinary linear kernel computation, since the moment matrix has many more columns than rows in the applications.*

Question V.103.6 (A selection mechanism with a larger advantage). *Can a different nonnegative selection kernel distinguish respected and non-respected arrangements by more than the ratio $1 + 2^{1-n}$, while retaining manageable degeneracy conditions and pointwise probabilities in $[0, 1]$? Better exceptional-set counting alone does not remove the exponential loss in (II.92.12). Higher Fourier support may improve the advantage but introduces coefficient relations beyond ternary ones.*

Question V.103.7 (Uniform extension to other defining relations). *Replace $w = (1^d, -1^d)$ by an arbitrary nonzero coefficient vector w with $\sum_j w_j = 0$. Which support and coefficient conditions force every non-parity witness to have codimension at least two? The rank argument indicates the role of the support of w , but the exact projective hyperplane count and the exceptional low-support cases require a separate treatment.*

Question V.103.8 (End-to-end quantitative propagation). *Integrate the explicit selection threshold into the corrected multilinear-piece and final density-increment arguments in ProveIt. Track both the field-size threshold and the retained arrangement density. Only such an end-to-end calculation could justify a claim about an improved final Szemerédi or van der Waerden bound. The current manuscript deliberately stops short of that claim.*

V.104 Conclusion

Source 25, delivered Section 11.

The full arrangement moment system is more rigid than the one-polynomial estimate used to count its exceptions. A lowest nonzero Walsh layer gives an explicit diagonal linear minor. At the sole remaining adjacent layer, the last-coordinate moments force a second independent equation, except on already visible cross-section degeneracies. As a result, all codimension-one exceptions are classified and their exact number is $k + H_d$, with H_d given by a balanced ternary projective count.

This yields an asymptotically optimal local replacement for Lemma 15.4, a finite-field and arbitrary- d purification theorem with explicit parameters, and a concrete reduction of the ambient-size cost of the exceptional set. The unresolved issues are correspondingly more focused: second-order geometry, compression of the residual witness family, and improvement or replacement of the Riesz-product selection advantage.

V.105 Source comparison and remaining questions

Source 26, delivered Section 5.

V.105.1 The precise repository interface

The mathematical source pin is commit

`c94998a5db18ba63c815a3bf6c3877a0fde91930`.

At that pin, `Section05.lean`, lines 242–259, defines the proposition `corollary_5_8` [116]. It assumes disjoint two-comparable proper modular progressions covering A , local degree-at-most- k polynomial correlations, and $\alpha > 0$. Its length conclusion is

$$\frac{(N/M)^{1/K}}{8}, \quad K = (k!)^2 2^{(k+1)^2},$$

and its density conclusion is $\delta + \alpha/16$. The original paper prints an $\alpha/8$ gain in Corollary 5.8, on printed page 493 (PDF page 29). The source comment records that this conclusion was corrected to the $\alpha/16$ actually supported by the proof. We compare with this pinned corrected interface rather than silently switching between the two constants.

The definition of `PolynomialOn 1 Finset.univ` is an existential coefficient sum over `Fin 2`: it expands to $c_0 + c_1x$ [117]. Thus the affine hypothesis here is exactly the degree-one source condition, not an extra linearization assumption. At $k = 1$, $K = 16$. For every modulus $N \geq 2$, Corollary I.41.3 replaces the source’s length $(N/M)^{1/16}/8$ by $(N/M)^{1/3}/8$ and the gain $\alpha/16$ by $\alpha/3$, with no added scale premise. Nonempty parents are automatic in that source specialization: positive correlation implies $A \neq \emptyset$, and comparability would force all parents to be empty if any one were empty. Their disjointness then gives $M \leq N$, so $N/M \geq 1$ and the larger exponent indeed strengthens the old length bound throughout the nonvacuous range.

The separate source file `Proofs05Corollary58.lean` defines a scale-qualified repair with a common target and lower bounds ensuring that the needed recurrence and phase-freezing estimates apply [118]. Its theorem derives that repaired proposition from `corollary_5_6`. Those added scale conditions are not premises of the displayed catalogue predicate. The argument here supplies a written, threshold-free proof of the full degree-one specialization; it is not a Lean implementation of that specialization.

[write] **6 October 2026; sources 21–27.** *Checked at HEAD 2dfe46f44.* The pinned lines 242–259 of `Section05.lean` are unchanged (same blob), and `corollary_5_8` is still open in the ledger; `PolynomialOn` is at `Definitions.lean`, line 222, and `corollary_5_8_with_scale_holds` at `Proofs05FullPartition.lean`, line 94. The “full degree-one specialization” holds trivially when $N/M \leq 2^{48}$ (note in Section F.31).

The remaining source modulus $N = 1$ is vacuous: its balanced function is identically zero, so the positive-correlation hypothesis cannot hold. Thus the written result covers every modulus in the source’s degree-one specialization. Higher-degree phases are outside the present theorems. The output is proper modular geometry, as encoded in the pinned Lean definitions; it need not satisfy every ordinary-integer geometric convention of the original paper.

V.105.2 The classical mechanisms and the limited novelty claim

Gowers’s proof contains the Dirichlet input and the square-root modular-to-integer decomposition: see Lemma 5.4, the one-axis Lemma 5.12, and its whole-partition consequence Lemma 5.13 [1]. The product almost-cover in Appendix I.44 is an elementary explicit wrapper around this type of construction.

Zhao’s Lemma 6.4.5 partitions an interval into phase-flat progressions on the cube-root scale under an explicit size threshold; Lemma 6.4.6 uses such a partition in a Roth density increment [100]. This provides a direct reason not to portray the cube-root exponent or phase partitioning as new. Lewko’s 2026 preprint uses moments of progression sums in Section 5 and extraction of a genuine integer progression in Section 6 [101]. It likewise provides precedent for these methods; it is not invoked as a proof of our exact local-cover statements.

The contribution established in this report is the explicit threshold-free local-cover combination, its exact-mass formulation and correlation-dependent tradeoff, relative to the pinned repository interface. A comprehensive literature-priority investigation has not been completed. The numerical constants are convenient and are not claimed optimal.

V.105.3 Questions that remain open here

1. Can the explicit $(N/8)^{1/3}$ ceiling in the strongest exact-mass formulation be relaxed? It arises from our sufficient condition $N \geq L^3$ for removing nonproper directions; it does not restrict the simpler normalized-cover or comparable-parent conclusions.

2. Can correlations be used more efficiently to obtain an α -independent square-root guarantee? Theorem I.41.2 proves only an α -dependent square-root alternative.
3. Which exact constants and gains are optimal for this local-cover interface? The ceiling/floor losses, $\pi < 4$, and positive-mass averaging leave deliberate slack.
4. What is a threshold-free higher-degree replacement for the phase-flat refinement, and how would its small-correlation regime be handled? No such result is supplied here.
5. Can the elementary pair-counting, residue partition, and signed-mass lemmas be formalized and then composed into the precise all-modulus $k = 1$ predicate? No Lean theorem was produced or kernel-checked in this report.
6. Can the integer-box almost-cover be connected to a source-faithful exact-partition and base-loss interface? Appendix I.44.1 identifies the two distinct obligations.

V.106 The exact companion and reproducibility

Source 26, delivered Section 6.

The Python companion uses only the standard library, integer arithmetic, and exact rational arithmetic for its mathematical checks. Its role is diagnostic: finite tests can expose a wrong midpoint, a pair-counting failure, an omitted endpoint, or an invalid rounding convention. They cannot prove the arbitrary-parameter theorems, which are proved in Sections I.42–I.43.

The companion checks cover ordered modular pair counts and the exact variance identity in its permitted range, all-direction coset covariance and bad-direction removal, elementary Dirichlet residue cells and lossless balanced chunking, the exact cover-mass identities, and a regression distinguishing the reduced and unreduced midpoints. The command-line bound is finite and capped. The optional larger run changes the finite coverage, not the proof status. The source archive’s README gives the exact commands and coverage labels printed by the final companion.

The offline builder compiles the supplied trusted TeX in fresh external staging, runs tests and diagnostics in normal and optimized Python modes, rejects inventory mismatches, and writes a deterministic ZIP with an exact public-file manifest. It does not download dependencies or require network access. Reproducing the PDF byte-for-byte requires the same TeX toolchain and fonts. The file-handling checks and disabled shell escape are useful safeguards for this trusted-source workflow; they are not a sandbox guarantee for hostile TeX or a concurrently malicious filesystem. The archive includes all source and tests required for its stated checks.

V.107 Verification and repository integration

Source 27, delivered Section 12.

V.107.1 What the supplied computation verifies

The package contains a single main verifier, `code/verify.py`, and its exact rational data, `code/exact_certificate.json`. The default verifier uses only the Python standard library. It reconstructs the certificate from scratch and checks that it agrees with the stored file. It verifies the 484/459/15

class inventory, every line and point incidence, the 7296 rank certificates, and the exceptional-prime set $\{2, 3, 5, 7\}$. It also enumerates the balanced profile classes for lengths 4, 6, 8 in characteristics 2, 3, 5, 7, 11, checking all fifteen instances of Theorem II.95.1.

A deterministic additional check constructs all 170 large-characteristic core profiles in the cases $(k, d) = (1, 2), (2, 2), (3, 2), (4, 2)$, chooses bases satisfying (II.97.5), and verifies every squarefree moment exactly modulo the chosen prime. These checks test the signs and normalizations in the Boolean-core formula; they are not substitutes for its proof.

The optional `--subset` mode uses NumPy to perform the independent exhaustive tests in Table II.100.2. It does not import or use the rational line certificate. The command

```
python3 code/verify.py -subset -write
```

regenerates the stored verification report. Without NumPy, omit `--subset`. The optional `--minors` flag, together with `--write`, writes the individual nonzero-minor witnesses; these are reconstructible and need not be stored to reproduce the proof.

No floating-point computation is used to prove a count, rank, or incidence. No numerical experiments are presented as evidence of novelty. The code has been executed successfully for the distributed report; its results are recorded in `verification.json`.

V.107.2 Source correspondence

The following map uses names actually present in the inspected statement file [120]. It proposes new additions; it does not claim that any such additions already exist.

Table V.107.1: Correspondence with the existing Section 15 interface.

Existing name or mathematical object	Proposed use
<code>GeneralArrangement</code>	Preserve the labelled side, bases, and cross-section parameters. Specialize the present field to a prime $\mathbb{Z}\text{Mod}N$ first.
<code>arrangementParityCoefficient</code> <code>arrangementMoment</code>	Identify it with $e_{\varepsilon,j}$ and prove all its moments vanish. Prove the Boolean expansion and the paired moment identities. Do not delete any subset index.
<code>GeneralArrangement.IsDegenerate</code>	Retain the ternary condition and modular-multiple exclusion; build the quotient-direction counting lemmas around this existing definition.
<code>degenerateGeneralArrangementCount</code>	Multiply the probability bounds by N^D to obtain integer-count statements, then cast to the existing real-valued bound style.
<code>lemma_15_4</code>	Add a sharper companion theorem, preserving the original statement and proof ledger rather than silently changing them.
<code>lemma_15_5</code>	Use the new bound only at the place where an absolute exceptional-arrangement budget is needed; rerun that threshold calculation separately.

V.107.3 A realistic formalization order

A useful first milestone is Theorem II.96.3 over odd prime fields, because it strengthens the existing interface without requiring the most detailed core classification. Its dependencies are: intrinsic moment vanishing; Boolean inversion; codimension-one counts in U ; the elementary rank lemma; and a finite union bound. The ternary affine-orbit formulas can initially be replaced by finite cardinalities of explicitly defined sets, then proved as a separate arithmetic-combinatorial layer.

A second milestone is Theorem II.97.8: formalize the minimal Boolean degree split, the affine core form, the width-two classification, and the rank-four intersection statement. The all-characteristic version should use a finite-field abstraction rather than force the extension-field argument through $\mathbf{ZModN}$ for composite N , which is generally not a field.

The exact theorem has a distinct final dependency: a verified finite certificate checker for rational row spaces and reduction modulo permitted primes. It should not be imported as an unproved numeric fact. A modest initial target is to formalize (F.32.10), whose proof is entirely symbolic and independent of that certificate.

V.107.4 Provenance and status

The source audit identifies the inspected repository blobs and the printed paper pages. These are snapshots, not a claim that a rapidly changing `main` branch will retain those contents. The research directory already contains numerous local refinements; the present article focuses on the degeneracy count rather than reproducing phase partitions, additive cube expansions, or random-selection redesigns. The targeted review did not establish a complete literature priority result. The mathematical statements here should be treated as proposed research contributions with proofs supplied for review.

No GitHub write, source replacement, or claim of formal completion is made by this delivery. The suggested repository location is

```
Combinatorics/Ramsey/Research/GowersSzemerédi/  
arrangement-degeneracy/
```

with later integration into a merged report at the maintainer's discretion.

V.108 Further research questions

Source 27, delivered Section 13.

The following questions are deliberately more specific than a request to improve the global theorem. Some are finite classification problems suitable for immediate computation; others require genuinely new structural input. They are proposed questions of this article, not claims that each has been previously advertised as an open problem in the literature.

Research question V.108.1 (The cross-section intersection statistic). Find a closed form, recurrence, or efficient exact algorithm for $b_{2,d,p}$ in (II.99.1), particularly in the stable large-characteristic regime. This would turn Corollary II.99.2 into a numerical second-order formula for every d , including the $d = 8$ case of the selection step.

A first computational target is $d = 3$, where there are 51 hyperplanes in large characteristic. Enumerating their pair intersections is much smaller than enumerating all arrangement coefficient arrays. The main issue is recognizing coincident rank-two spans, not sampling arrangements.

Research question V.108.2 (A third-order structural theorem). Classify the non-core coefficient directions whose zero sets on the regular region contribute at order q^{-3} . Can the residual term $(R_{k,d} - S_{k,d})q^{-3}$ be replaced by an explicit third-order family plus an $O(q^{-4})$ remainder?

The proof already distinguishes directions with a new cross-section constraint from those forcing two separate rank-two base systems. The latter are automatically fourth-order. Exploiting this distinction before using the final union bound should reduce the next-stage inventory.

Research question V.108.3 (Higher Boolean degree and increasing codimension). For a direction of minimal Boolean coefficient degree r , how many independent base-coordinate systems can be extracted simultaneously? Is there a sharp codimension bound in terms of $k - r$ and the ranks of the vectors c_A modulo s ?

The rank-four argument uses just two coordinates outside one minimal set. A broader theorem would need to control overlaps among right sides and cross-section constraints, rather than repeatedly invoke independence without checking it.

Research question V.108.4 (Intermediate characteristics). Determine the exact number of core directions for $5 \leq p \leq 2k + 2$ and the corresponding intersection pattern. The cases $p = 2, 3$ are answered by Theorem II.99.3, and the width argument already supplies the large-characteristic core count for $p > 2k + 2$. What is the sharp threshold, and which smaller characteristics have genuinely different core families?

The remaining gap is to classify profiles below the proved no-wrap threshold, not merely to replace $p > m$ by $p > 2k + 2$. For larger alphabets, however, new affine symmetries and wider Boolean profiles must be accounted for.

Research question V.108.5 (Exact counts in fixed small characteristic). Find exact formulas for $\Delta_{1,2}(p^a)$ in characteristics 2, 3, 5, 7. The first two coefficients in characteristics 2, 3 are already determined here; the large-characteristic polynomial fails at $q = 5, 7$.

The same line-enumeration method can be performed directly over $\mathbb{F}_p$ and then lifted to extensions. In characteristic two, the subset-sum test must be reformulated because the two integer signs have the same residue.

Research question V.108.6 (Beyond eight vertices). For $(k, d) = (1, 3)$ or $(2, 2)$, is the degeneracy count eventually a polynomial in q outside finitely many characteristics? If not, what arithmetic variation occurs in the lower-dimensional residual loci?

Only the hyperplane part is automatically a polynomial count in fixed characteristic. The full higher-degree moment varieties need not inherit that property without further analysis, so polynomiality is a question, not an inference from the eight-vertex example.

Research question V.108.7 (Minimal moment families). Which subfamilies of squarefree moments retain the same first-order or second-order degeneracy asymptotics? Can one preserve the cubic-remainder bound while discarding a substantial fraction of the moment conditions?

The paired moments used in Lemma II.94.2 identify a necessary organizing principle. A universal fixed subfamily would have to work for every possible minimal Boolean coefficient set; the weaker definition mentioned after Gowers’s Lemma 15.4 is not automatically sufficient.

Research question V.108.8 (Efficient degeneracy testing). Can the quotient-profile structure yield a deterministic test significantly faster than enumerating 3^m relations or 2^m subset sums, while producing a short certificate of either degeneracy or nondegeneracy?

The exact low-dimensional example suggests preprocessing by cross-section hyperplanes and then by the core family. A useful algorithm must also handle the remaining coefficient directions without an exponential worst-case scan disguised as preprocessing.

Research question V.108.9 (Relative distribution rather than ambient bounds). For arrangement collections arising from a dense set or a product-property hypothesis, can the hyperplane contribution be bounded by their actual cross-section distribution instead of the ambient L_d/q union bound?

Proposition II.101.1 loses a factor equal to the reciprocal of collection density. Avoiding it would require structural information about the collection, not just its cardinality. A weighted version could be directly relevant to selection arguments.

Research question V.108.10 (The single-pair regime). Classify the dominant degeneracy loci for $d = 1$ and arbitrary k . Does the common final coordinate reduce the problem to a useful arrangement of relations among two translated cubes?

Proposition II.102.1 settles only $k = 1$. The rank collapse is systematic and should be treated as a separate geometry rather than forced into the $d \geq 2$ proof.

Research question V.108.11 (A complete Section 15 threshold audit). Substitute the cubic bound into the actual corrected Lemma 15.5 proof and propagate the resulting threshold through Lemma 15.6 and the later inverse steps. Which local improvement survives, and which other parameter becomes dominant?

This is the precise route from the present local result toward a global quantitative consequence. It needs a complete ledger of dependencies and is not settled by the numerical comparisons in Table II.101.1.

Research question V.108.12 (Formal proof and verified finite certificates). Formalize the sharp first-order theorem, then the second-order theorem for $d = 2$, and finally the exact eight-vertex count with a small verified rational-incidence checker. Which combinatorial and finite-dimensional linear-algebra interfaces can be reused in other parts of Gowers’s proof?

The separation between symbolic general proofs and a finite exact certificate makes this an incremental task: useful theorems can be checked before the final enumeration infrastructure is complete.

V.109 Conclusion

Source 27, delivered Section 14.

The large coefficient in Gowers’s degeneracy bound is not the true leading coefficient of the exceptional-set count. After coefficient arrays are identified modulo the intrinsic relation, the bad set

splits into three quantitatively different parts: explicit hyperplanes, a classified family of rank-two affine systems, and a residual set costing at least three powers of the field size. The resulting estimates are sharp to first order in all characteristics and to second order once the cross-section hyperplane statistic is known. For two pairs of cross sections that statistic is explicit, and in the smallest nontrivial case the entire count is an exact polynomial.

These results answer concrete local questions about the proof: what actually creates the leading degeneracy, how much of the ternary union bound is avoidable, and which additional moment constraints supply the extra savings. They also leave a clear boundary between established local proofs, a finite certified specialization, and the further work needed for new global consequences.

V.110 Reproduction checklist and file inventory

Source 27, delivered Appendix A.

The archive contains the following files, all under one top-level directory:

File	Purpose
<code>article.tex</code>	Complete self-contained LaTeX source
<code>article.pdf</code>	Compiled article
<code>README.md</code>	Results, scope, and reproduction instructions
<code>SOURCE_AUDIT.md</code>	Primary sources and repository snapshot identifiers
<code>FORMALIZATION.md</code>	Proposed Lean dependency plan
<code>Makefile</code>	Build and verification targets
<code>code/verify.py</code>	Exact reconstruction and independent checks
<code>code/exact_certificate.json</code>	Rational lines, points, and incidences
<code>verification.json</code>	Results of the executed checks

Run `makepdf` with a standard TeX installation containing the packages listed in the preamble. Run `makeverify` for the standard-library checks, or `makeverify-full` for the additional NumPy subset-sum checks. The article uses no external figures, fonts, bibliography database, shell escape, or network requests. Its source can therefore be compiled independently of the verifier.

V.111 An explicit interface for further development

Source 28, delivered Section 9.

*Delivered part heading of source 28: **Verification, integration, and further research***

V.111.1 What a downstream theorem can use

The first part produces four distinct kinds of information. Keeping their roles separate makes an integration into the existing argument more transparent.

1. **A prescribed spectrum.** The character set is obtained from $g(s) = |X_s|$, with the threshold in equation (F.33.2). No label information is used to choose it. A downstream step can therefore synchronize spectra using domain data.

2. **A large set of valid labels.** The set Y has the explicit relative size $\alpha p(\alpha)/20$. It is selected after seeing ϕ . Its projection to G need not have that relative size, since distinct points in a fibre can have multiplicity.
3. **An exact map on a neighborhood.** The identity equation (F.33.7) holds for all eligible pairs in Y . The local map respects order-seven relations on its entire Bohr domain, not only on the differences realized by pairs of Y .
4. **Quantitative geometric control.** Both the frequency count and the radius are explicit. The resulting volume estimate is equation (II.127.2). For an existing application that fixes the old frequency set, corollary II.126.2 supplies a compatible restricted map with the same retained fraction and radius.

These properties should be passed as separate fields in a theorem interface. A mere assertion that a large subset admits some additive model would discard the original-spectrum information. Conversely, requiring a global homomorphism $G \rightarrow H$ would strengthen the conclusion beyond what the proof establishes.

V.111.2 A proposed formalization sequence

The following names are suggestions for new modules, not existing or compiled files in this deliverable. The current article is a mathematical and reproducibility supplement; it contains no Lean code.

Table V.111.1: Suggested proof interfaces and their dependency order.

Suggested module	Mathematical content to formalize
<code>WeightedAnchor</code>	Finite energy bounds, local error transfer, and the single weighted selection of an anchor in section II.123.
<code>LogWindowSelection</code>	The two center intervals, their clipped inclusion probabilities, the weighted boundary estimate, and equation (II.124.8).
<code>AnchoredModalRepair</code>	Comparison between the $b_d(w)$ -weighted error and uniform direction error, existence of a unique modal increment, and the row restriction.
<code>StoppedPathRigidity</code>	Subprobability transport with killing on exits and wrong labels; shared endpoint coupling; the order-fifteen conclusion.
<code>OriginalSpectrumModel</code>	Fourfold smoothing, radius selection before the anchor is chosen, the final slice, and the order-seven local model.
<code>UFourDualCosine</code>	The integer sign counts 222, 111, 27, 1, including the separate order-three quotient calculation.
<code>HigherUniformityGap</code>	The concentration inequalities, rational threshold comparison, two-harmonic certificate, and positive first-variation recurrence.

The logarithmic-window argument has a finite alternative to an abstract probability-space formalization. Each point contributes finitely many center endpoints: its two outer endpoints and its two inner endpoints in each coordinate. Together with the endpoints of I_q, I_R , they partition the center rectangle into finitely many open rectangles. Membership in W , membership in its boundary,

and the selection functional are constant on each such rectangle. Their weighted finite average is the integral in equation (II.124.8). A rectangle with value at least the average yields the chosen window. Endpoints have zero area and can be handled independently.

This reduction also suggests a constructive, though not optimized, selection algorithm. Compute the anchor statistics, sort the center endpoints, evaluate one interior center in each nonempty rectangle, and choose a maximum of the functional. Real logarithm comparisons would still need certified handling for an exact implementation; the present program tests the finite mechanisms and does not implement a certified end-to-end model finder.

V.111.3 The existing formalization remains a separate object

The inspected status ledger explicitly distinguishes established theorems, conditional results, migrated statements, and outstanding obligations [131]. Several prerequisites in Sections 13, 16, and 18 remain open at the pinned snapshot. In particular, the source records the need for additional bilinear extraction, a closing quantitative comparison in the multilinear stage, and sufficiently strong phase removal and iteration thresholds.

Some of those issues concern the statement being formalized rather than an isolated numerical loss. Examples recorded by the repository include integer representatives of box axes, shared partition requirements, and a transcription's closing comparison whose proposed direction has already been disproved. None can be discharged by inserting a better Section 10 constant. A proposed integration should first state the exact downstream predicate and then verify that the local model satisfies it.

V.112 Exact computations and the scope of verification

Source 28, delivered Section 10.

V.112.1 Finite checks of the selection and transport mechanisms

The script `code/verify_selection.py` uses integers and exact rational arithmetic for its main checks. The fixed seed is 20261006; the output records the examples and all summary counts. Its coverage includes:

- 648 exact window-membership cases, including 200 exact core inclusion probabilities and 192 clipped noncore cases;
- 10 368 boundary-probability comparisons, including 6 272 positive boundaries;
- exact integration of the weighted selection functional over 1 483 constant-membership cells from four abstract examples;
- 14 376 shifted-interior checks in three cyclic integer fibre profiles, using 84 proper windows, with 168 actual exits before the boundary is removed;
- all 314 721 ordered pairs of the 561 probability distributions on three symbols with denominator 32, testing the modal-agreement implication;
- 228 coupled two-path checks, including positive label error and mass leaving the selected set;

- stopped-prefix and longer common-endpoint checks that retain unnormalized surviving mass, together with exact verification of the order-fifteen inequality.

For example, the deliberately conservative long-path budget used in the manuscript is the exact fraction

$$(30 + 210 \cdot 2^{-27}) \left(\frac{1}{31} + 2^{-21} \right) = \frac{4222187282107575}{4362862139015168} < 1.$$

The script also checks the algebraic parameter identities against a rational enclosure of $\log 2$ of width $1/884569308258492$.

A separately labelled numerical section uses actual natural logarithms in three additional profiles, totaling 1 205 cells. The maximum discrepancy between the two evaluations of the expected functional is about $1.49 \cdot 10^{-11}$, within the stated $2 \cdot 10^{-9}$ tolerance. These examples need not satisfy the tiny final invariance parameter. They check the window calculation, not the full approximate-homomorphism theorem. Abstract examples and physical fibre examples are also identified separately in the output.

V.112.2 Exact norm certificates

The script `code/verify_u4.py` uses only integers and rational numbers. It reproduces the following identities and comparisons:

1. the full-cube cosine count and all three pairs of dual coefficients;
2. the order-three count and its phase-dependent minimum;
3. every coefficient of the two-harmonic polynomial, by combining two three-dimensional faces;
4. the five-point example, by exact derivative energies;
5. the seven-point example, both by modular coefficient counting and by direct cube summation in a cubic number field;
6. the rational split at $159/160$, including both alternatives in the universal gap;
7. the exact value of the witness at $b = -1/7$, and explicit one-third-harmonic assignments in dimensions 4 through 8.

The polynomial identity is reproducible by enumerating $4^8 = 65\,536$ choices on one three-face. Group choices by their moment vector and number of third harmonics, then convolve the count polynomial for each vector with the one for its negative. This computes equation (III.70.20) directly. The generic and small-order computations are intentionally separate: replacing equality of integers by congruence changes the answer.

The rational comparison in the universal bound can be checked without decimal approximations. One of its final steps is precisely

$$111 \cdot 3200 \cdot 5147^{16} > 104329 \cdot 5550^{16}.$$

The large integers in the witness are likewise exact. The plot in figure III.70.1 has an explanatory role and is not used to infer the sign of a derivative or locate a global optimum.

V.112.3 Independent review and its limits

The selection proof, the averaged repair, and the higher-order norm argument were separately checked by other reasoning agents during the preparation of this report. This review caught interface details, including nonemptiness hypotheses and the need to describe stopped-path marginals as subprobability laws. It also independently reproduced dual-function counts for character orders 3, 5, 7, 9, 11.

Such review is useful evidence of internal consistency. It is not an external referee report, a proof-assistant certificate, or an exhaustive search for counterexamples. The general theorems stand on their written proofs. The package records exact computations to make sensitive finite steps easier to assess and repeat.

V.113 Further research questions and topics

Source 28, delivered Section 11.

The most useful next projects are those that separate a genuine structural obstruction from a loss specific to the present proof. The following questions are proposed in that spirit.

V.113.1 Selection and local structure

Research question V.113.1 (Are both logarithmic losses necessary?). Can the retained fraction in theorem F.33.1 be improved to $\Omega(\alpha/\log(1/\alpha))$, or even $\Omega(\alpha)$, while preserving an original-domain spectrum with comparable size and radius?

There are two independently selected scales here, for q and R . An obstruction for arbitrary weighted profiles would not automatically be an obstruction for the profiles arising from an additive convolution. A useful first step is to construct or rule out domains whose anchored energy is spread nearly uniformly over both logarithmic coordinates. Correlations forced by the convolution may reduce the number of scales that need to be selected.

Research question V.113.2 (Can the defining frequency count be reduced?). Can one replace $O(\alpha^{-3})$ in the local-model theorem by a smaller density power, or by a bound on an independent generating set of frequencies with a controlled loss of radius?

The present count is Parseval's bound α/λ^2 . The main technical requirement is uniform control of the fourfold convolution under the resulting directions. A spectrum compression argument must record how character combinations change the Bohr radius. Counting independent generators and counting all coefficients above a threshold are different tasks, with different downstream interfaces.

Research question V.113.3 (A general defect–mass–radius trade-off). What is the best simultaneous dependence on an arbitrary order-eight defect ε , retained fraction, and local radius?

The proof fixes $\varepsilon = 2^{-21}$ to keep one readable set of constants. Its intermediate inequalities allow parameters such as the modal threshold, window aspect ratios, direction-hole budget, and Bohr-overlap budget to vary. Optimizing those parameters should produce a family of explicit sufficient trade-offs. Whether such a family is sharp would require examples with genuinely inconsistent labels, not just adverse fibre sizes.

Research question V.113.4 (The exact output order). With the same input defect, can the local model be made to preserve order eight, or arbitrary fixed order, without materially weakening its mass and radius?

The current argument obtains order fifteen on D , then order seven on $D - D$. The restriction to fifteen is the displayed path budget; it is not an impossibility theorem. Better use of correlated label errors, a stronger modal threshold, or a direct relation argument on the difference set may improve the conclusion.

Research question V.113.5 (How much input order is needed?). Which conclusions survive if the order-eight assumption is replaced by order four or order two, while the defining spectrum must still come from the original domain?

The exponent eight enters through the fourfold difference domain, whose fibres have a nonnegative fourth-power Fourier transform. Reducing the input order calls for a different smoothing device or a direct argument that retains the same original-spectrum control. An arbitrary structured subset theorem would not resolve this more specific requirement.

Research question V.113.6 (A certified finite construction). Can the logarithmic selection and modal repair be implemented with certified arithmetic in a running time substantially better than enumerating all relations and all center rectangles?

The existence proof gives a finite search once the statistics are available. Useful algorithmic improvements would include implicit weighted rectangle maximization, sparse convolution when the group permits it, and exact decisions at logarithmic endpoints. The output should include a certificate of every required fibre and relation identity, rather than only a candidate model.

V.113.2 Higher-order norm geometry

Research question V.113.7 (The sharp fourth-order constant). Determine c_4^{odd} , or substantially narrow the interval in equation (III.70.4).

The interval is still wide. On the upper-bound side, the present proof compresses all secondary Fourier coefficients into a single remainder mass. Keeping separate information at χ^3 and χ^5 , or using the dual function of a two-harmonic trial function, could give stronger constraints. On the constructive side, additional phase-aligned odd harmonics may improve the explicit example.

Research question V.113.8 (Do bounded spectral profiles suffice?). Is the fourth-order supremum attained by a function with a uniformly bounded number of Fourier coefficients? Is a two-harmonic family ever globally optimal?

The first variation rules out one character pair, but gives no support bound for a maximizer. One can first investigate the exact finite polynomials for three harmonics and their stationarity conditions. A proof that all further harmonics are unfavorable would be a separate and more demanding step.

Research question V.113.9 (Small torsion versus large character order). How does the optimal constant depend on the allowed character orders, and does a fixed finite cyclic group attain the unrestricted supremum?

The order-three branch of the upper bound and the seven-point polynomial show why congruence aliases must be kept visible. One may define suprema restricted to a fixed exponent, to cyclic groups, or to groups with no characters of small order, then compare them. A limiting Fourier profile on the circle could behave differently from every fixed finite model.

Research question V.113.10 (The asymptotic higher-order constants). What is the behavior of c_d^{odd} as $d \rightarrow \infty$?

Monotonicity makes this a nonincreasing sequence, and equation (III.70.3) supplies one strict bound for every $d \geq 4$. The positive first-variation recurrence proves an obstruction to cosine extremality at each order. It gives neither the rate of decay of c_d^{odd} nor even a positive lower bound uniform in d . Those are distinct extremal questions.

Research question V.113.11 (Stability near the true norm extremizers). If a function has ratio close to c_d^{odd} , what structural information can be forced about its Fourier spectrum?

The dominant-pair parameter p already gives two complementary inequalities, but closeness to our upper estimate should not be confused with closeness to the unknown optimum. A stability theory should begin with an actual extremizer or a proved limiting variational problem. This is also distinct from the near-maximal absolute Gowers-norm problem studied by Eisner and Tao [7].

V.113.3 Returning to the full Gowers argument

Research question V.113.12 (Propagate the local improvements through Section 13). Can the larger spectrum threshold and retained fraction improve the bilinear extraction parameters while maintaining a common grid and the required relation domains?

The first milestone should be a completely stated replacement for one downstream proposition, with its grid, characteristic, and domain hypotheses visible. The original-spectrum corollary offers a conservative route when an existing interface fixes the old threshold. A more ambitious route uses the smaller new spectrum throughout.

Research question V.113.13 (A quantitative repair of the multilinear closure). Which altered induction invariant closes the outstanding Section 16 comparison with synchronized proper partitions?

The repository records that one proposed closing inequality has the wrong direction. Research should therefore seek a new argument or a repaired target bound, rather than attempt to prove that inequality. Candidate invariants should track the graph count, minimum width, common refinement, and integer representatives together.

Research question V.113.14 (An end-to-end explicit density increment). After the remaining phase-removal and partition steps are supplied, what final Szemerédi estimate follows from the strengthened local parameters?

This requires a complete recurrence with all density losses, model changes, rounding terms, and stopping thresholds. The local volume exponent $\alpha^{-3} \log(1/\alpha)$ is useful input, but its effect on the final recurrence cannot be read off from that exponent alone. A strong outcome would be an independently checkable numerical recurrence accompanied by a proof of every transition.

Research question V.113.15 (Comparison with modern inverse-theorem interfaces). Can the original-domain spectral information in the present theorem be retained while substituting a modern quantitative inverse theorem for later parts of the argument?

The quasipolynomial inverse-theorem program [3] is relevant context, but its input and output data differ from this local approximate-homomorphism interface. The research question is to identify a precise bridge and evaluate its full parameter cost. A comparison should use matching hypotheses and outputs before comparing asymptotic labels.

V.114 Source provenance and attribution

Source 28, delivered Section 12.

The comparison baseline is the repository snapshot

`e3125e6982abe2d44bd7cb9369063d4e69d41a2d`.

The source audit included the Section 10 transcription and status ledger, the combined earlier article, the supporting material for later reports, and the incoming characteristic-five, degree-stratification, and sharp threshold manuscripts. The two historical manuscripts most directly relevant to the present result were recovered separately: source 07 for transport-sensitive rigidity and source 12 for dense extension and Bohr radii. This matters because the combined article and its README describe the first five reports and do not exhaust the later collection.

The following attribution boundaries are intentional.

- Gowers’s Section 10 supplies the original local-model strategy, the approximate-homomorphism framework, and the original-spectrum requirement [1].
- Source 07 supplies the prior transport and collision-to-mode viewpoint, including longer paths [133].
- Source 12 supplies prior dense Freiman extension, elementary Bohr regularization, full-fourth-moment smoothing, and the α^5 retention already available in the previous proof [134].
- Source 04 supplies the sharp third-order real norm comparison and the exact quartic cube-count framework [132].
- The present contribution is the logarithmic selection and weighted boundary argument, its directly normalized repair and complete improved parameter chain, and the higher-order norm results proved here.

[write] **6 October 2026; sources 28–33.** *A pin as printed.* The pin of source 07 given in this source’s bibliography ([133]) and in its `data/source_provenance.json` (shipped as `data/28-log-selection-source_provenance.json`) has 39 hexadecimal digits; source 07’s pin is `ae0e895748209f0dd079c6b5ca6df6c6fc065a81`, with a 6 after `6df6c` that is missing here. Recorded, not edited; the other identifiers of that record match the repository (checked at intake). “The combined article and its README describe the first five reports”: at the pin they did; the fifth write of this report covers sources 01–27.

No statement in this report is labelled a resolution of Szemerédi’s theorem’s quantitative optimum. Nor is the cosine calculation described as a refutation of a published conjecture. It settles the concrete question of whether the earlier single-character equality model extends locally to higher orders under the stated hypotheses.

V.115 How to use these results in the ProveIt project

Source 29, delivered Section 10.

V.115.1 Three interfaces, with different domains

The most useful integration is modular. The moment theorem supplies a scalar norm conversion, the stability theorem supplies a structured model together with its selector, and the restriction theorem supplies a large collection of almost entirely respected configurations. Each conclusion has an explicit normalization and domain.

Original location	Present interface	Hypotheses to preserve
Section 3 and Lemma 3.10	Theorems III.68.1 and III.68.3; equation (III.69.7)	The uniform improvement uses real functions with no self-inverse Fourier support. On odd-order groups, centering is sufficient.
Proposition 6.1	Theorems II.110.1, II.111.1, and II.112.1	The hypothesis is proximity to the absolute derivative-correlation endpoint. Selectors have row sums at most one.
Lemma 9.3	The restriction theorems of Section II.120	The ambient domain and codomain are vector spaces over a fixed finite field; all prescribed relations have coefficient sum zero.

Table V.115.1: Connections to Gowers’s paper [1]. The new statements are intended as separately named lemmas with explicit hypotheses.

For the cube application, retain the exact quartic coefficient P_d , then use the smaller factor B_d only when converting $\|f\|_{U^2}^4$ to $\|f\|_{U^d}^4$. This preserves higher-degree terms for whatever counting estimate is being used. In particular, one cannot replace a full cube-expansion remainder by its quartic term without an additional estimate.

For Proposition 6.1, the normalization can be checked directly. An unnormalized derivative sum has N times the normalized Fourier coefficient, and summing its squared magnitude over all h has N^3 times the normalized graph energy. If $|f| \leq 1$ and the full graph sum is at least $(1 - \varepsilon)N^3$, then $T_\phi(f) \geq 1 - \varepsilon$ and $m = \mathbb{E}|f|^2 \leq 1$. Since $T_\phi(f) \leq m^2$, the relative endpoint deficit satisfies

$$1 - \frac{T_\phi(f)}{m^2} \leq \varepsilon.$$

Thus the joint theorem applies in its stated small-defect range. The supplied graph must be defined on all shifts, or extended in a way whose missing shifts are included in the selector defect.

The repository’s formal statement named `lemma_9_3` is a statement for $\mathbb{Z}/N\mathbb{Z}$ with arbitrary nonzero modulus N . The present restriction theorem is for $\mathbb{F}_q$ -vector spaces. It gives a stronger fixed-field local interface, including polynomial retention and a much smaller threshold, but its field-dependent constant is not uniform in N . For $V = \mathbb{F}_p$, allowing p to grow also makes $S_{p,s}$ grow. In that situation the displayed threshold may be larger than every possible $|B|$. The threshold-free conclusion is still valid, but can be as weak as a singleton. This explains exactly why the finite-field result alone cannot replace the all-moduli lemma inside the full original proof.

[write] 6 October 2026; sources 28–33. Checked at HEAD 5d4718772. `lemma_9_3` is at Sections 08_09.lean, line 77, a statement over $\mathbb{Z}/N\mathbb{Z}$ with $N \neq 0$, with the exact companion `lemma_9_3_holds` (Proofs09Restriction.lean, line 376); `proposition_6_1` is at Sections06_07.lean, line 37 (companion

proposition_6_1_holds, Proofs05_10.lean, line 505); lemma_3_10 at Sections01_03.lean, line 340 (companion at Proofs03CubeUpper.lean, line 82). The comparison above is accurate; no statement of this source is formalized.

V.115.2 A proposed formalization order

The proofs separate into components that can be formalized and checked independently. A productive order is the following.

1. **Positive Fourier moments.** Define inverse-pair orbits on the non-self-inverse part of the dual group. Prove the balanced multinomial sub-sum inequality with nonnegative coefficients, then derive the Gowers comparison by the existing recursive norm identity. State the torsion profile separately so that no implicit odd-order hypothesis enters the general theorem.
2. **Repair and integration.** Formalize the majority-repair lemma for arbitrary finite abelian groups and the inequality $\delta \geq 3\theta - 6\theta^2$. Next prove the averaged symmetry identity and integrate a symmetric bicharacter using cyclic coordinates. The latter step should use circle-valued phases; division by two inside the coefficient ring would lose the even-order cases.
3. **Projection and endpoint stability.** Prove the two exact Hilbert-space identities for derivative distance and mixed-array distance. The quantitative self, soft, and mixed theorems then follow from norm inequalities, finite Fourier orthogonality, and scalar estimates with rational constants.
4. **Rank and restriction.** Define the full affine-relation space K_x and the error map on that full space. Prove graph rank $= r + e$, the weighted rank-counting lemma, and the expected signed certificate. Keep the prescribed relation space $\mathcal{R}$ distinct from K_x , since they coincide only on generic tuples.

The present package supplies mathematical statements, full proofs, and executable finite diagnostics. It adds no Lean declarations and does not alter the repository's proof-status ledger. In particular, the experiments below do not certify a new formal theorem.

V.116 Verification and reproducibility

Source 29, delivered Section 11.

V.116.1 What was checked

The three proof families were reviewed independently during preparation. Separate scripts exercise the identities, boundary cases, and examples most vulnerable to normalization or sign errors. Integer and rational checks are distinguished from floating-point diagnostics.

The direct norm checks multiply the cube-vertex values, providing a calculation independent of the derivative/Jensen route used in the proof. The torsion-profile checks include pure two-torsion, mixed torsion, and odd-order groups. The exact sharpness examples use a character of sufficiently large order; its order need not be prime. The additional odd-cyclic examples have one zero value

Check	Arithmetic	Coverage
Norm comparisons	Exact rational	65 direct cube-product cases; 480 further Fourier-convolution profile checks; 25 sharp moment cases; 50 odd-cyclic lower-bound examples
Displayed coefficients	Exact integers and rationals	The 222 balanced four-cube choices, the complete three-cube profile, and 50 instances of the interval lower-bound formula
Restriction	Exact finite fields	Five cases, with 294,881 map-tuple incidence checks, including repetitions, degenerate tuples, multiple relations, and vector-valued images
Quadratic integration	Exact rational phases	96 symmetric bicharacters on eight groups; 11,376 polarization identities and 11,376 derivative identities
Majority repair	Exact finite enumeration	All 65,536 maps $\mathbb{F}_2^4 \rightarrow \mathbb{F}_2$, including 240 nonhomomorphisms meeting the repair hypothesis; all 81 maps $C_4 \rightarrow C_3$
Mixed identities and stability	Complex floating point	80 shift/modulation checks, 96 averaged-symmetry checks, 56 self and 56 mixed reconstructions, and six sharp-rate examples

Table V.116.1: Finite diagnostics included with the source. Counts refer to the recorded runs, not to the number of cases in the general proofs.

and equal numbers of 1 and -1 , giving a second realization of the dimension-independent $1/3$ lower limit.

For restriction, the program enumerates the random maps and checks the exact survival probability λ^{r+e} for individual tuples. It also checks both weighted product bounds. The recorded field computations use $\mathbb{F}_2$ and $\mathbb{F}_3$. The proof over arbitrary prime-power fields uses only finite-dimensional linear algebra and the cardinality of affine spans; no extrapolation from these two fields is needed for that proof.

For quadratic rigidity, rational phase arithmetic verifies integration even when the needed phases have order larger than the exponent of the underlying group. The mixed diagnostics verify the signs in the shift/modulation identity and the affine selector $\rho\psi(h)$. Floating-point agreement is only an implementation check of the displayed identities. The output records its observed maximum residual and the separate exact checks.

V.116.2 Contents and build commands

The source package contains the complete L^AT_EX manuscript, its compiled PDF, the vector figure used in the article, a figure generation script, the four verification scripts, their JSON outputs, a source-audit manifest, a short README, and a Makefile. It contains no copies of third-party papers.

From the package directory, the ordinary build command is

```
latexmk -pdf -interaction=nonstopmode -halt-on-error \
gowers_moments_stability_restriction.tex
```

The verification commands are

```
python code/verify_moments.py --output data/moment_verification.json
python code/verify_coefficients.py --output data/coefficients.json
python code/verify_rank_restriction.py --output data/rank_verification.json
```

```
python code/verify_joint_rigidity.py --output data/joint_verification.json
```

The moment, coefficient, and restriction checks use Python’s standard library. The joint numerical diagnostics require NumPy. Regenerating the scientific figure requires Matplotlib; the supplied figure is already sufficient to compile the manuscript. The Makefile provides `all`, `verify`, `figures`, and `clean` targets.

V.117 Further research questions

Source 29, delivered Section 12.

The questions below are unresolved by the present arguments and, where specified, by the inspected project reports. They are proposed research targets rather than assertions of exhaustive priority or universal open-problem status.

V.117.1 Sharp higher-norm comparisons

Question V.117.1 (Determine the fourth-dimensional constant). *What is the exact value of c_4^{odd} ? The present bracket is*

$$(8/111)^{1/4} \leq c_4^{\text{odd}} \leq (8/35)^{1/4}.$$

Is a single Fourier inverse pair extremal, or can a more distributed spectrum produce a larger ratio?

The autocorrelation moment theorem is sharp, but its equality model has a substantial gap in the recursive norm estimate. A sharp proof must control these two losses together. A useful first target is an improved inequality for $\|\Delta_h f\|_{U^3}^8 - |c_f(h)|^8$ averaged over h , expressed in Fourier quantities compatible with the pair-concentration estimate. The direct four-cube expansion offers a second route, through positive families of balanced vertex labelings.

Question V.117.2 (The limit of the extremal constants). *Determine*

$$c_\infty^{\text{odd}} = \lim_{d \rightarrow \infty} c_d^{\text{odd}}, \quad \frac{1}{3} \leq c_\infty^{\text{odd}} \leq \frac{1}{2}.$$

Can the upper bound $1/2$ be approached by a family of real centered functions as the dimension increases?

The proof of the upper bound takes a supremum over groups and functions for each d . One cannot interchange that supremum with a limit for a fixed function without justification. A productive experiment would compare long interval models, sparse Fourier models, and bounded functions with increasingly complicated sign patterns. Any numerical search should report the group, the dimension, and the normalization separately.

Question V.117.3 (An optimal profile at fixed self-inverse mass). *For a prescribed τ , determine the sharp bound for $\|f\|_{U^2}^4 / \|f\|_{U^d}^4$ among real functions having self-inverse Fourier fourth-mass fraction τ .*

The polynomial $K_m(\tau)$ solves the corresponding uniform autocorrelation-moment problem. Passing to the Gowers norm can introduce a further gap, just as it does at $\tau = 0$. It would be useful

to know whether a sharp norm profile depends only on τ , or whether finer information about the orders and relations of the active characters must also enter an effective bound.

Question V.117.4 (Stability for actual norm near-minimizers). *Can a function whose ratio is close to the sharp higher-norm constant be classified up to a controlled error in a natural norm?*

Proposition III.68.2 gives U^2 concentration only when the autocorrelation moment is near its own lower bound. It is not a stability theorem at the unknown sharp Gowers ratio. A successful result would identify the relevant models first and then show that near equality in all necessary steps forces proximity to those models. For an L^2 conclusion, additional amplitude or spectral-tail information may be needed.

V.117.2 Joint rigidity beyond the present endpoint

Question V.117.5 (Optimal constants and a larger defect range). *What are the best constants in the joint function-selector stability theorem, and how far can its small-defect range be enlarged while retaining a single global quadratic model?*

The 24 and 192 constants are explicit common bounds, not optimized values. The positive-amplitude example forces squared function error of asymptotic order $\varepsilon/2$; the soft-selector example forces missing graph mass of order ε . Sharper homomorphism-testing theorems, such as [122], can refine the repair step. The remaining losses come from the derivative projection and the passage from the repaired graph to one Fourier atom. Studying the exact two-point and cyclic examples may indicate which losses are intrinsic.

Question V.117.6 (Remove the row constraint in a natural normalization). *Find a joint stability theorem for ambiguity or mixed short-time Fourier transforms when the selector is not required to have row sums at most one.*

The class of exact models must then change with the normalization. Subgroup-localized quadratic phases and isotropic phase-space supports occur in the existing exact theory [123]; critical- L^p Gowers near-extremizers likewise allow coset localization [7]. A well-posed next theorem should first specify its energy normalization and model class, then measure distance both in function space and in phase-space support. Extending the current statement verbatim would suppress genuine exact examples.

Question V.117.7 (Higher-degree joint derivative selectors). *For $d \geq 4$, can near-maximal capture of $(d - 1)$ -degree derivative structure recover a degree- d phase together with the supplied family of derivative models, with a linear squared-error bound?*

The quadratic proof repairs a map into an abelian character group and then integrates a symmetric bicharacter. Higher degree introduces compatibility among several differences and, in small characteristic, nonclassical circle-valued polynomial phases. A useful first case is a finite vector space over a field of characteristic greater than the degree, with all derivative models supplied on the full domain. The challenge is simultaneous consistency of the models, beyond pointwise applications of an inverse theorem.

Question V.117.8 (Effective reconstruction and certification). *Can the joint theorem be converted into an algorithm that reconstructs Q, ψ, ρ from approximate derivative data and outputs a checkable error certificate?*

The proof already identifies operations: choose large Fourier coefficients, apply majority repair,

test symmetry, integrate the bicharacter, and find a Fourier atom after twisting. Exhaustively performing those operations is finite but can be expensive. The algorithmic questions concern sample complexity, treatment of noisy coefficients, and time bounds in the group size or its presentation. For a small fixed group, an exact reconstruction tool would also be a useful bridge to formal verification.

V.117.3 Sharper and broader restriction

Question V.117.9 (Optimize the complete rank profile). *Given the counts $G_{r,e}$ and $U_{r,e}$, optimize the exact certificate*

$$\sum_{r,e} (\eta G_{r,e} - U_{r,e}) \lambda^{r+e}$$

over the admissible values $\lambda = q^{-t}$. What information less expensive than the full profile still gives a substantial improvement over the worst-case coefficient?

The present theorem replaces all respected graph ranks by s and all unrespected error ranks by one. Data with few low-rank bad tuples or many low-rank good tuples can behave much better. The signed polynomial is already an exact certificate, so concrete improvements can be proved without changing the random selector. The last coordinate of that selector already supplies a uniform affine offset. Moreover, a mixture of restriction depths gives a convex combination of the corresponding signed certificates, so it cannot improve their maximum for a fixed full profile. A remaining question is whether a different selection family can avoid the loss associated with discrete depths.

Question V.117.10 (Quantify degeneracy more geometrically). *Can the product $z \prod_{i=0}^{s-2} (z + q^i)$ be replaced by a bound in terms of actual affine-span intersection statistics of B , or by a sharper universal polynomial?*

At each step the proof permits up to q^{j-2} points in the current affine span, independently of earlier choices. This is sufficient for the linear threshold but often very wasteful. Cap sets, subspace-evasive sets, and sets with small intersections with low-dimensional flats should give stronger estimates. Any improvement for the generic higher-error-rank theorem must still control low-domain-rank unrespected tuples; a generic rank gap alone says nothing about them.

Question V.117.11 (An efficient deterministic restriction). *Can one find a map A meeting the expected signed certificate in time polynomial in a useful input representation?*

Exhaustive search over all linear maps proves effective existence. Conditional expectations may derandomize the proof, but computing the conditional potential from the full tuple list can already cost $|B|^\ell$. A meaningful algorithm should exploit the relation matrix, Fourier structure, or a compressed rank profile. It should also distinguish the task of exhibiting B' from the task of certifying its proportion of respected relations.

Question V.117.12 (A useful growing-modulus analogue). *Can actual-rank or multiplicity-sensitive survival improve the prime-cyclic restriction theorem with constants that remain useful as the prime grows, and eventually handle arbitrary cyclic moduli?*

This is the principal unresolved obstacle to using the fixed-field improvement as a replacement for the original Lemma 9.3. The prior manuscript [136] also contains a Fejér-filter method in cyclic groups. A possible direction is to track the survival of repeated or low-rank configurations inside that filter, while accounting for approximate relations and torsion. The finite-field product proof by itself gives no such uniformity.

V.117.4 From local estimates to a global bound

Question V.117.13 (A complete quantitative substitution). *Which of the local improvements in the accumulated project reports survive a full quantitative inverse and density-increment argument, and what explicit progression-free-set bound follows?*

This question requires a dependency calculation, not just a list of smaller constants. Every invocation must preserve its domain, normalization, density loss, length threshold, and error budget. The fixed-field and cyclic branches should be analyzed separately. A useful deliverable would be an executable symbolic recurrence, verified against the corrected statement of each invoked lemma, and then compared with an established global result such as [2]. The present article supplies several improved local inputs for that project.

Among these directions, three immediate targets have especially clear interfaces: improving the explicit c_4^{odd} bracket, optimizing the complete finite-field rank certificate on structured sets, and formalizing the joint stability theorem over arbitrary finite abelian groups. Each can be pursued independently and tested against a fully specified theorem above.

V.118 Repository crosswalk and exact validation

Source 30, delivered Section 10.

V.118.1 Pinned interfaces

The repository pin used for the direct statement comparison is

8d65d3c9febe4d0e9efe945e11b53af5f19d1435.

The relevant files are under `Combinatorics/Ramsey/Lean/GowersSzemerédi/`. The inspected blob identifiers are

File	Git blob identifier
<code>Definitions.lean</code>	97113b7afa6925a2dd4b76641eeaeff09597ab6a
<code>Section10.lean</code>	302e8a223f56dcdabf29f30ca3c80ac62a7adbfc

The definition of `bohr` uses the centered absolute residue of kd bounded by ρN , exactly matching the normalization here. `section10Translate` translates by addition of d . `InducesDifferenceMap` expresses the identity $\psi(x) - \psi(y) = \psi_1(x - y)$ used in this manuscript.

Repository interface	Proposed mathematical companion
<code>lemma_10_10</code>	Theorem II.130.2, first for cyclic groups and $0 < \rho \leq 1/4$; retain the intrinsic shell inequality as a reusable lemma.
<code>corollary_10_11</code>	Corollary II.132.1 with unchanged overlap margins; Corollary II.132.2 as a separate larger-domain theorem.
<code>lemma_10_12</code>	Theorem II.133.1 and Corollary II.133.2, with all finite-fibre nonemptiness hypotheses explicit.
<code>theorem_10_13</code>	A future propagation target, not a theorem proved by this package. Its spectrum and parameter construction must be audited separately.

The earlier local-quantitative-refinements README and the transport-rigidity integration note were inspected to avoid simply repeating the existing work on phase partitions, cube expansions, transport rigidity, and restriction arguments. That inspection is not an exhaustive text comparison with every pending manuscript. The source audit accompanying this package distinguishes pinned reads from earlier moving-branch reads.

V.118.2 Formalization route, not claimed formalization

The shortest plausible implementation begins with finite sets in $\mathbb{Z}/N\mathbb{Z}$, not with a general Haar-measure library. Useful stages are:

1. Prove the two exit-cardinality identities and the abstract disjoint translation lemma. It is best to index the $2m$ tubes by a sign and a positive integer, so that same-sign and opposite-sign collisions are separate proof cases.
2. Establish a real or integer centered-residue lift lemma through $2m$ steps. This is the only non-return ingredient and is where the $\rho \leq 1/4$ hypothesis is used.
3. Prove the three-cell partition with unambiguous endpoint assignments. Translate each nonempty cell to inject it into the original Bohr set. Do not count only the image of the character map without accounting for its fibres.
4. Combine the cardinal inequalities before introducing real division. Keep the exact intrinsic form and obtain the 3^r form as a corollary.
5. Prove the general tree budget and the induced difference identity; then translate the tuple formulation of Freiman relations into the repository's exact API.
6. Prove the compatibility theorem with the two exceptional direction sets measured against $|A|$. Keep positivity of the common fibre as an explicit premise.

No Lean file has been compiled for the new results in this package. The presence of a proposition-valued declaration in the existing catalogue is not a substitute for a proof. The proposed theorem names and dependency order in `FORMALIZATION.md` are implementation suggestions, not a report of successful kernel checking.

[write] **6 October 2026; sources 28–33.** *Checked at HEAD 5d4718772.* `Definitions.lean` and `Section10.lean` have the blobs recorded above; `lemma_10_10`, `corollary_10_11`, `lemma_10_12` and `theorem_10_13` are at lines 362, 374, 401 and 473 of `Section10.lean`, with exact companions `lemma_10_10_holds` and `corollary_10_11_holds` (`Proofs10Bohr.lean`, lines 277, 607), `lemma_10_12_holds` (`Proofs10Induced.lean`, line 145) and `theorem_10_13_holds` (`Proofs10Main.lean`, line 1292); `bohr` is at `Definitions.lean`, line 282. No statement of this source is formalized; the names in its `FORMALIZATION.md` (shipped as `30-fixed-radius-bohr-FORMALIZATION.md`) are proposals. The recorded output `results/verification.json` named above is shipped as `data/30-fixed-radius-bohr-verification.json`.

V.118.3 Exact finite checks

The delivered `code/verify.py` uses only the Python standard library, integers, and rational fractions. It uses explicit exceptions rather than `assert`, so optimization mode does not disable validation. The run recorded in `results/verification.json` completed the following checks:

Suite	Recorded coverage
Cyclic Bohr sets	13 404 parameterized sets; 135 182 admissible shift/length instances, of which 11 642 have positive exit count.
Unequal-width product groups	500 seeded parameterized sets; 4 588 admissible instances, including 676 with positive exit count.
Four-vertex budgets	269 759 finite intersection inequalities, including repeated positions and negative lower bounds.
Sharpness	Exact interval equality and exact 3^r packing examples.
Scalar and local-map tests	1 140 rational parameter checks; a nonconstant map from 73 points into $\mathbb{Z}$, with induced orders two and three on a nine-point neighborhood.
Spiked sets	Exhaustive product-group membership for $s = 1, 2, 3$; explicit cyclic parameter certificates for $s = 1, \dots, 6$.
Cyclic brute force	Direct enumeration of the rank-three CRT example with $N = 90\,799$, $ B = 19$, and defect 3.

The cyclic suite enumerates moduli 2 through 32, with character representatives from 0 through $\lfloor N/2 \rfloor$, six rational widths, and $m \in \{1, 2, 3, 4, 8\}$. It includes lists of size at most two throughout and lists of size three through modulus 17. Opposite frequencies give the same single-coordinate constraints, which is why these representatives suffice for the stated suite. The product suite is seeded, not exhaustive. Every qualifying tube is explicitly checked for non-return, pairwise disjointness, and containment in the *direction-dependent* enlarged shell.

The large CRT certificates check all elementary parameter inequalities, pairwise gcd conditions, distinct explicit frequencies, and exact step values. They do not enumerate their enormous ambient groups; the general membership and cardinality formulas for those groups are established by Theorem II.135.3. The finite checks are diagnostics and reproducibility evidence, not proof-assistant certificates or an independent review of the general argument.

V.119 Research questions and next integration targets

Source 30, delivered Section 11.

The first three questions concern the central quantitative limitation. The later ones concern effective use and formal integration. None is assumed in any proof above.

Question V.119.1 (Optimal exponential base). *Determine the asymptotic growth of $\mathcal{L}_r$. Is its exponential rate $\sqrt{3}$, 3, or another value? Even improving either side of (II.135.8) by an exponential factor would clarify which part of the geometry the box-packing argument loses.*

Question V.119.2 (Prime cyclic groups). *What is the analogue of $\mathcal{L}_r$ when the ambient group is restricted to $\mathbb{Z}/p\mathbb{Z}$ with p prime? Can one realize an exponential boundary obstruction without the transverse Chinese-remainder factors, or does prime order permit a substantially better universal bound?*

Question V.119.3 (Joint sharpness of escape and packing). *Classify, even approximately, the Bohr sets for which $2mb_B(d)$ is close to $|B(3\boldsymbol{\rho}/2)| - |B|$ and the latter is close to $(3^r - 1)|B|$ simultaneously. The separate sharpness examples show why optimizing the two inequalities independently is insufficient.*

Question V.119.4 (Intrinsic growth from spectral structure). *The spectra produced in Section 10 are not arbitrary lists of characters. Can their additive structure, or the structure of the fibre-count function that generates them, force D_B far below 3^r at the original radius? A positive result could combine the intrinsic theorem with information already present upstream, rather than use worst-case rank alone.*

Question V.119.5 (Adaptive anisotropic widths). *When some characters constrain the proof much more tightly than others, can one choose unequal widths before the partial map is constructed so as to optimize the final extension neighborhood? A correct optimization must preserve every earlier invariance premise; choosing widths after the map has been constructed can change the problem.*

Question V.119.6 (Optimal dense-domain extension budget). *For exact Freiman maps, how far can the sufficient condition $(2k - 1)\kappa + 2k\eta < 1$ be improved? Can overlaps among the exceptional sets be exploited uniformly, or are there examples where the tree budget is close to optimal? The question should separate failure of set inclusion $C \subseteq A - A$ from failure of the higher-order relations.*

Question V.119.7 (Compatibility thresholds). *Is the $5/14$ threshold in Corollary II.133.2 optimal under only the explicitly stated pair-overlap and finite-fibre hypotheses? Can target-fibre information improve the condition $\theta < 1/2$ when the two good-value sets are not arbitrary subsets of the common fibre?*

Question V.119.8 (Propagation through Theorem 10.13). *Re-run the complete corrected proof with a separate radius parameter provided by Corollary II.132.1. Determine an explicit replacement for the final local-model radius, while retaining the corrected integer spectrum bound, density conclusion, and nonempty-fibre conditions. This is a concrete next theorem, but it has not been established by a symbolic substitution in this manuscript.*

Question V.119.9 (Global relevance). *After such propagation, which losses dominate the final quantitative Szemerédi theorem? Does removing this power-of-radius loss change only constants, an iterated exponent, or a genuine asymptotic class in a fully specified implementation of the argument? This requires an end-to-end parameter ledger, not just a local comparison table.*

Question V.119.10 (Beyond rectangular character constraints). *For which other finite sets does a small translation admit the same $2m$ non-return property? Can convex constraints on several character coordinates be handled using directional widths, with a covering number replacing 3^r ? The abstract escape lemma already applies once the non-return and enclosure properties are proved.*

Question V.119.11 (Efficient exact growth certificates). *Can one certify an upper bound for D_B substantially below 3^r without enumerating all of G ? Lattice descriptions or compressed descriptions of the character-map fibres may provide smaller exact certificates for large cyclic moduli.*

Question V.119.12 (Kernel-checked integration). *Implement the intrinsic escape theorem, packing theorem, and margin-preserving extension in the repository’s toolchain, followed by an axiom audit. The most important proof obligations are endpoint-safe non-return and opposite-sign tube disjointness; the final scalar inequalities are comparatively small.*

V.120 Conclusion

Source 30, delivered Section 12.

The decisive change is to count translated exits inside a controlled Bohr enlargement, rather than count a boundary in the ambient group and then divide by a small density. The resulting inequality retains the original set and replaces a power-of-width loss by an exponential-rank loss. It gives a substantially larger neighborhood for the dense-domain Freiman step, supports higher-order extension and exact compatibility budgets, and has a matching qualitative obstruction: exponential rank cannot in general be replaced by polynomial rank without further hypotheses. The exact exponential rate and the prime-order case remain specific, well-defined research targets.

V.121 Build, verification, and file layout

Source 30, delivered Appendix A.

The manuscript is self-contained as a single `article.tex`; its bibliography is embedded below. No source paper, repository snapshot, or font file is redistributed. A standard TeX Live or MiKTeX installation with the packages named in the preamble is sufficient.

```
python3 code/verify.py --output results/verification.json
latexmk -pdf -interaction=nonstopmode -halt-on-error article.tex
```

The delivered package also contains `README.md`, `SOURCE_AUDIT.md`, `FORMALIZATION.md`, `Makefile`, the exact verification script, and its recorded output. The Python check suite is deterministic; the product-group sample uses seed 20261006. Build logs and render checks are summarized in `results/build_validation.json`.

V.122 Verification and a proposed formal integration

Source 31, delivered Section 10.

The mathematical proofs are the justification for the universal claims. The accompanying programs check finite identities, constructions, normalizations, and endpoint constants. They distinguish exact integer or rational checks from complex floating-point diagnostics. None of the programs is a proof assistant.

Program	Purpose
<code>code/verify_spectral_rigidity.py</code>	Weyl mass and self-duality; subgroup and phase examples; the quartic equality and inverse formulas
<code>code/verify_weighted_extraction.py</code>	Finite weighted extraction; vertical-defect injection; prime-field progression selection and the order- k condition
<code>code/verify_weight_defects.py</code>	Exact defect inequality and counterexample formulas; selected-graph endpoint diagnostics

The recorded JSON files in `data/` state the actual test ranges and numerical tolerances. Run `makeverify` to reproduce them. The article compiles with pdfLaTeX through `makepdf`, without shell escape or a network dependency. A source ledger records the repository revision and the provenance of the principal inputs.

V.122.1 Interfaces already present in the repository

At the inspected revision, `Sections06_07.lean` defines `proposition_6_1`, `lemma_7_5`, and `corollary_7_6` as propositions. The file `Proofs07FreimanRestriction.lean` proves `lemma_7_5_holds`; its private vertical-fiber bound uses C^{4k} . The proposed change to that local proof is concrete: use (II.116.3), then use the finite progression selection of Theorem II.116.1, and retain weights in the averaging step. Existing statements can be recovered as weaker corollaries.

[write] **6 October 2026; sources 28–33.** *Checked at HEAD 5d4718772.* `proposition_6_1`, `lemma_7_5` and `corollary_7_6` are at lines 37, 183 and 197 of `Sections06_07.lean`; `lemma_7_5_holds` is at `Proofs07FreimanRestriction.lean`, line 267, and its private bound `cor75_verticalFiber_bound` (line 110) is C^{4k} , as the text says. The formal `lemma_7_5` retains $|B|/(8kC^{4k})$ for a prime modulus; Theorem II.116.1 implies its conclusion, as source 10’s theorem already does. Nothing here is formalized.

The spectral argument needs a separate finite complex inner-product layer: Weyl operators, symplectic orthogonality, common eigenspaces, and finite character projectors. The tail-energy identities should be proved first over nonnegative finitely supported functions on an abelian group. This isolates the exact polynomial algebra from the linear-algebra proof of the extremal subgroup.

V.122.2 Suggested order of implementation

1. Formalize the weighted graph extraction and the actual vertical defect set. These mostly use finite sums, finite sets, and the Plünnecke–Ruzsa interface already needed by the repository.
2. Prove (II.107.6), the unequal-pair estimate for C_0 , and the quartic deficit identity over an abstract finite abelian label group. Keep every subtraction in the reals or in a division-free nonnegative formulation.
3. Establish the Weyl mass and self-duality identities, followed by the $3/2$ small-difference lemma and the noncommuting subgroup gap.
4. Prove the trace formula for character projectors and identify their one-dimensional ranges with quadratic coset phases.
5. Assemble the sharp spectral theorem; prove monotonicity and the two quadratic inversions separately. Then derive the full and partial graph corollaries.
6. Formalize the weight-defect decomposition and the two finite counterexample families. Complexity-dependent L^1 estimates and measurement transfer can be added afterward.

This is an integration plan, not delivered Lean code. We did not run the repository’s Lean build and do not alter its proof-status ledger. An ordinary proof, a correct match to the source statement, and kernel verification are distinct requirements.

V.123 Further research questions

Source 31, delivered Section 11.

Research question V.123.1 (The full critical-norm profile). Determine the optimal universal function relating $\kappa(f)$ and $F(f)$ beyond $1 - \kappa < 1/120$. Does the two-state curve remain extremal

on a larger interval, and at which first value do other configurations take over? The cutoff here is sufficient, not a candidate optimal transition.

Research question V.123.2 (Odd-order sharpness). Find the optimal second and higher coefficients in the odd-order infidelity profile. Theorem II.107.3 excludes the universal order-two equality mechanism, but its odd-order envelope is not claimed sharp. A two-state configuration of odd-order label has a different outside fourth moment, suggesting a more refined analysis of phase interference.

Research question V.123.3 (Stability of the extremizers of the envelope). Turn (II.107.4) into a quantitative classification of all near-equality states by their distance to an embedded two-state configuration. The tail concentration is explicit; the remaining task is a sharp phase-alignment estimate for the outside Weyl coefficients.

Research question V.123.4 (The optimal joint graph budget). The separate graph and phase bounds in (II.108.2) are sharp. Determine the exact feasible region of $(\varepsilon, t, z, \beta)$. In particular, replace the valid but not certified-sharp coefficient $1 - 8t(1-t)$ in (II.108.1) by its optimal counterpart, or identify the additional statistic needed for such a formula.

Research question V.123.5 (The actual defect-set geometry). In Theorem II.116.1, optimize the weight retention using the set V_k itself rather than only $|V_k|$. Intervals are a convenient way to avoid nonzero defects, but other target sets may retain substantially more weight for structured V_k .

Research question V.123.6 (Torsion-sensitive target restriction). Extend the finite weighted restriction to composite cyclic and general finite abelian targets. The prime proof uses invertibility of the integers $1, \dots, kL$. A general result should charge the sizes of their kernels and the distribution of the defect set across those kernels, rather than silently importing the prime case.

Research question V.123.7 (Better weighted extraction exponents). Use the square-root mass theorem in Appendix II.118, or a sharper weighted BSG theorem, to improve the powers in (II.116.4) while preserving the originally specified weight. Separate the loss from structural extraction, the choice of one point per fiber, and exact Freiman restriction.

Research question V.123.8 (Replacing the worst fiber size). Can K^{2k+2} be replaced by a profile involving the masses and largest atoms of individual fibers? The present proof already admits the actual mass of the maximum-weight graph as an input. A stronger theorem should retain this distribution through the small-doubling step as well.

Research question V.123.9 (Compatible restrictions across slices). Construct the exact Freiman restrictions for different derivative slices compatibly. This is the missing link between the local correlation-preserving theorem and Gowers' later multilinear integration. A favorable exponent for each slice alone does not establish a favorable global exponent.

Research question V.123.10 (Weights under weaker complexity assumptions). Replace finite Fourier support and a finite number of occupied cosets in (II.109.2) by effective entropy or tail norms. The two counterexamples show that some such hypothesis is necessary. A useful formulation should recover L^1 control without demanding literal sparse support.

Research question V.123.11 (The optimal coupled weight defect). Determine the sharp dependence of $\mathcal{E}(w) - a^4$ on the norm deficit δ , the energy-saturation error η , and the mean a . Proposition II.109.4 gives an exact linear transfer identity. The subsequent fourth-power estimate in (II.109.7) need not be jointly optimal; retain the mean and the eigenbasis collision mass to sharpen it.

Research question V.123.12 (Mixed functions and higher norms). Classify the equality and near-equality pairs in the mixed derivative inequality for two different input functions. For higher Gowers norms, identify an analogue of the spectral subgroup construction and the finite tail-energy envelope. Neither extension follows merely by changing the exponent eight.

Research question V.123.13 (A checked quantitative application). Choose one fixed progression length, integrate the new local interfaces into a complete dependency ledger, and verify every resulting threshold. Only after that calculation would it be justified to claim an improved bound produced by this proof route. Comparison with modern bounds would then be a further step.

V.124 A short dictionary for the extremal geometry

Source 31, delivered Appendix B.

Additive-combinatorial description	Finite operator description
Derivative Fourier coefficient	Weyl matrix coefficient
Normalized squared derivative spectrum q/N	Characteristic-function probability distribution of a pure state
Quadratic phase on a coset	Common eigenstate of a maximal commuting Weyl subgroup
Full-support quadratic phase	Extremal subgroup projecting bijectively onto the translation coordinate
Critical ratio κ	Normalized fourth moment of Weyl coefficients
Tail labels relative to an extremizer	Other characters in its common eigenbasis

This dictionary explains the relevance of the stabilizer literature without imposing a prime-power assumption on the finite abelian group. All operator arguments used in the article were proved directly. For general finite abelian groups, “stabilizer” here means the maximal commuting Weyl-eigenstate description; no transitivity claim for a particular definition of a Clifford group is needed.

V.125 The pinned source and the literature

Source 32, delivered Section 6.

V.125.1 The full degree two source implication

The precise repository target is `corollary_5_8` in `Section05.lean`, lines 242–259, at commit

`c94998a5db18ba63c815a3bf6c3877a0fde91930`.

Direct links are in the references and `SOURCES.md`. This is a comparison with the predicate at that pin, not a claim that its general-degree proof has been formalized or that a repository build was rerun.

The source constant is

$$K = (k!)^2 2^{(k+1)^2}, \quad K|_{k=2} = 4 \cdot 512 = 2048.$$

Its degree-two conclusion is a proper progression with length at least $S^{1/2048}/8$ and density at least $\delta + \alpha/16$. The source uses this corrected gain rather than the original paper's displayed $\alpha/8$.

[write] **6 October 2026; sources 28–33.** *Checked at HEAD 5d4718772.* `Section05.lean` and `Definitions.lean` have the blobs read at the pin (882b17a, 97113b7); `corollary_5_8` still starts at line 242 and is open in the ledger, which records 105 exact companions and 15 open statements. The translations below are accurate: `ModAP.IsProper` (`Definitions.lean`, line 93) is injectivity of the parameterization. The SHA-256 values in `SOURCES.md` (shipped as `32-quadratic-increments-SOURCES.md`) are of the files with one line feed appended, the retrieval convention of source 26's record; source 41's placement records the same finding.

The hypotheses translate without an extra restriction:

1. The source's `PolynomialOn 2 Finset.univ` means there exist three coefficients with $\phi(x) = c_0 + c_1x + c_2x^2$ for every x . This is exactly the coefficient-polynomial convention used here, including composite moduli.
2. The definition `ModAP.IsProper` is equality of carrier cardinality and parameter length. Since the carrier is the image of a finite parameter set of that size, this is exactly injectivity. Despite an informal source comment mentioning wrapping, the definition does not require nonwrapping standard representatives.
3. Empty parents are syntactically permitted by the source, but cannot occur with its other premises. If one parent is empty, two-comparability forces every parent to be empty. Then the cover forces A to be empty, and all balanced correlations vanish, contradicting $\alpha N > 0$.
4. The source assumes $N \neq 0$. Its $N = 1$ case has identically zero balanced function for either possible subset, so positive correlation is impossible. For $N \geq 2$, the identity $|A| = \delta N$ identifies its δ with the density here. Its balanced function and exponential are the same $\mathbf{1}_A - \delta$ and e_N used above.
5. Disjointness, coverage, two-comparability, and the summed correlation agree literally. The source does not require the concluding progression to lie in the cover.

The prefactors 17 and 8 require an explicit comparison; comparing exponents alone is insufficient. In fact, for every $S \geq 1$,

$$\max \left\{ 1, \frac{S^{1/39}}{17} \right\} \geq \frac{S^{1/64}}{8} \geq \frac{S^{1/2048}}{8}. \quad (\text{V.125.1})$$

If $S^{1/64}/8 \leq 1$, the first inequality follows from the singleton bound. Otherwise $S > 8^{64}$ and

$$S^{1/39-1/64} > 8^{25/39} > \sqrt{8} > 17/8.$$

Here $25/39 > 1/2$, and $8 > (17/8)^2$ is the integer inequality $512 > 289$. Dividing gives $S^{1/39}/17 > S^{1/64}/8$. The second inequality in (V.125.1) uses $S \geq 1$. The gain $\alpha/3$ is greater than $\alpha/16$. Thus the very same progression from Theorem F.37.1 satisfies the complete pinned degree-two conclusion at every permitted scale.

V.125.2 Primary literature comparison

Gowers [1], Section 5, develops Weyl-type recurrence and polynomial-to-affine localization; Lemmas 5.3–5.5 and Corollaries 5.6–5.8 are the relevant chain. Corollary 5.8 on printed page 493 concerns the same disjoint comparable-cover mechanism. The present proof uses its own explicit quadratic recurrence and a second-moment alternative, rather than importing a large-threshold polynomial localization statement without verifying its scale premise. The comparison above is specifically to the edited repository predicate [142], whose gain is $\alpha/16$.

Green and Tao [128], Appendix A, Proposition A.2, give simultaneous quadratic recurrence for real $\alpha_1, \dots, \alpha_d$: there is $1 \leq n \leq X$ with $\|n^2 \alpha_j\| \ll dX^{-c/d^2}$. The following discussion records Schmidt’s stronger asymptotic exponent $-1/(d^2 + d) + \epsilon$ and explains why dependence of implicit constants on dimension matters. Their Section 6 treats linearization. These results confirm the classical nature of recurrence followed by localization. Our weaker single-coefficient estimate has a fully displayed uniform constant and is proved here to keep the numerical interface self-contained.

Maynard [72], Theorem 1.1 and Corollary 1.2, treats systems of real polynomials with zero constant term. For m polynomials of degree at most d , the corollary gives simultaneous fractional parts $\ll_{d,m} X^{-c_d/m}$ for some $1 \leq n < X$, uniformly in their coefficients. This is a substantially more general recurrence theorem; the displayed corollary leaves its constants implicit. We neither claim that R^5 is the best quadratic recurrence rate nor infer any optimality for $1/39$ from it.

The specific claim established here is the explicit, all-moduli, threshold-free local-cover theorem and its pinned source implication. Priority for that exact formulation has not been established. No argument here turns this local improvement into a better final Ramsey or Szemerédi estimate, handles all polynomial degrees, or supplies an integer-rectification theorem.

V.126 Reproducibility and further questions

Source 32, delivered Section 7.

V.126.1 What the companion establishes

The accompanying Python program uses integer and rational arithmetic for bounded structural checks. It tests progression injectivity, subgroup-coset pair counts and variance, removal of nonproper directions, cover-mass identities and positive-cell extraction, residue-chain chunking, quadratic phase lifts, reduced curvature, and the reduced-midpoint regression. It also checks the integer identities behind the constants and root-free ceiling choices. Small rational recurrence examples exercise the recurrence interface; they are not a proof about every real coefficient.

The full mathematical proof is in Sections I.45–I.48. The companion does not enumerate a partition of size $2^{116}L^{38}$, even at $L = 2$, and it does not approximate complex exponentials and call the result a certificate. Its finite coverage, argument caps, and limitations are reported in its JSON output and documented in `README.md`. Input-validation failures remain runtime errors under optimized Python. Tests and diagnostics run under both normal Python and `-O`; deterministic diagnostic output must agree.

The offline builder verifies an exact source inventory and, for a packaged distribution, the manifest hashes. It rebuilds the PDF using an installed trusted TeX toolchain with shell escape disabled and writes a deterministic ZIP with fixed member order and metadata. It rejects unexpected source

members, source aliases, and unsafe output locations, and bounds subprocess time and output. These are reproducibility and regression controls for trusted source, not a sandbox for hostile TeX or Python and not a guarantee against an actively malicious concurrent filesystem owner. Hashes establish byte agreement with the manifest, not authorship or mathematical truth.

The ZIP contains only this article, its PDF, the original companion and tests, the builder, public documentation, and its manifest. It contains no third-party paper or private review material. The exact commands and platform requirements are in `README.md`; the archive digest is supplied outside the archive to avoid a circular hash.

V.126.2 Questions suggested by the proof

1. **Better recurrence with explicit small-scale constants.** If an unconditional estimate $p \leq CR^\kappa$ is available, the present choices $H \asymp L^3$ and $R \asymp L^7$ make the partition cost proportional to $L^{7\kappa+3}$. The large-correlation cover step loses one further factor of L , suggesting length exponent $1/(7\kappa+4)$ with appropriately checked constants. This is parameter bookkeeping for a future argument; Remark I.45.4 does not supply $\kappa = 4$.
2. **A more economical quadratic partition.** The two-stage construction first suppresses curvature and then suppresses an affine slope. Can these stages be combined to improve the power 38, while retaining every point and allowing arbitrary real coefficients? Any proposed replacement must preserve the small-scale rounding and properness checks.
3. **Parent-contained small-correlation increments.** The variance alternative uses the whole group. Requiring $Q \subseteq U$ or $Q \subseteq P_i$ would be an additional conclusion and needs a separate argument or an obstruction; it is not implicit in the present theorem.
4. **The next polynomial degree.** The source bridge is complete for degree two. Extending the threshold-free strategy to degree three would require an explicit cubic recurrence/localization budget and a fresh check that the large-correlation branch pays for it. Nothing in the degree-two proof establishes that extension.

V.127 Further research questions and a concrete program

Source 33, delivered Section 9.

The questions below are proposed by the present analysis. Unless an external source is specifically cited, they are not being represented as previously published open problems. Each is separated from the proved claims above.

Research question V.127.1 (The optimal common-prime quadratic coefficient). For fixed even s , determine the smallest coefficient c_s^{prime} for which a uniform small-error estimate of the form

$$\delta \leq \varepsilon_s/s + c_s^{\text{prime}}\varepsilon_s^2 + O_s(\varepsilon_s^3)$$

holds on $\mathbb{F}_p^2 \rightarrow \mathbb{F}_p$ for all sufficiently large odd primes. Theorems F.38.2 and II.141.3 give the rigorous bounds

$$\frac{3s-2}{4s^2} \leq c_s^{\text{prime}} \leq \frac{2(s-1)}{s^2}$$

whenever the optimal coefficient is formulated as an infimum of such uniform expansions. For $s = 16$ these bounds are $23/512$ and $15/128$. Can cancellation between two erroneous derivatives close the gap?

Research question V.127.2 (The next coefficient for higher arrangements). For $s \geq 6$, determine the optimal cubic coefficient after the two sharp all-group coefficients have been fixed. The full bound F_s , the simpler quadratic inverse, and the binary extremal family give different third-order information. A useful first target is $s = 6$, where one can classify low-weight error patterns while retaining the missing sixth independence degree exactly.

Research question V.127.3 (Equality and near-equality in the sharp cubic). Classify the maps with $0 < \delta < 1/4$ and $\varepsilon_4 = 4\delta - 24\delta^2 + 32\delta^3$. The proof forces simultaneous equality in the modal collision estimate, the increment cap, the missing-moment bound, and the one-error implication. Do these conditions characterize binary row-defect constructions, perhaps after quotients, products, and addition of an exact model? A quantitative near-equality theorem would identify the actual obstruction to a better repair modulus.

Research question V.127.4 (The activation threshold and the global distance spectrum). How far can the small-branch theorem extend? The bound $1/(240(s-1))$ was chosen to make the elementary bootstrap automatic. A sharper noisy-affine lemma, or a direct spectral gap argument, may increase this threshold substantially. Separately determine the feasible pairs (δ, ε_4) away from zero. The vanishing of F_4 at $1/4$ shows why extrapolating its inverse without a structural argument is not a solution to the global problem.

Research question V.127.5 (A sharp theorem from row profiles). Theorem II.140.3 retains $\bar{t}/\delta$, while the uniform-row cap retains only $\max_x \delta_x$. What is the optimal defect bound given the complete row distributions p_x , or just the first few moments of δ_x ? Such a result could distinguish diffuse errors from concentrated row defects before passing to a worst-case constant.

Research question V.127.6 (Sparse domains with quantitative mixing). Replace near-full density by explicit assumptions that conditioned arrangement queries have approximately uniform marginals and that increment cocycles have enough common witnesses. Can one prove $\delta_A \leq C\eta$ with polynomial dependence on these mixing parameters, instead of paying the invalid-arrangement error $2s\tau$? The precise challenge is to replace the three full-product steps: auxiliary-label independence, mode comparison at every increment, and rowwise integration. This is the most direct route toward the sparse setting of Gowers's Sections 12–13.

Research question V.127.7 (Nonzero increments and nonrepeated vertices). Determine exact conversion bounds when the test excludes $h = 0$ or forbids repeated vertices. Conditioning changes both the total count and the independence law. The crude invalid-event argument gives an initial estimate, but a sharp normalization should distinguish genuine collisions from repetitions forced by the balanced relation. In small characteristic, these distinctions may affect extremizers.

Research question V.127.8 (Two-direction testing and the row gauge). Add the horizontal analogue of the arrangement test. The vertical test alone cannot constrain $a(x)$, while a horizontal test should force compatibility with an affine function of x . Establish a quantitative repair theorem to a fully biaffine map, with explicit dependence on the two failure rates and sharp first-order constants. The intersection of the two exact model classes is easy to describe; robust intersection with optimal constants is the substantive issue.

Research question V.127.9 (Higher multilinear arrangement models). For products of three or more groups, formulate the gauge class left invisible by a prescribed family of directional difference

tests. Can the coarse derivative synchronization be iterated without an exponential accumulation of error constants? The multilinear structure problems in [129] and directional norms in [130] provide relevant settings, but the exact high-agreement tester and its nullspace should be fixed before estimating constants.

Research question V.127.10 (Fast decoding rather than exhaustive slopes). The exact cyclic decoder avoids exponential enumeration of row functions but still enumerates all permitted (b, c) . Can random derivative queries identify these coefficients in near-linear time in the table size, under the high-agreement promise? A robust decoder should output both a model and an efficiently verifiable disagreement count; it should also expose its sample complexity and failure probability rather than hide them in an informal majority vote.

Research question V.127.11 (A formally checked probabilistic core). Formalize the auxiliary-label correction lemma, affine separation, proper-coordinate independence, and the one-error inclusion–exclusion identity. These components are small enough to isolate from the full Szemerédi development. Once checked, they would certify the main theorem without requiring a formalization of a general inverse theorem for Gowers norms. The initial target should be the rational inequality $\varepsilon_s \geq s\delta - 2s(s-1)\delta^2$ on the proved small branch, not a real square-root expression.

Research question V.127.12 (Actual propagation through the Gowers pipeline). Find a point in the sparse structural argument where a near-full product or a quantitatively mixing product can be produced without losing the information needed later. Only then compare the complete parameter recurrence with the existing one. A successful answer must keep track of domain density, valid-arrangement mass, failure rate, model agreement, and the eventual progression length. This is the necessary bridge between the present local refinement and a claim about a global Ramsey or Szemerédi bound.

The most immediate mathematical targets are the first and third questions: the common-prime quadratic constant and the equality classification. The most consequential integration target is the sixth, because the present proof deliberately does not solve the sparse-domain mixing problem.

V.128 Repository integration and formalization interface

Source 33, delivered Section 10.

V.128.1 Recommended placement and source pin

A distinct research subdirectory is preferable to silently replacing an existing lemma:

```
Combinatorics/Ramsey/Research/GowersSzemerédi/  
respected-arrangement-stability/
```

The mathematical entry point is Theorem F.38.2, with Corollary F.38.4 as the eight-arrangement specialization. The article and its code do not alter the repository’s formalization ledger.

The source crosswalk was checked at repository commit

9f83dbe0f15205c10b1e6efc6af69b09969f8e03

The corrected Gowers transcription has blob identifier

41085a0efde8c1932e86e80c791984f52841c22e.

The local-refinements README at that pin has blob identifier

b0edfc23a3624a09c7a2087a336d447a4378622c.

The repository was changing during preparation; earlier exploratory reads were from the moving branch. The pinned reads above, not an assumption that every exploratory read had the same commit, support the final source crosswalk. The accompanying source audit records the specific ranges and the scope of the comparison.

[write] **6 October 2026; sources 28–33.** *Checked at HEAD 5d4718772.* The transcription blob 41085a0 is unchanged; the README of this report has changed (writes of sources 11–27). `lemma_12_3`, `lemma_12_5` and `lemma_12_6` are at lines 151, 170 and 183 of `Sections12_13.lean`; none has a counterpart for the repair theorem, and nothing here is formalized.

V.128.2 Suggested formal layers

The proof can be implemented over finite additive commutative groups, using finite sums and rational probabilities initially. There is no need to import an unproved sparse inverse theorem.

Layer	Mathematical content	Main dependency
Arrangement domain	Balanced tuples, occurrence counts, proper-coordinate independence	Finite group bijections
Labeled correction	Difference modes, exact additivity, $e/(1 - 2e)$ repair	Finite averaging and union bounds
Derivative synchronization	Affine-map group, separation, increment cocycle	Labeled correction
Local defect	Row modes, collision profile, one-error probability	Independence and finite inclusion–exclusion
Repair theorem	Small branch and quadratic inequality	Coarse and local estimates
Higher orders	Exact moment formula and monotonicity	Finite Fourier analysis
Sharpness	Cyclic models, exact example counts, series coefficients	Elementary finite algebra

Table V.128.1: A proposed formalization dependency order; no row is represented as already implemented or checked in Lean.

The cycle deficit lemma can be formalized independently as a finite probability-vector inequality, followed by its subprobability extension. The accompanying moment interpolation should retain ambient count normalization in the partial-domain statement.

For $s = 4$, all ingredients of the repair theorem can be stated without Fourier analysis. For higher even s , one can formalize the moment identity separately and reduce to that coarse decoder. The local polynomial inequality is itself Fourier-free for every s .

A formal implementation should distinguish an exact count from its normalization, a function-valued equality of affine maps from pointwise agreement on most x , and an auxiliary label sampled at each occurrence from a fixed random section. The last distinction is especially important for repeated coordinates. The proof also needs the positivity hypotheses $1 - 2e > 0$ and $1 - 12d > 0$ at their precise uses, rather than after clearing denominators without a sign check.

V.128.3 Claim ledger

All mathematical results proved in this manuscript are unconditional under their displayed hypotheses. The conditional statements are the erasure corollary's explicit coverage assumptions and the clearly posed future research questions. No novelty claim is used as a proof input. The majority-correction method is classical in origin, while the arrangement-specific estimates and constructions are developed here. The exact cubic and sharp asymptotic coefficients are offered as research contributions for scrutiny, not as refereed literature facts.

No new statement in this package is asserted to be Lean-compiled or kernel-verified. The supplied Python checks are ordinary exact-arithmetic programs. No new global estimate for $r_k(N)$ or van der Waerden numbers is claimed. These limitations are part of the mathematical scope, not missing hypotheses to be filled by optimism.

V.129 Normalization and audit checklist

Source 33, delivered Appendix A.

V.129.1 A compact normalization table

Quantity	Convention
Gowers arrangement order	$m = s/2$
Vertical difference occurrences	s
Point occurrences	$2s$
Free horizontal coordinates	$s - 1$
Independent vertical base points	s
Common increments	one element of H
Total full-domain arrangements	$ G ^{s-1} H ^{s+1}$
Distance	uniform pointwise disagreement on $G \times H$
Character average over target	$ K ^{-1} \sum_{\chi \in \widehat{K}}$
Frequency sum over horizontal group	$\sum_{\xi \in \widehat{G}}$

V.129.2 Degenerate inputs and boundary cases

The all-zero increment is included, even though it always passes. This matters for both the binary and the prime extremizers. Repeated vertices and repeated horizontal coordinates are also included. The auxiliary-label proof remains valid for those repetitions because labels are resampled per occurrence. In a partial-domain test, validity means that every occurrence has a value; repeated occurrences do not require separate membership choices.

For $\delta = 0$, ratio expressions involving $\bar{t}/\delta$ are not used; exact classification supplies the zero-error conclusion. For empty valid-arrangement sets, conditional failure is undefined. For trivial target groups, every function is an exact model and every theorem reduces to zero error. The order parameter is always even and at least four; none of the signed inclusion–exclusion claims has been extended to odd orders without proof.

V.129.3 Numerical evaluation of the repair formulas

For small u , cancellation can make the expression $1 - \sqrt{1 - 8(s-1)u/s}$ numerically inconvenient. An equivalent stable form is

$$R_s(u) = \frac{2u/s}{1 + \sqrt{1 - 8(s-1)u/s}}. \quad (\text{V.129.1})$$

The exact verification suite avoids square roots entirely: it verifies that δ is on the increasing branch and that $Q_s(\delta) \leq u$. For the cubic inverse one may use bisection on $[0, 1/12]$, since the cubic is strictly increasing there. A floating-point root returned without checking the interval is not a substitute for that branch condition.

V.129.4 Reproducibility commands

From the package directory, the following commands need only a standard Python installation and a conventional pdfLaTeX distribution:

```
python code/verify.py --extended
python code/verify_erasures.py
python code/arrangements.py data/example.json --orders 4 16
pdflatex -interaction=nonstopmode -halt-on-error article.tex
pdflatex -interaction=nonstopmode -halt-on-error article.tex
pdflatex -interaction=nonstopmode -halt-on-error article.tex
```

The third LaTeX pass stabilizes the table of contents if page numbers changed on the preceding pass. The package README and Makefile supply the same routes. All mathematical labels in this source use the prefix **ras:** to reduce collisions when integrating with a larger article; macros and theorem environments still need the normal editorial merge.

V.130 Consequences, limitations, and a research program

Source 34, delivered Section 11.

The results above settle several questions in the audited repository: the exact values $h(7), h(11)$, the leading asymptotic of $h(p)$, the support cost and classification of positive cyclic detectors, and the proposed single-pair model for the fourth-norm extremizer. Appendix II.163 settles the strict threshold in the nonuniform directional model. The following questions identify the remaining mathematical gaps. They are proposed research targets; we do not assert that every formulation is historically new or unresolved throughout the literature.

V.130.1 Binary determinants and arithmetic configurations

Research question V.130.1 (Divisibility versus exact cyclic isolation). Is $h(p) = h_{\text{cyc}}(p)$ for every prime p ? If not, what is the first prime where they differ, and how large can the difference be?

Theorem III.75.2 concerns a determinant divisible by p , while $h_{\text{cyc}}(p)$ requires that the complete row quotient be exactly $\mathbb{Z}/p\mathbb{Z}$. These conditions agree in every small case proved here and in their leading asymptotic, but neither conclusion proves exact equality in general. A useful finite search should store full row-lattice indices and full-support characters, not only one determinant. Existing determinant spectra can supply many immediate values before any new exhaustive search is attempted.

Research question V.130.2 (The second-order support term). With $L = \log p$, $\lambda = \log L$, and $\mu = \log \lambda$, does there exist a constant a such that

$$h(p) = \frac{2L}{\lambda} \left(1 + a \frac{\mu}{\lambda} + o\left(\frac{\mu}{\lambda}\right) \right)?$$

Ask the same question for $h_{\text{cyc}}(m)$ as m runs through all integers. Can the coefficient 3 in the proved upper comparison be reduced toward the coefficient 1 in the Hadamard comparison?

The bounds here place any such second-order coefficient between one and three; they do not establish its existence. Improving the consecutive determinant range and improving the representation of one specified prime are different problems. The latter could admit a better upper bound even if an all-integer interval is more costly.

Research question V.130.3 (The secondary loss in the consecutive cyclic range). Can every positive integer up to

$$\exp\left(\frac{1}{2}N \log N - o(N \log \log N)\right)$$

be realized as the sole nonunit Smith factor of a binary matrix of order N ? More modestly, can the coefficient of $N \log \log N$ be made strictly smaller than one?

In the present construction, the bounded first row is encoded at a cost proportional to $\log A$. Balancing that cost against the number of radix positions leads to an auxiliary order of scale $N/(\log N)^2$. This explains the current secondary loss within this construction. A smaller loss would likely need a more efficient use of the first row or a different composition mechanism. The cyclic condition should be retained throughout; a determinant construction alone does not resolve the stronger question.

Research question V.130.4 (Exact positive support and finite-size efficiency). Determine $h_{\text{pos}}(m)$ exactly for a substantial range of cyclic orders. When is the doubling bound $h_{\text{pos}}(m) \leq 2h_{\text{cyc}}(m)$ strict, and what is the second-order term in $h_{\text{pos}}(m)$?

The leading constant four and the inverse-pair classification are proved here. The remaining finite problem is closely related to ternary matrices with a prescribed cyclic quotient. The doubling construction gives a simple bridge from binary matrices, but it need not minimize the number of pairs. A useful search should retain a full-support faithful quotient vector and certify the whole lattice index. The corresponding positivity classification for noncyclic finite quotients is a further structural question.

Research question V.130.5 (Prescribed finite abelian quotients). For a finite abelian group A , determine the least size of an affinely independent Boolean configuration with row quotient A and with every coordinate generator nonzero. How does this size depend on $|A|$, the number of invariant factors, and their prime power structure?

The cyclic construction controls a single nonunit invariant factor. Direct sums of binary presentations give an upper bound for general A , followed by affine augmentation and deletion of coordinate generators that vanish in the quotient. The substantive question is whether several invariant factors can share the same Boolean coordinates efficiently. Prime powers also distinguish a rank drop modulo p from its full p -adic depth.

Research question V.130.6 (From first occurrence to a complete coefficient). Classify all full-support lattice types at the first few unresolved support degrees, and compute their multiplicities as functions of the cube dimension. In particular, can the sixth- and seventh-order coefficients be expressed in a finite, explicit basis of Fourier statistics with a dimension-uniform remainder?

The onset theorem supplies necessary dimension and support thresholds, and the explicit matrices supply terms that must be present. They do not enumerate all rational dependencies, all Smith types, or all cancellations among supports of the same size. A practical approach is to classify coordinate-pattern orbits, attach integral presentations to each orbit, and then derive closed multiplicity formulas. A useful theorem must keep the distinction between Smith torsion and reductions of pre-existing integer relations.

V.130.2 The actual Gowers norm extremizers

Research question V.130.7 (The sharp odd fourth-norm constant). Determine c_4^{odd} inside the proved interval

$$\left[\frac{4804}{5465198316262956^{1/4}}, \frac{2}{3} \right].$$

Is the supremum attained on some finite group, or only approached along groups of growing order? What are the extremizing Fourier supports and phases?

The dual identity identifies why the single-pair guess fails, and the resonance argument controls a concrete way to exploit that failure. It does not classify genuine minimizers. On a fixed group, the finite-dimensional variational equation in Remark III.71.8 is a necessary condition. Across all groups, an additional compactness or approximation argument would be needed. Merely optimizing the two-pair family does not establish a global optimum.

Research question V.130.8 (Stronger coupled certificates). Can the dominant pair and its resonant harmonics be retained jointly through all positive autocorrelation terms and the dual inequality, so as to improve $2/3$? Can a finite family of explicit dual tests provide a sharp certificate?

The proof uses only the balanced monomials and the families with seven first harmonics and one third or fifth harmonic. Further families impose additional positive costs on the same Fourier mass. Their phase-sensitive dual contributions may also be useful. A sound computational program should first produce exact polynomials and rational inequalities, then prove the resulting optimization bound. Floating-point minimization by itself supplies a candidate, not a universal norm inequality.

The displayed two-pair polynomial gives a particularly accessible subproblem. Its nonzero stationary parameters satisfy

$$(1 + t^4)P'(t) - 16t^3P(t) = 0.$$

Exact root isolation can determine the best member of that family. One must then test perturbations in additional harmonics to decide whether a family optimizer is even locally extremal in the full function space.

Research question V.130.9 (Higher dimensions and quantitative stability). Determine the asymptotic behavior of c_d^{odd} as $d \rightarrow \infty$, and develop stability statements for near-minimizers of $\|f\|_{U^d}/\|f\|_{U^2}$ for $d \geq 4$.

The sequence is nonincreasing by norm monotonicity. The incoming moment estimate and the profile refinement in Remark III.71.10 give explicit upper bounds, but the fourth dual function stops improving the moment endpoint in sufficiently large dimensions. Computing $\mathcal{D}_d$ on a small Fourier support becomes a Boolean balancing problem related to the configuration analysis in the first half of the article. Stability must be formulated for the genuine norm minimizers; stability of an intermediate autocorrelation inequality has a different equality set and is not enough.

V.130.3 Returning to the density-increment argument

Research question V.130.10 (A constrained density-and-norm envelope). For fixed $0 < \delta < 1$ and small u , determine or sharply bound

$$\sup\{Q_4(F) : 0 \leq F \leq 1, \mathbb{E}F = \delta, \|F - \delta\|_{U^4} = u\}.$$

Can the quartic contribution and the higher-order remainder be bounded jointly using their compatible Fourier phases?

The coefficient $100c_4^{\text{odd}}$ describes the unrestricted small-amplitude leading term for real perturbations. The box constraint $0 \leq F \leq 1$ becomes more restrictive at larger amplitudes. In addition, the individual support bounds used in the remainder need not be simultaneously sharp. A joint envelope could therefore improve the useful finite-error range even before the exact value of c_4^{odd} is known.

Research question V.130.11 (Propagation through a complete iteration). Recompute a specified, fully normalized density-increment scheme after replacing the local fourth-dimensional cube bound and the directional rigidity threshold by the results proved here. Which final constants or exponents actually change?

The appropriate calculation must track density, progression or ambient-set size, uniformity thresholds, and all recursive dependencies. A smaller local coefficient may affect only a final constant; in some parameter regimes another loss may dominate it entirely. The current article supplies explicit replacement inequalities but makes no unverified claim about their global effect. This is also the setting in which the prime-order and nested hypotheses of the original inverse argument must be preserved.

V.131 Reproducibility and proposed ProveIt integration

Source 34, delivered Section 12.

V.131.1 What is proved mathematically and what is checked finitely

The statements for every prime, every cyclic order, and every finite odd-order group are proved by algebraic and analytic arguments in the article. Their validity is not extrapolated from a numerical search. The finite computations have three roles: certifying specific matrices, supplying an exhaustive negative certificate for two small primes, and verifying exact coefficients or rational comparisons in the analytic proof.

Component	Exact verification	Role in the proof
Small prime supports	Determinants and full-support syndromes for 7, 11, 13, 17	Positive finite certificates
Seven-vertex exclusion	All 104 and 204 projective orbit representatives; every Boolean row and integer annihilator	Exhaustive negative proof for 11, 13
Positive cyclic construction	36 moduli; two direct spatial moment checks	Implementation check of an all-parameter proof
Determinant construction	144 bounded-row encodings and 92 complete compositions; exact determinants, Smith forms, and unit cofactors	Check of signs, dimensions, and rounding
Fourth norm	Dual counts, resonant coefficients, order-three polynomial, rational $2/3$ inequalities	Exact confirmation of identities proved in the text
Two-pair example	All 4^8 face assignments and exact evaluation at $-1/7$	Finite coefficient certificate

Table V.131.1: The verification methods and their logical roles are distinct.

The code and data are included in the archive. The torsion and norm verifiers use Python’s standard library. The determinant gadget verifier uses exact SymPy arithmetic; the dependency is recorded in `requirements.txt`. No floating-point result is needed for a theorem stated here. Decimal values in the text are provided for orientation; the defining expressions and decisive inequalities are exact.

The negative certificates deserve a particularly clear trust boundary. Their generator uses rational elimination to find an annihilator, but the verifier checks the supplied nonzero integer vector directly against every admissible Boolean row. The verification does not trust a rank routine. Exhaustiveness comes from an explicit enumeration of sorted tuples and all nonzero scalar multiples. This structure is suitable for a later formal certificate checker.

V.131.2 Source control and placement

The suggested new location is a research directory beside the existing merged report:

`Combinatorics/Ramsey/Research/GowersSzemerédi/prime-torsion-norm-gaps/`

The package contains a single self-contained TeX source, the compiled PDF, a build file, exact verification scripts, certificate data, and a source ledger. It can be placed independently without renumbering statements in the existing merged article. A later editorial merge should retain source attribution and stable theorem labels.

The inspected formal baseline is `Proofs03CubeUpper.lean`, in the existing `Combinatorics/Ramsey/Lean/GowersSzemerédi/` directory. At the pinned commit, the status ledger records `lemma_3_10`

as `exact_companion`, with companion `lemma_3_10_holds`. That existing proof was inspected. This report does not supply new Lean proofs or report a fresh repository build.

[write] **6 October 2026; sources 34–39.** *Checked at HEAD 89c1cbc38.* `lemma_3_10` is at `Sections01_03.lean`, line 340, with the exact companion `lemma_3_10_holds` (`Proofs03CubeUpper.lean`, line 82; the file has the blob `c017515` the source records). No declaration concerns c_d^{odd} , prime torsion of cube expansions or the transport model of Appendix A; nothing of this source is formalized. The suggested separate directory was declined at placement (`bf2fe146d`): the source answers questions already open in this report.

V.131.3 A concrete formalization sequence

1. Define the augmented Boolean matrix and its integer row quotient. Formalize the Fourier constraint identity and the link between rank drop modulo p and Smith torsion.
2. Prove the affine-minor reduction and the minimal-order full-support lemma. These require finite-dimensional linear algebra and elementary determinant identities, without the Alon–Vu theorem.
3. Add the small explicit matrices and the finite certificate checker. The $p = 11, 13$ lower bounds can then be checked using integer dot products and finite orbit enumeration.
4. Formalize the positive cyclic presentation and cyclic support compression. State the Alon–Vu input separately before formalizing the determinant gadgets and asymptotic corollaries. No unproved external input should be hidden behind a theorem named as if it had been established internally.
5. Formalize the exact dual polynomial, positive balanced and resonant moment sums, and the order-three calculation. Derive the rational $2/3$ bound from these ingredients, then connect it to the existing normalized cube-count interface.
6. Formalize the finite-fiber sampling model in Appendix II.163. Keep its general-group sharpness theorem separate from any stronger claim at the original prime-order inverse-theorem interface.

The most valuable initial formal additions are the exact reduction, the small prime certificates, and the fourth-norm inequality. They have compact inputs and conclusions, and do not require formalizing the entire asymptotic matrix construction first.

V.132 Evidence, source scope, and formalization

Source 35, delivered Section 8.

Delivered part heading of source 35: **Verification, integration, and further research**

V.132.1 What the accompanying calculations check

The mathematical proofs above establish the infinite families of statements. The programs serve a narrower purpose: they reproduce finite identities, verify the exact numerical certificates, and test the delicate conventions on complete small examples. They use the Python standard library only. No floating-point optimization is an input to a theorem.

Arrangement selection. The program `verify_graded_selection.py` examines all $3^8 = 6,561$ coefficient arrays for $k = 1, m = 4, p = 3, L = 2$. It removes the universal line, computes the parity-removed degree, and solves the resulting linear feature systems exactly over $\mathbb{F}_3$. The maximum success probabilities are

$$Q_0(3) = \frac{1}{3}, \quad Q_1(3) = \frac{11}{81}.$$

These maxima attain the stated individual-certificate estimates. The program also checks the dimensions of balance subspaces on separate small examples and records exact rational product masses. An attained certificate probability does not imply sharpness of the full selection threshold.

For a direct check of actual subset selection, the same program takes $B = \mathbb{F}_3^2$ and $\phi(x, z) = x^2z$, enumerates all 6,561 arrangements, and averages over all 243 field seeds. It uses products over distinct physical points for the actual probabilities and products over labels for the Fourier comparison. In this example there are 3,753 respected and 2,808 unrespected arrangements. The difference between the expected actual and labelled bad counts is

$$\frac{9,891}{128} - \frac{84,687}{2,048} = \frac{73,569}{2,048} > 0.$$

Thus omitting the repeated-vertex compensation would be a real error, not merely a missing discussion of an empty exceptional set. The program further verifies 54 exact rational instances of the explicit bandwidth budget and recomputes the exponent table through $k = 16$.

The fourth-order norm gap. The program `verify_norm_gap.py` checks all 17 rational comparisons used in the scalar certificate. Comparisons involving fourth roots are reduced to powers of positive rational numbers. It also enumerates all 2^{15} sign assignments for the cosine dual and all 2^{16} assignments for the full order-three cube. The resulting coefficient dictionaries are

$$\{-5 : 1, -3 : 27, -1 : 111, 1 : 111, 3 : 27, 5 : 1\}$$

and

$$\{-12 : 8, -6 : 16, 0 : 286, 6 : 16, 12 : 8\},$$

respectively. These checks support the combinatorial proofs of Lemmas III.72.3 and III.72.4; the analytic energy and scalar arguments remain explicitly proved in the text.

Polynomial obstructions. The program `verify_polynomial_obstruction.py` tests 285,915 starting-residue and step-residue pairs in the three examples tabulated in Part III. Arc diameters are computed by the largest-gap formula on integer residues, so endpoints and wraparound do not involve rounding error. It also tests all 422,500 length-three integer progressions in the 1,301-point interval of the prime-modulus approximation, using the prime

$$N = 54,121,601.$$

At tolerance $1/32$, the good steps in that interval are exactly 217 and 434, both divisible by the predicted period 217. The prime test is local to this interval.

Reproduction. The archive includes recorded JSON outputs and a runner, `verification/verify_all.py`, that reruns the suites into a temporary directory and compares their outputs with the records. It leaves the supplied evidence files unchanged. The L^AT_EX source contains its own bibliography and does not depend on external graphics, a bibliography database, or the original repository being available at build time.

V.132.2 Which ingredients are inherited

The arrangement architecture, the respected relation, and the use of positive Fourier expansions originate in Gowers’ argument [1, 158]. The one-stage Fejér selector and its polynomial retained-count powers already appear in [160]. The degree-sensitive certificate geometry is developed in [161]; we reprove it for the arbitrary field coefficients needed here. The contribution is to place the necessary top-degree balances *inside the probability-mass estimate*, combine degree and codimension before summing, and carry the physical-collision correction through that weighted calculation.

The real centered U^3 comparison and the centered cube expansion are in the merged collection [159]. The fourth-order cosine identities and the first uniform higher-order norm gap are in [162]. The strongest inspected fourth-order comparison before this article is the moment coefficient $35/8$ in [163]. Our additional positive Fourier configurations increase that coefficient to 5. At higher orders the existing moment theorem remains stronger than the constant obtained just by propagating 5.

For polynomial partitions, the linear divisibility-and-conductor argument is in [165]. The preceding polynomial volume obstruction is in [164]. The present descending-degree construction supplies a divisor that is forced at every initial point; this is the additional property needed to multiply the polynomial obstruction by the semigroup conductor.

V.132.3 The literature comparison and its limits

The foundational context is Gowers’ 2001 proof [1]. The global progression-free bound cited in the introduction is from Leng, Sah, and Sawhney [2]. Neither the size threshold of a local restriction nor an improvement of its numerical exponent can be identified with an improvement of that global bound without a further complete argument.

On the analytic side, Eisner and Tao study large values and near-extremizers of Gowers and Gowers–Host–Kra norms [7]. Kovač and Rogers study L^p variants, degree-lowering estimates, and strict log-convexity [71]. Their Theorem 1.1 assumes a nonnegative function and a group without compact open subgroups; its stated strict log-convexity conclusion consequently does not apply to finite groups. Our comparison concerns signed real centered functions on finite odd-order groups and relates U^4 directly to U^2 . These are different hypotheses and inequalities. This distinction is useful context, but is not an exhaustive priority search.

For polynomial phases, Green and Tao’s quantitative work on polynomial orbits provides broader context for smoothness estimates [148]. The small-arc lemma used here has its own finite-difference proof and does not invoke a nilmanifold equidistribution theorem.

The source audit therefore supports precise comparisons with the inspected statements. It does not certify that every intermediate lemma or the final combination is absent from all earlier literature. The manuscript is intended for mathematical review and integration as a research contribution, with its proofs available for independent checking.

V.132.4 A concrete formalization route

The repository’s statements and their formal companion proofs must be distinguished. We inspected the ledger and the relevant section files at the source pin; no new Lean file is included or claimed to compile. The present theorems are conventional mathematical proofs, supported by exact computations. Table V.132.1 gives separable proof obligations for a future formal development.

[write] 6 October 2026; sources 34–39. Checked at HEAD 89c1cbc38. lemma_15_5, lemma_14_8

Component	First formal target	Main dependencies
Weighted selection	Product mass of an affine subspace; dimension D_t	Finite product probability, coordinate projections, Boolean multilinear interpolation
Certificate geometry	The t and $2t$ minors, including constant levels	Finite-field rank and counting; independent linear forms
Subset extraction	Expected labelled counts, collision correction, score outcome	Additive-character orthogonality; a distribution on finite subsets
Real norm gap	The energy inequality with $J(\lambda)$	Normalized Fourier identities; finite group parity and torsion facts; cube Cauchy–Schwarz
Scalar constant	The rational two-interval certificate	Positive fourth roots, differentiation, rational arithmetic
Polynomial obstruction	Short-arc lifts and descending divisibility	Finite differences, interpolation, prime divisibility, numerical semigroups

Table V.132.1: Formalization tasks; no row is presented as completed Lean work.

and `lemma_5_9` (`Section05.lean`, line 261; companion `lemma_5_9_holds`, `Proofs05FullPartition.lean`, line 98) are exact; `lemma_3_10` is exact (companion `lemma_3_10_holds`, `Proofs03CubeUpper.lean`, line 82). No statement of this source is formalized; the transcription it cites has the same blob 41085a0 at HEAD.

For integration with the existing normalization, the first interface checks should be the ordered-arrangement count q^M , the density upper bound (II.145.2), and the conversion between normalized and unnormalized Fourier coefficients. For the partition result, encode a proper progression with an integer lift and explicitly quantify over all target lengths as in Corollary I.61.6. Those choices avoid apparent numerical discrepancies caused solely by differing conventions.

V.133 A proposed research programme

Source 35, delivered Section 9.

The following questions are ordered by their proximity to the proved arguments. Each has a concrete first target. Questions about optimality are proposed problems, not consequences of the bounds already established.

V.133.1 Arrangement selection: beyond the present exponent

Research question V.133.1 (Top-degree rank, not only top-degree size). Can the coefficient strata be refined by the rank of the matrix

$$(A_{j,T})_{\substack{1 \leq j \leq m \\ |T|=t}}$$

so that several lowest Boolean moments contribute independent restrictions simultaneously?

The present proof selects one nonzero moment vector. Multiple independent vectors could force more restrictions on both the levels and the anchors, while their rank constraints also reduce

coefficient mass. A meaningful first result would compute the joint rank-and-mass profile for $k = 2$ or 3 , prove its exceptional varieties have the predicted dimension, and improve the explicit exponent 23 for $k = 2, m = 16$. Summing a list of pointwise rank bounds without controlling the mass of each rank class would not suffice.

Research question V.133.2 (Exact mass of the arrangement balance spaces). How close is the product Fejér law to the upper bound μ^{s-D_t} on $\mathcal{V}_t$? Can its exact additive convolution structure replace the largest-atom estimate?

The mass lemma is sharp for arbitrary coordinate subspaces, whereas $\mathcal{V}_t$ comes from many Boolean evaluations and balanced sums. Even an exponential-in- s constant improvement would affect practical thresholds. A changed power of L would require proving that the particular support intersects these spaces less efficiently than a general subspace. An anisotropic version could assign different bandwidths to cube positions, provided the respected universal signal remains large enough.

Research question V.133.3 (Optimize the kernel against the whole error budget). Among nonnegative trigonometric polynomials $K \leq 1$ with nonnegative Fourier coefficients, which best balances universal signal, coefficient-stratum mass, and point marginal probability?

The earlier positive-Fourier report studies the signal and its retained-mass powers [160]. The present theorem adds a different objective: the entire graded error budget. A kernel that maximizes the scalar ratio $\sum c_n^s/c_0^s$ need not minimize $\sum_t q^{-t-1} \Pr(b \in \mathcal{V}_t)/c_0^s$. A finite-bandwidth optimization for $k = 2, m = 4$, followed by an exact certificate for the optimizer, is a manageable first problem.

Research question V.133.4 (Small characteristic and torsion in the target). Can one obtain a comparable theorem when the characteristic is fixed while $\alpha\eta$ tends to zero, or when the target has small torsion?

The current restriction $p > 2(L - 1)$ serves a definite purpose: the integer Fourier band must embed without collisions, and nonzero universal frequencies must not annihilate a defect. Simply replacing q by a large extension-field cardinality does not remove this restriction. A possible approach is a multidimensional kernel on the dual of a larger auxiliary group, with enough linear maps to detect every nonzero target defect. The corresponding universal signal and mass estimates would have to be proved anew.

Research question V.133.5 (Intrinsic lower bounds for selection). What obstruction forces a lower bound on the ambient field size for any subset satisfying both the desired purity and a retained count of order $\alpha^s \eta^{s-1} T_0$?

The asymptotic $E_{k,m} \sim 2s/k$ describes our sufficient threshold, not a matching necessary one. A serious lower bound would need a family of maps and domains defeating *all* candidate subsets, not just one kernel or one relation-counting proof. It would be useful first to separate optimality within positive-Fourier selectors from optimality for unrestricted subset selection.

V.133.2 Norm gaps: sharpen the analytic certificate

Research question V.133.6 (The exact fourth-order extremal constant). Determine c_4^{odd} , or narrow substantially the interval in (III.72.7). Is a maximizing sequence supported on a bounded number of Fourier frequencies?

The retained statistic $J(\lambda)$ sees every amplitude three-term progression, while the proof of the coefficient 5 uses only a small part of it. A first improvement could retain all terms involving the dominant pair and its third and fifth harmonics, then prove an exact polynomial inequality on their amplitudes and phases. Numerical optimization can suggest a candidate but must be followed by a uniform certificate and a treatment of character-order coincidences.

Research question V.133.7 (Quantitative structure near the minimum). If $\|f\|_{U^4}^{16} / \|f\|_{U^2}^{16}$ is near its infimum, what Fourier concentration and phase alignment are forced?

The inequalities $R \geq (5 - 3p)^2$ and (III.72.17) already restrict the largest pair and its third harmonic. They do not yet classify near minimizers. A useful stability theorem should identify a metric, quantify its distance to a candidate family, and be uniform over all finite odd-order groups. It must also accommodate the non-cosine examples already present in [162].

Research question V.133.8 (Higher-order gains beyond central-binomial moments). Can the full cosine dual D_{dg} , together with higher positive Fourier configurations, improve the established central-binomial comparison for $d \geq 5$?

The target here is a new coefficient that actually beats [163] at the specified order. Monotonicity from our U^4 result is insufficient. A tractable first step is to derive and exactly verify the dominant harmonic terms of D_{5g} , identify which Fourier energy terms penalize their negative directions, and separate the finitely many exceptional small character orders.

V.133.3 Polynomial partitions: necessity versus sufficiency

Research question V.133.9 (A matching quadratic upper theorem). For ν arbitrary quadratic phases, is the universal prescribed-length threshold bounded by

$$C_\nu L^{3\nu+2} \varepsilon^{-2\nu}$$

up to logarithmic or subpower factors, in an appropriate integer-interval formulation?

Our construction proves the corresponding lower power scale. A matching upper result would have to combine simultaneous quadratic flatness with exact coverage by lengths $L, L + 1$. Finding one long flat progression does not solve the coverage problem. A useful intermediate goal is an upper theorem allowing a small exceptional set whose dependence on L, ε, ν can be compared with the exact gap formula (I.61.10).

Research question V.133.10 (Prescribed length width and exceptional mass). How does the best universal threshold change when the allowed lengths are $L, \dots, L + w$, and how much does allowing an exceptional set reduce it?

The constructed phases give the exact conductor $L[(L - 1)/w]$ and exact uncovered mass. This provides a two-parameter family of lower benchmarks. The first upper target should interpolate between fixed w and w comparable with L , rather than treating a prescribed pair and an arbitrary-length partition as unrelated problems.

Research question V.133.11 (Prime moduli of comparable size). Do the same polynomial obstruction powers hold when the ambient modulus is prime and is constrained to be comparable with the interval length?

The periodic example is exact at a composite modulus $N = R + 1$; the prime approximation permits a much larger N . A construction respecting both primality and $N \asymp R$ would need to replace exact divisibility by a robust local condition. Conversely, a better upper theorem in this regime would show that the modulus constraint has genuine content.

V.133.4 Integration and constructive extraction

Research question V.133.12 (Quantitative propagation through the complete proof). What bound follows when the graded selection theorem is inserted into the entire corrected Gowers argument and every subsequent parameter choice is optimized consistently?

Corollary II.148.3 provides one completed substitution. The next stage should be a dependency table carrying the domain density, respect fraction, field size, characteristic, model dimension, and purity through every use. A claimed global improvement should be stated only after that propagation is complete, and then compared directly with the best applicable published theorem.

Research question V.133.13 (An effective subset algorithm). Can the expectation proof be converted into an efficient algorithm that finds B' with an explicit running-time bound in the natural input model?

The proof already yields a finite randomized construction, and exhaustive search would find a successful outcome. Efficient derandomization is a different question: computing the score $\eta X - Y$ itself can dominate the cost. A first result could use a conditional-expectation procedure for fixed k, m , with a sparse representation of ϕ and an explicit arrangement-counting oracle. Its guarantee should include both the theorem's parameters and the algorithm's complexity.

Research question V.133.14 (A reusable formal library of weighted configurations). Can the common proof components be formalized once so that future refinements change only a rank estimate, a coefficient mass, or a finite energy identity?

The product-law subspace lemma, the score-extraction argument, and the conductor packing formula are independent of most of Gowers' proof. Establishing them as reusable lemmas would make later improvements easier to check. Exact computation could then discharge the finite cosine identities and rational inequalities, while the proof assistant checks the general probability and algebraic arguments connecting them.

V.134 Computational checks and reproducibility

Source 36, delivered Section 11.

The accompanying `checks/verify.py` is an executable audit of normalizations, endpoint constructions, finite tensor cases, and boundary examples. It uses a fixed seed, 20261006. The proofs above do not rely on a numerical search or an unverified pattern.

The supplied run used Python 3.13.5 and NumPy 2.3.5. Integer tensor calculations are exact modulo the specified prime. Other tests involving complex exponentials use double precision and tolerance 3×10^{-10} ; they are not exact cyclotomic or formal verifications. The machine-readable output is `checks/results.json`.

Check	Observed result
All 81 bilinear matrices on $\mathbb{F}_3^2$; one quadratic unit-modulus extremizer for each	All attained 3^{-r} ; maximum absolute error 4.45×10^{-16}
372 mixed-function tests in dimensions 2 and 4	No violation of the alternating-rank bound within tolerance
All $3^9 = 19\,683$ functions $\mathbb{F}_3^2 \rightarrow \{1, e_3(1), e_3(2)\}$ for $B(h, x) = h_1 x_2$	Maximum $1/3$; 324 exact maximizers
All $3^8 = 6\,561$ trilinear tensors on $\mathbb{F}_3^2$, with $f = 1$	81 fully symmetric; nonsymmetric maximum $45/81 = 5/9$; 120 endpoint tensors
Both slice-profile bounds for every tensor in that census	Passed by exact integer comparison
256 tensor profiles with one seeded nonconstant bounded function	Both amplitude-sensitive bounds passed
18 432 sampled polarization tuples in characteristics 5 and 7, degrees 3, 4, 5	Exact modular identities passed
12 full $\mathbb{F}_5^2$ pointwise spectral-shift tests	Maximum pointwise error 4.86×10^{-17}
All 81 tuples in the $\mathbb{F}_3$ nonclassical example	Exact triple differences modulo 9 passed

Supplementary checks also verified both profile directions for 256 seeded multiaffine selectors with affine offsets. A direct model of $\mathbb{F}_9 = \mathbb{F}_3[t]/(t^2 + 1)$ checked 24 mixed bilinear cases, the bilinear endpoint $1/9$, and the exact trilinear endpoint count $1377/6561 = 17/81$.

The trilinear census is particularly useful for detecting the wrong threshold. A tensor has eight coefficients; its selector is evaluated on all 81 ordered pairs of increments. With $f = 1$ its energy is the number of pairs giving the zero frequency divided by 81. Symmetry is tested against swaps of the final slot with each earlier slot. Slice ranks in dimension two are zero or two and can be detected by the off-diagonal alternating coefficient. Thus the entire census, including its profile inequalities, can be checked with integer arithmetic and no Fourier approximation.

The phase-function census is also exact. If a Fourier sum has a, b, c occurrences of $1, \omega, \omega^2$, where $\omega = e_3(1)$, its squared modulus is $a^2 + b^2 + c^2 - ab - ac - bc$. The script uses this integer formula; its output includes the histogram of all energy numerators over the common denominator 729. It exhausts this finite family, not all complex-valued bounded functions. The polarization tests sample tuples and tensors, even though the computations on each sample are exact. These distinctions are recorded in the JSON and should be preserved in any integration summary.

To reproduce the checks and the document from the package root:

```
python checks/verify.py --output checks/results.json
latexmk -pdf -interaction=nonstopmode -halt-on-error sharp_symmetry.tex
```

A Makefile and a minimal dependency file are supplied. No network access is required for the mathematics or checks once NumPy and a standard LaTeX distribution are installed.

V.135 ProveIt integration and formalization plan

Source 36, delivered Section 12.

V.135.1 Placement and source fidelity

The repository comparison is pinned to 6c2e2172bab8; the full commit is

6c2e2172bab8a0af4aed6b62d53ae7cde9252e8d

The inspected corrected transcription is

Combinatorics/Ramsey/Papers/
sz-thm-gowers-proof/sz-thm-gowers-proof.tex.

Its Proposition 17.2 already has the repaired degree and characteristic hypotheses. The existing local-quantitative-refinements README describes numerous contributions on density transfer, cube expansions, floor patterns, and the local phase extraction. This manuscript focuses instead on alternating-rank certification for a global finite-field selector. This is a scoped comparison, not a claim to have exhaustively audited every pending manuscript.

A suggested independent destination is

Combinatorics/Ramsey/Research/GowersSzemerédi/
sharp-symmetry-certification/.

The label prefix `ssc:` is used throughout. Importing the text into a larger report can retain all labels, including bibliography keys. The repository has not been modified by this delivery.

V.135.2 Theorems to formalize in dependency order

The proof deliberately separates finite algebra, spectral linear algebra, and Fourier normalization. A useful dependency order is:

1. Prove Lemma IV.19.1 for finite vector-valued multilinear maps, including the empty-tuple convention. Prove the separately affine extension as a distinct statement.
2. Define the forward multiplicative derivative and normalized Fourier transform, then prove Lemma IV.16.1. Relate forward and backward derivatives by translation before connecting to an existing source predicate.
3. Formalize alternating bilinear rank, its symplectic splitting, and Lemma IV.17.2. Establish the cocycle law with its exact sign and factor $1/2$.
4. Formalize the positive operator M_g , its trace, and the invariant-eigenspace argument. This proves the main bilinear inequality without requiring the later equality classification.
5. Deduce the frozen-slice estimate and the sharp threshold. Construct the endpoint using two independent dual vectors.
6. Prove diagonal polarization and the pointwise identity. This part is independent of the spectral proof once symmetry is supplied. It is the most direct equality-form companion to the global scalar phase-extraction statement.
7. Add noise, coset, and multiaffine interfaces. Formalize the block decomposition and stability only after the main theorem is complete.

No theorem name in this plan is claimed to exist already in Lean. No uncompiled Lean skeleton is included, and no existing source statement should be marked proved on the basis of this article.

[write] **6 October 2026; sources 34–39.** *Checked at HEAD 89c1cbc38.* The transcription has the blob `db4a37e` the source records, and `proposition_17_2` is exact (companion `proposition_17_2_holds`, `Proofs17PhaseRemoval.lean`, line 373); `proposition_17_7` is exact (companion `proposition_17_7_holds`, `Proofs17LocalizedPhaseRemoval.lean`, line 2941). The suggested separate directory was declined at placement (`bf2fe146d`); the labels keep their `ssc`: stems under this report’s prefix. Formalization candidate recorded at intake, claimed by nobody: Theorem IV.17.1 for rank-two forms.

In particular, a proof of the global scalar corollary is not a proof of the local-box Proposition 17.7 or the final density increment. The companion `FORMALIZATION_PLAN.md` expands the data types and proof obligations, without inventing checked status.

V.135.3 A normalization checklist for the source interface

An integration review should check five concrete points. First, the Fourier transform in the article is normalized, so passing to the source sums introduces $|V|^{k+2}$. Second, the polynomial degree and norm order are both $k + 1$. Third, odd characteristic is used in the bilinear gauge, whereas $p > k + 1$ is only needed in classical polarization. Fourth, the input selector must be globally multilinear unless the separately affine theorem is being invoked. Fifth, the strict threshold cannot be weakened to a non-strict one. Each of these has an explicit test or counterexample in this package.

V.136 Further research questions

Source 36, delivered Section 13.

The questions below are proposed problems arising from these results. They are not all claimed to be previously unpublished, and the established low-characteristic integration results and known approximate-symmetry counterexamples remain in force.

Research question V.136.1 (All endpoint configurations). For $k \geq 2$, classify the pairs (f, σ) with T nonsymmetric and $\mathcal{A}_f(\sigma) = \vartheta_{k,p}$. Equality in the proof requires a minimum-support defect, rank two on every defective slice, full amplitude there, and a bilinear extremizer on each such slice. Which compatible global configurations occur beyond products of linear functionals and their phase/gauge variants?

The finite census in Section V.134 supplies small examples for this question, not a classification. A solution would clarify whether the endpoint is essentially a zero-selector phenomenon or whether equally extremal nonzero spectral organization exists.

Research question V.136.2 (Stability at the symmetry threshold). If T is nonsymmetric and $\mathcal{A}_f(\sigma) \geq \vartheta_{k,p} - \varepsilon$, what structural conclusion follows as $\varepsilon \rightarrow 0$? Can the defect be approximated by a product-supported rank-two defect, and can the slice extremizers be made coherent? Determine an appropriate metric before asserting a power-law bound.

Theorem IV.20.3 controls individual bilinear slices. It does not imply this global statement, because the defect support and the dependence of the frozen functions must be stabilized as well.

Research question V.136.3 (Simultaneous alternating defects). Can one improve the minimum over individual profiles in (IV.18.5) when two or more independent slot defects are present? Identify

a joint rank invariant that yields a sharp bound strictly below each single-profile estimate for a natural class of tensors.

Multiplying the separate upper bounds is not justified. Any stronger estimate must account for the fact that all slice tests use the same function and overlapping tuples.

Research question V.136.4 (Below-threshold coherent rank reduction). For energies $a \leq \vartheta_{k,p}$, can the popular low-rank slices in (IV.18.7) be organized into a structured global subspace or multilinear variety on which the remaining defect vanishes? What loss is unavoidable for a one-function derivative array, as opposed to an arbitrary multilinear form?

The intended problem retains the derivative-spectrum hypothesis. It is not the disproved unrestricted approximate-symmetry statement.

Research question V.136.5 (Arithmetic boxes and boundary losses). Develop a version of alternating-rank orthogonality for derivatives localized to arithmetic progressions or Bohr sets, with an explicit boundary error and a normalization compatible with Section 17 of Gowers’s argument. Which additional local-extension hypotheses are sufficient to turn it into a genuine refinement of Proposition 17.7?

Uniform translation of the index set was used to make M_g commute with every U_h . A local result must replace that exact step, rather than just restrict the average and reuse the global proof.

Research question V.136.6 (Lower-order multiaffine components). After Theorem IV.23.1 certifies symmetry of all nonconstant components, what is the optimal procedure for removing the lower-order frequency terms? Is there a lossless identity in an enlarged space, or an optimal quantified loss on the original space?

Example IV.23.2 rules out simply integrating the top homogeneous component and retaining the same energy.

Research question V.136.7 (Exact nonclassical certification). In small characteristic, which additional repeated-variable identities of the total form are forced by an energy threshold close to one? Can a sharp threshold certify the precise hypotheses needed for an existing nonclassical integration theorem, rather than only ordinary permutation symmetry?

[write] **7 October 2026; sources 40–46.** Answered over $\mathbb{F}_2$ in every degree by source 43 (its Theorems IV.38.2 and IV.38.4); odd small characteristic stays open (its Research question V.160.5).

The integration theorem itself is not the unresolved part of this question; the new target is a sharp spectral certification of its additional hypotheses.

Research question V.136.8 (Composite-modulus rank profiles). For finite abelian groups of odd composite exponent, express the optimal bilinear factor using the elementary divisors of the alternating bicharacter. Then seek an analogue of the multilinear support bound that yields an exact symmetry threshold and sharp examples over $\mathbb{Z}/m\mathbb{Z}$.

[write] **7 October 2026; sources 40–46.** Advanced by source 43: the bilinear factor d_B^{-1} from the elementary divisors (its equation (IV.35.9)) and the exact symmetry threshold on every finite abelian group (Theorem IV.36.4); integration on composite groups is open (its Research question V.160.6).

The finite-field support probability $1 - 1/p$ no longer describes all nonzero module maps. A useful theorem must keep this arithmetic information rather than hide it in an unspecified constant.

Research question V.136.9 (Characteristic two). Formulate and prove an equally explicit characteristic-two version of the bilinear orthogonality and spectral certification steps, including the phases required to replace division by two. Determine which parts retain the threshold $1 - (1 - 1/2)^k$ and which extra integration obstructions remain.

[write] **7 October 2026; sources 40–46.** *Answered for symmetric trilinear forms* by sources 46 and 43 (Section IV.25): exact energy $2^{-r/2}$ and codimension $r/2$; in every degree the threshold $1 - 2^{1-d}$ certifies nonclassical integrability (source 43’s Theorem IV.38.4).

The present proof assumes odd characteristic and does not claim to settle this extension. A suitable projective-operator formulation is a concrete starting point.

Research question V.136.10 (Certification from limited data). Suppose a selector is supplied by a coefficient tensor together with sampled derivative Fourier coefficients. Design a reliable test that combines multilinearity checks, a certified energy lower bound, and the robust margin $a - \eta - \vartheta_{k,p}$. Determine its sampling and arithmetic complexity without treating numerical phase evaluations as exact certificates.

Research question V.136.11 (A useful inverse-theorem regime). In which quantitative inverse arguments can the global selector be obtained with energy a and characteristic $p > k/a$ without a loss that destroys the advantage of exact certification? Track all parameters through at least one complete finite-field inverse step before claiming an improvement to a final bound.

Research question V.136.12 (A formal proof with a small analytic footprint). Can the eigenspace-multiplicity proof of the bilinear estimate be formalized using only finite-dimensional spectral theory already available in the target proof library, and then connected to the repository’s corrected global phase-extraction predicate? A useful first milestone is the exact scalar identity, followed by the vector-valued support lemma and the rank-profile theorem.

V.137 Conclusion

Source 36, delivered Section 14.

The central output is an exact extremal answer: a nonsymmetric multilinear selector on $\mathbb{F}_p^n$ can carry at most $1 - (1 - 1/p)^k$ of the normalized one-function derivative-spectrum energy, and that amount is attained. The underlying rank-profile inequality is stronger and retains information that a binary symmetry test discards. Once symmetry and the factorial-invertibility condition hold, an explicit diagonal polynomial converts the tested spectrum into a lower Gowers power with equality, even before averaging over the derivative directions.

This is a local refinement and vector-space generalization of the global phase-extraction mechanism. Its scope, counterexamples, and normalizations are explicit enough for a formalization project. Whether the sharp profile and its stability theory can be made to improve a full quantitative inverse argument is left as a separate, well-defined research task. The package supplies proofs and checks for the results stated here; it does not claim formal verification, literature priority, or an improved final Ramsey bound.

V.138 Verification and repository integration

Source 37, delivered Section 10.

V.138.1 What the accompanying checks do

The archive contains `verify.py`, its dependency list, the captured run, and `verification_results.json`. The random seed is fixed at 20261006. The run used Python 3.13.5, NumPy 2.3.5, SciPy 1.17.0, and SymPy 1.14.0. The checks have the following coverage.

Check	Number
Exact symbolic autocorrelation identities	36
Exact symbolic moments in the $R = 2$ example	2
Polynomial, matrix, root, and weight cases ($1 \leq R \leq 24$)	120
Independent discretized empty-gap minimax programs	50
Mass-minimization linear programs with contact nodes	200
Nonempty finite-cyclic indicator cases ($3 \leq N \leq 12$)	5,411
Random critical-stability measure checks	300
Exact rational recurrence-rounding checks	1,000

The largest root-modulus residual was $2.42 \cdot 10^{-14}$ after rounding up, and the largest extremal-moment residual was $8.93 \cdot 10^{-14}$. The independent gap programs used 2001 mesh points and exceeded the exact formula by at most $4.94 \cdot 10^{-7}$, as expected from discretization; the smallest difference was about $-1.90 \cdot 10^{-13}$ from solver error. The mass programs, with exact contact locations included numerically, had maximum absolute error below $1.90 \cdot 10^{-8}$.

These are regression checks, not proof certificates. In particular, floating-point semidefiniteness, unit-modulus roots, and optimal LP values are not used to establish the mathematical theorems. The analytic proof of attainment is Theorem I.52.2 together with Lemma I.53.1. The exact rational rounding checks verify the arithmetic inequalities in the recurrence conversion, not the external Weyl estimate. No Lean formalization is included or claimed.

V.138.2 Suggested integration boundary

A suitable new directory is

`Combinatorics/Ramsey/Research/GowersSzemerédi/sharp-missing-intervals/`.

The manuscript should initially remain a research source. Existing `Section05.lean` targets should not be silently redefined, and the status ledger should not be marked proved on the basis of this PDF. A separate collection of strengthened statements can preserve compatibility with the already formalized statements.

A practical formalization can be split into two tracks. The lower-bound track needs only the coefficient formula, positivity, a finite Fourier expansion, and summation against nonnegative weights. It does not need the moment-existence theorem, unit-circle root geometry, or measure separation. The equality track adds the supported moment criterion and the rank argument. This separation prevents the sharpness proof from becoming a dependency of the useful finite-cyclic inequality.

Proposed statement	Main mathematical dependencies
Positive gap certificate	Trigonometric recurrence; autocorrelation identity
Weighted linear-cutoff lemma	Certificate; finite Fourier sum; nonnegative weights
Exact first-window optimum	Arc positivity; Toeplitz/localizing matrices; rank
Noisy-gap uniqueness	Certificate slack; Vandermonde injectivity
Critical concentration	Sine polynomial; elementary sine lower bound
Recurrence conversion	Weighted lemma; Dirichlet; existing Weyl companion
Short-step interface	Recurrence conversion; integer square-root inequalities

V.138.3 A finite Fourier interface

The following is a mathematical specification, not Lean code:

For $N \geq 2$, $1 \leq M$, $2M \leq N$, and $w : \mathbb{Z}/N\mathbb{Z} \rightarrow \mathbb{R}_{\geq 0}$, if $\sum w > 0$ and w vanishes on $|x|_N < M$, there is an integer $1 \leq r < N$ with $r \leq N \operatorname{div} M - 1$ and

$$-\operatorname{Re} \hat{w}(r) \geq \frac{M}{N-M} \sum_x w(x).$$

Using an integer frequency and then casting it into $\mathbb{Z}/N\mathbb{Z}$ avoids ambiguity about centered representatives. A second lemma can convert to the existing `centeredAbs` interface. The empty-weight case should be handled separately rather than divide by zero.

For empirical measures, the implementation should use a finite sum over sample indices or a multiplicity function. Replacing it by the image set would change both the mass and the Fourier sum. The existing repository already contains the needed collision-safe pattern.

V.139 Further research problems

Source 37, delivered Section 11.

The following problems separate plausible extensions of the present calculation from much larger conjectural consequences. They are proposed research questions, not claims that the wider literature has no answers.

Question V.139.1 (Beyond the first window). *Determine $\inf_{\mu \in \mathcal{P}(K_a)} \max_{1 \leq r \leq R} |\hat{\mu}(r)|$ when $a > 2\pi/(R+1)$, including exact extremizers and transition points. Does a finite sequence of contact-pattern changes lead to an explicit piecewise algebraic description in $\cos a$ for each fixed R ?*

The prescribed equimoment matrix ceases to be positive once $\rho > 1/R$, so continuing the tangent formula is not justified. A successful extension must change either the active moment pattern or the primal support. The small-dimensional cases can be explored by the supplied LP code, but attainment and optimality still require analytic certificates.

Question V.139.2 (Exact finite-grid corrections). *For fixed N, M, R , solve the same extremal problem with support restricted to $\mathbb{Z}/N\mathbb{Z}$, and distinguish open from half-open exclusions. Quantify the excess over the continuous optimum in terms of the distances from the continuous contact nodes to the grid.*

The lower certificate survives sampling exactly, whereas the equality measure may not fit the grid. A second-order upper approximation is plausible when all relevant nodes can be moved within the allowed arc; endpoint constraints can produce a different first-order behavior. A complete result must account for both effects and positivity of the perturbed masses.

Question V.139.3 (Uniform stability constants). *Obtain useful bounds for κ and σ in Theorem I.56.3 as $R \rightarrow \infty$ with $(R+1)a$ in a compact subinterval of $(\pi, 2\pi)$. Can a suitable rescaling of angular distance give constants independent of R ?*

The critical estimate (I.56.1) suggests geometric control may be much better than a generic Vandermonde estimate. Weight recovery is likely the more delicate part. One should distinguish transport toward an unweighted contact set from transport to the uniquely weighted extremizer.

Question V.139.4 (Unequal Fourier budgets). *Given $\varepsilon_1, \dots, \varepsilon_R$, determine the least possible $\mu(I_a)$ subject to $|\hat{\mu}(r)| \leq \varepsilon_r$. Characterize the region of budget vectors for which the certificate of Section I.51 remains optimal.*

The available lower bound is $d - 2 \sum f_r \varepsilon_r$. Equality would require a measure on the same contact set with prescribed negative real moments. This turns local optimality into a finite feasibility problem; its positivity constraints may describe a computable cone or polytope in a suitable parameterization.

Question V.139.5 (Several forbidden arcs). *Find sharp Fourier detection results for a union of missing arcs, and compare their cutoff requirements with the total excluded length and the largest individual gap. Which arrangements of arcs force simultaneous large coefficients at several frequencies?*

The one-arc sign factor $\cos \theta - \cos a$ is no longer sufficient. Products of sign factors give certificates, but their Fourier coefficient signs and optimal degrees become nontrivial. This connects directly with multi-band moment representations rather than with a routine rescaling of the single-gap argument.

Question V.139.6 (Parameter optimization in the recurrence conversion). *Use the exact frontier $\rho_R(2\pi\delta)$, rather than the simplified $\delta/(1-\delta)$ bound, and optimize the cutoff, Dirichlet scale, and constant allocations simultaneously. Determine the best constant obtainable from the fixed Weyl input and this one-step architecture.*

The exponent $1/(D+1)$ in the present conversion reflects the powers in that architecture. Improving its numerical constant is a different task from proving that no more efficient recurrence argument exists.

Question V.139.7 (Propagating the short-step estimate). *Rework the degree induction for polynomial phase partitions using (I.57.16). What improved target-length exponent and threshold follow once every lower-coefficient term and every integer rounding loss is retained? Then propagate only the verified improvements through the later inverse and density-increment steps.*

This is the direct route from the present local work toward a stronger quantitative Szemerédi statement. A plausible local improvement is not itself the global theorem; a full parameter ledger is needed.

Question V.139.8 (Additional structure in polynomial empirical measures). *Can the moment problem be improved when the measure is known to be $T^{-1} \sum_{n \leq T} \delta_{an^k}$, rather than arbitrary? In particular, can its near equality with $\mu_{R,a}$ be excluded or exploited to force a better recurrence estimate?*

The extremizers here have $R+1$ specially placed atoms and negative equal moments. A polynomial orbit may approximate such a measure only for special arithmetic reasons. Turning that observation into a quantitative dichotomy would use the equality and stability theory rather than only the numerical coefficient bound.

Question V.139.9 (Certified symbolic extremizers and formalization). *For algebraic $\cos a$, produce exact algebraic descriptions of the contact nodes and positive weights, with certificates small enough for a proof assistant. Formalize first the finite lower-bound track and then the independent sharpness track described in Section V.138.*

The recurrence proof for w , the coefficient identity, and the rank-one matrix decomposition are natural certificate objects. Root-location verification need not be a separate numerical task because the moment-rank argument proves it structurally.

Question V.139.10 (Classical extremal interpretations and priority). *Identify the precise relationship of the formula (I.50.4) and the extremizing quadrature to classical trigonometric moment bounds, extremal positive polynomials, and finite power-sum inequalities. Which parts are known in equivalent language, and which refinements or stability statements are genuinely new?*

The general positivity machinery is already classical. Establishing the historical status of the closed formula and its consequences requires a more targeted literature comparison than recognizing that machinery. The proofs in this manuscript do not depend on a novelty claim.

V.140 Conclusion

Source 37, delivered Section 12.

The missing-interval step admits a sharp, exactly attainable Fourier formulation in the first spectral window. Its certificate has three useful features at once: the correct sign on the complementary arc, strictly positive nonconstant Fourier coefficients, and an explicit equality measure certified by a rank-one localizing matrix. This yields a robust mass tradeoff and rigidity, not just an isolated large-coefficient lemma.

For the selected Gowers argument, the immediate substitution is concrete: frequency at most $\lfloor N/M \rfloor - 1$ and coefficient at least $|A|M/(N - M)$, instead of the proof-supported quadratic cutoff and $|A|M/(4N)$. Optimizing the following rational approximation gives the explicit exponent b_k in (I.57.13), with its constant and short-step threshold displayed. The package is intended as a research source for careful integration and formalization. Global parameter propagation and historical priority remain separate tasks.

V.141 Source audit and reproducibility notes

Source 37, delivered Appendix C.

The following distinctions are material to integration.

Source or assertion	Treatment in this manuscript
Original Gowers Lemma 5.2	The proof's $1/4$ coefficient is the comparison baseline; the printed $1/2$ is not called false.
<code>Section05.lean</code>	Source for the corrected target, Fourier convention, and explicit thresholds.
<code>Proofs05MissingInterval.lean</code>	Existing proof-supported missing-interval development; not modified.
<code>Proofs05PolynomialPartition.lean</code>	Existing collision-safe multiplicity correction and integer-length issues are retained and credited.
<code>Proofs05Weyl.lean</code>	Its displayed <code>lemma_5_3_holds</code> supplies the cited explicit Weyl input; no build or re-verification is claimed here.
Supported moment criterion	Classical machinery, proved here for completeness and related to Yang–Xie.
Exact tangent formula and extremizers	Established by the proofs in this manuscript; historical novelty not asserted as settled.
Recurrence bounds	Consequences of a stated external Weyl estimate; no record comparison or global Szemerédi consequence asserted.
Computational checks	Finite symbolic and numerical regression tests, clearly separated from the proofs.

Build the document with `latexmk-pdfsharp_missing_intervals.tex`, or run `pdflatex` three times. The bibliography is embedded, so no external bibliographic database is needed. Run `pythonverify.py` after installing the packages in `requirements.txt`. This overwrites the local `verification_results.json` with a fresh report. Neither the build nor the verification script accesses the network or modifies a repository.

V.142 What the calculations verify

Source 38, delivered Section 8.

Delivered part heading of source 38: **Verification, integration, and further research**

The universal assertions in Parts I–III follow from the written proofs. The accompanying programs check finite identities, rational constants, symbolic series, and representative numerical instances independently. Their roles differ, and the output files identify which operations are exact and which use floating-point arithmetic.

V.142.1 Algebraic and finite checks

The exact symbolic calculation in `code/verify_quotient.py` reconstructs the fixed-phase norm solution and checks the coefficients through tenth order. Its separate finite-group calculation evaluates the full Fourier-square sum on $\mathbb{F}_5^2$, compares it with the centered polynomial, and checks the retained projection defect. It uses 160 reproducible random inputs, including functions close to a principal Fourier pair. Among these, 62 satisfy the local coercivity hypotheses with a numerically

resolvable positive norm loss. The largest centered polynomial discrepancy is less than $5 \cdot 10^{-16}$; the smallest observed improvement divided by $t^4 \Delta$ is greater than 3.18. These are consistency checks on examples, not estimates used in the dimension-uniform proof.

The separate program `code/verify_twelfth_order.py` checks the norm recursion, the Hessian, amplitude and phase displacements, and all terms in the optimized twelfth-order coefficient by exact symbolic arithmetic. It also verifies the signed-parameter symmetry. Its high-precision calculation solves the exact stationary equations at three positive parameter values. The mathematical compactness and implicit-function argument, rather than this numerical solver, establishes that the stationary branch gives every global maximum near zero.

For the broader odd-order expansion, the program `code/verify_odd_cube_expansion.py` directly enumerates physical cubes on $C_3, C_3^2, C_5, C_7, C_9, C_{15}$ and compares every coefficient with the Fourier formulas. Thus the test includes nonprime cyclic orders and order-three torsion. It is independent of the Fourier-square implementation in the characteristic-five test.

The standard-library program `code/verify_odd_rigidity.py` checks the exact three-point and five-point support multiplicities, then verifies the Weyl expansion and the finite envelope on 120 reproducible random vectors over $C_3, C_5, C_7, C_9, C_{15}, C_{25}$. The largest expansion residual is below $8 \cdot 10^{-16}$. Finally, `code/verify_six_ap_defect.py` performs the exact finite-field computations detailed in Part III. Those checks use integer arithmetic and exhaust all relevant field elements and target values for the two stated base fields.

V.142.2 High-precision illustrations

Figure V.142.1 displays two explicit families after subtracting the earlier terms in their asymptotic expansions. On the left, the five-point family uses the limiting phases and the corrected amplitude

$$b = (q_0/3)t^2 + (31q_0^2/27)t^4,$$

with the principal amplitude determined by the exact norm equation. This family attains the sharp tenth-order coefficient. Its phases have not been adjusted, so it does not attain the sharp twelfth-order coefficient. On the right is the exact three-point family in Part II. The variable ε there is its actual deficit $1 - \kappa$. The displayed residuals are

$$\begin{aligned} C_{10}(t) &= \frac{Q_{\text{fam}}(t) - 1 - 6\sqrt{2}t^4 - (2^{3/4}/3)t^6 - (20/9)t^8}{t^{10}}, \\ \mathcal{R}_{\text{odd}}(\varepsilon) &= \frac{t - \varepsilon/4 - 3\varepsilon^2/16}{\varepsilon^{5/2}}. \end{aligned}$$

The program `code/make_figures.py` writes the figure and its underlying CSV data. It uses 121 parameter values in each panel and records the precision and norm-equation residual. At the smallest plotted five-point parameter, the tenth-order residual differs from its limit by less than $4 \cdot 10^{-12}$. The high precision is useful because subtracting the preceding asymptotic terms at ordinary machine precision would conceal the coefficient being plotted.

V.143 Integration with the ProveIt development

Source 38, delivered Section 9.

Figure V.142.1: Residuals for two explicit families. The dashed lines are the proved limits $869/(216 \cdot 2^{3/4})$ and $\sqrt{2}/64$. The plotted values are computed at 120 decimal digits; they are illustrations, not numerical certificates of global optimality.

V.143.1 The exact connection to Gowers' lemmas

The direct strengthening of Gowers' Lemma 3.10 is Corollary III.85.5: for degree-two uniformity parameter α , it replaces the triangle-inequality envelope $(\delta + \alpha^{1/8})^8$ by the exact small-norm profile in the specified exponent-five setting. The fixed-odd-exponent theorem extends the structural reduction, even where the resulting cyclic profile has not yet been explicitly computed. These statements have narrower arithmetic hypotheses than the original all-modulus lemma and substantially more precise conclusions within that scope.

The proofs also strengthen how Lemmas 3.8 and 3.9 are used. Their usual upper estimates discard the location of Fourier mass. The retained energy inequality (III.84.1) and the linear seventh-degree estimate (III.84.4) turn a non-strict norm comparison into a strict improvement whenever a candidate has Fourier mass outside the selected cyclic subgroup. Part II addresses a different endpoint: it quantifies near equality in the critical U^3 – L^2 inequality, while Part III supplies an exact count for an extension of the layered norm method associated with the progression questions in Gowers' Section 4.

V.143.2 Formal status and normalization

The inspected checkpoint `FORMALIZATION_STATUS.txt` reports 206 compiled modules, 1,878 audited public Gowers theorems, 100 exact companion proofs, and 20 open catalogue statements [168]. These are the repository's reported results at the pinned commit. This project inspected the relevant source files; it did not reproduce that build. No new theorem in this article has been checked by the Lean kernel.

[write] **6 October 2026; sources 34–39.** *Checked at HEAD 89c1cbc38.* The counts above are those of the pin; at HEAD `FORMALIZATION_STATUS.txt` reports 410 modules and 2,840 audited public theorems, and the ledger 107 exact companions and 13 open statements (the source's `SOURCE_LEDGER.json`, shipped as

`data/38-quotients-SOURCE_LEDGER.json`, keeps the pin’s 206, 1,878, 100 and 20; recorded, not edited). `lemma_3_10` and its companion are unchanged; the four Lean files named in the table below exist with the blobs the source records. No statement of this source is formalized.

The existing declaration `lemma_3_10` and its companion `lemma_3_10_holds` should retain their present scope. The new theorems are separate refinements with explicit realness, centering, odd-order or exponent assumptions. In particular, a proof on $\mathbb{F}_5^n$ cannot be substituted for a theorem on arbitrary $\mathbb{Z}/N\mathbb{Z}$ without changing its statement.

The repository’s Section 3 cube form uses unnormalized sums. For a group of order N , its three-cube norm is $N^{1/2}$ times the normalized U^3 norm used here, and its three-cube count is $N^4\mathcal{C}_3(W)$. A formal interface should prove these normalization equalities first. For general cube dimension d , the corresponding norm factor is $N^{(d+1)/2^d}$. Losing these factors would change both the hypotheses and the powers of the density in the result.

Mathematical component	Existing interface inspected	New proof work
Cube Cauchy–Schwarz and triangle inequality	<code>Proofs03GowersCS.lean</code> ; <code>Proofs03Minkowski.lean</code>	Transport to normalized finite-group averages and subgroup projections
Sharper cube upper bound	<code>Sections01_03.lean</code> ; <code>Proofs03CubeUpper.lean</code>	Exact Fourier coefficients, coercivity, quotient pullback, finite algebra
Odd-order critical stability	No matching theorem was identified in the inspected files	Weyl orthogonality, finite spectral projectors, quantitative local expansion
Six-term norm extensions	The research reports supply the preceding mathematical context	Norm fibers, trace quadratic forms, centered interpolation, exact counting

A practical order is to formalize the finite algebraic statements before the analytic extremal expansion. The Fourier-square identity, the rational cutoff, the six-point interpolation matrix, and the quadratic-form count have exact finite certificates. The analytic profile additionally needs compactness, an implicit-function theorem, and a justified Taylor remainder; symbolic output alone is not a formal proof of these steps. The programs are designed to expose the identities such a development would need, without presenting uncompiled Lean placeholders as checked results.

The archive supplies a complete TeX manuscript, its bibliography and figure, verification programs, and build instructions. The source ledger records the inspected repository checkpoint and preceding reports, preserving the distinction between earlier and new results.

V.144 Proposed further research questions and topics

Source 38, delivered Section 10.

The following questions are proposed continuations of the proved results. They are not claimed to constitute an exhaustive survey of open problems. The characteristic-five eighth-order question and the odd-order asymptotic coefficient question from the preceding reports should be replaced by the resolved statements above. The problems below concern the stronger conclusions that remain out of reach of the present arguments.

1. **Determine the sharp range of exact quotient reduction.** Define c_5^* as the supremum of c for which every exponent-five maximizer factors through a five-point quotient whenever $0 < u/\delta < c$. Is c_5^* finite, and what first destroys the quotient conclusion? The proof gives $c_5^* \geq 10^{-5}$. A useful next step is to compute the exact second variation against off-quotient perturbations along the analytic five-point branch, then distinguish a local instability from a crossing with a distant competing maximum.
2. **Decide whether the odd-exponent cutoff must depend on the exponent.** The sufficient constant $10^{-8}m^{-8}$ comes from summing bounds over up to m^2 Fourier-square slots. Can a global square-sum estimate remove that dependence, giving one positive cutoff for all odd exponents? If not, construct an explicit sequence of odd-order groups and genuinely noncyclic extremizers at parameters tending to zero. Either outcome would explain the precise scope of the projection principle.
3. **Classify the cyclic profiles and their arithmetic transitions.** Compute the first unresolved terms of $\mathcal{M}_{1,\mathbb{Z}/m\mathbb{Z}}(t)$ for small odd m , and determine which character order supports a maximum when m has several odd prime divisors. Order three already supplies a fifth-degree contribution, whereas the exponent-five profile has the secondary scale studied here. A systematic classification should record the frequency relations responsible for each power and decide when fractional powers occur.
4. **Find an exact algebraic description of the five-point branch.** The norm constraint and stationary equations give a finite algebraic system after replacing phase angles by their sines and cosines. Can it be eliminated to an explicit equation for the extremal value with a certified branch-selection interval? Determine the first nonzero term, if any, in $\alpha(t) - \pi/10$ after its third-order cancellation, and the symmetries behind subsequent phase coefficients. An answer would make the convergence radius and the higher coefficient recursion more concrete.
5. **Optimize the quotient-stability constants and powers.** Determine the best constants, and the sharp dependence on the extremal deficit, in (III.84.6)–(III.84.7). The factor 256 comes from a general convexity estimate and has not been optimized for this Fourier geometry. Constructing perturbations in one additional frequency coset is a controlled way to test which exponents and constants can be improved.
6. **Describe the constrained weighted profile beyond the interior regime.** When the maximizing five-point function first reaches 0 or 1, which coordinates saturate, and does exact quotient reduction continue? Determine the resulting piecewise extremal profile at a fixed density. Separately, quantify how fast indicator sets in growing product groups can approximate these weights in the uniformity norms relevant to the cube count. The variance in L^2 must be treated on its own terms.
7. **Determine the next sharp odd-order stability coefficient.** Find the coefficient of ε^3 in $\mathfrak{S}_{\text{odd}}(\varepsilon)$. Does the three-point family remain extremal at that order, or can perturbations outside its two tangent eigencharacters improve the value? The tangent-rigidity corollary narrows the search to perturbations around an order-three pair. Resolving the next variation would also indicate whether there is an exact finite-parameter odd-order modulus.
8. **Solve the coprime-to-six local extremal problem more precisely.** With order-three resonance excluded, determine the optimal cubic term in the deficit and whether a fixed cyclic group realizes it. The two-state five-point family proves the displayed second-order sharpness, but it need not settle the subsequent coefficient. This is a separate problem from optimizing the coarse constant 104 in the finite envelope.
9. **Make local rigidity constructive from sampled derivative data.** The proof identifies a large Weyl subgroup and then a common eigenvector. Can this argument be converted into an efficient reconstruction procedure with error constants approaching the sharp modulus? The relevant input may be an approximate ambiguity table or samples of it, rather than the complete function. A useful formulation should distinguish arithmetic cost, sampling cost, and the dependence on the exponent.

10. **Develop sharp critical stability for higher Gowers norms.** For U^d , the natural critical exponent is $p_d = 2^d/(d+1)$ [7]. Determine the leading stability coefficient near a polynomial phase supported on a coset, and identify any torsion-dependent fractional corrections. The exact L^2 Weyl identity used here is specific to $d = 3$; a higher-order argument must replace that Hilbert-space mechanism.
11. **Calculate the eight-term and higher norm-extension defects.** The next complete core contains norms of degrees 1, 3, 5, 7. Determine the joint distributions of the polarized coefficients that remain after the top direction is fixed. In the six-term case only the quadratic statistic e_2 was needed; higher layers bring several interacting coefficients. An exact formula, or a uniform error estimate around its natural mean, would extend Part III in a substantive way.
12. **Obtain a stability theorem for small norm-extension defect.** If $A_6^{\text{sym}}(P)$ is close to its baseline, how close must R be to an additive quadratic? Formula (III.88.1) first controls the fraction of nonzero third and fifth differences. The remaining task is a quantitative polynomiality theorem with constants uniform in the number of added coordinates. Determine the correct dependence on the characteristic and on the extension degree of the base field.
13. **Resolve the global quintic four-term avoidance dimension.** The preceding degree-stratification report leaves the maximum dimension for a degree-five coloring without a nontrivial symmetric four-term progression between four and eight [173]. The independent-extension obstruction does not resolve this gap. Can a genuinely coupled quintic construction exceed the known four-dimensional construction, or does a stronger global argument force a smaller upper threshold than the pointwise degree count?
14. **Certify the new exact identities in the formal development.** Begin with the centered cube coefficients and the energy coercivity, then the finite-field fiber calculation and the Weyl-coset expansion. These pieces can be reviewed separately and are useful without the analytic optimization. A later proof of exact quotient reduction should preserve the strict deficit and the explicit cutoff, rather than formalizing only a weakened asymptotic bound.
15. **Locate a genuine bridge to global progression bounds.** Identify a density-increment or transference argument in which one of these sharper local statements survives all subsequent losses. Such an application must explicitly reconcile the bounded-exponent setting with the ambient group used to model long integer progressions. Write out the resulting recurrence and solve it before claiming an improvement of the global bound. This problem is logically additional to the local extremal theorems proved in this article.

V.145 A precise interface with the inspected Gowers development

Source 39, delivered Section 12.

V.145.1 Source controls and the already existing improvements

In this section q denotes the number of vertical affine classes and b the complexity parameter of each horizontal section. We deliberately do not use s for both a class size and a section complexity.

Let $c(u, \gamma, k)$ and $Q(u, \gamma, k)$ denote the source's positive scale and graph controls, represented by `multipleC` and `multipleQ`. For a horizontal section of complexity b , the relevant one-slice form is

$$a(\tau) = c(\tau/b, \gamma, k)^b, \quad L(\tau) = Q(\tau/b, \gamma, k)^b. \quad (\text{V.145.1})$$

These symbols retain their source meaning; the present article does not redefine their dimension-dependent exponents.

The inspected `Proofs16RecoveredSliceCover.lean` already gives a common refinement with

$$P \leq Q(\epsilon/(rb), \gamma, k)^{rb}, \quad (\text{V.145.2})$$

$$\text{base width} \geq M^{c(\epsilon/(rb), \gamma, k)^{rb}}, \quad (\text{V.145.3})$$

and a recovered candidate index set of cardinality

$$rP + r^2P^2. \quad (\text{V.145.4})$$

Its geometric successor imposes a short-parent width condition and performs synchronization without a further candidate blow-up [177, 179]. In particular, the linear dependence on r in the refinement exponent is *already present* in this snapshot; it is not a new conclusion being attributed to this article.

V.145.2 Replacing the sample while keeping the existing interface

Proposition V.145.1 (Sampled-or-anchored output). *Suppose ϕ on a partial subset D of $H \times J$ is covered, on every vertical fibre, by at most q affine functions over a field. For every $1 \leq r \leq m$, there is an injectively enumerated sample of r columns and sets $K \subseteq F \subseteq H \times J$ such that:*

- (i) *the complement of F has ambient mass at most $2q(m-r)/(m(r+1))$;*
- (ii) *every point of $D \cap F$ is either in K or on a sampled column;*
- (iii) *every point of $D \cap K$ has two distinct sampled anchors in the same row, both in $D \cap K$, from whose values it is recovered by (II.159.4).*

These are the mathematical contents needed by the repository's `Section16SampledOrAnchoredOn` interface.

Proof. In each row assign each point of D to one of the affine graphs that covers it, for example the first one in a fixed ordering of the q graphs. This makes a disjoint class partition. Apply Theorem II.153.2 with $t = 2$. Let $F = E_R$ be its ambient good set and let K be the union, over all rows, of the full classes containing at least two sampled columns.

Every such full class is contained in F , so $K \subseteq F$. A domain point of F not in K survives precisely because its column is sampled. For a point of K , choose two sampled members of its own class. They too belong to that full class and hence to $D \cap K$. They have distinct column values, and the affine interpolation identity follows from the common affine class function. Enumerating the set R produces an injective sample. $\square$

[write] 6 October 2026; sources 34–39. Checked at HEAD 89c1cbc38.

Section16SampledOrAnchoredOn is at Proofs16ShortColumns.lean, line 27; the seven Proofs16 files the source cites have the blobs it records. The proposition is a formalization candidate (an exact double count over $(r+1)$ -subsets), claimed by nobody; the same $O(q/\sigma)$ sampler is source 19's (note in Section F.44), which should be credited first. lemma_16_10 (Section16.lean, line 851) is open; nothing here changes that, as the source says.

The point that the anchors belong to K , not just to the larger set F , is useful: it matches the nested anchored-subset predicate in the repository. This is why we take K to contain whole sufficiently sampled classes, rather than just the nonsampled targets.

In the finite-field implementation $J \subseteq \mathbb{Z}/N\mathbb{Z}$ with N prime, distinct column values have invertible difference. The set-theoretic sample theorem itself does not need primality. Over a general ring the same algebraic interface would need unit differences for the chosen anchors; nonzero difference alone would not suffice.

V.145.3 A parameter-explicit local replacement

Theorem V.145.2 (Local affine lift with the existing common-cover bounds). *Assume the vertical affine cover of Proposition V.145.1, and assume the horizontal sections satisfy the source's common-cover hypothesis with parameters (γ, b, k) . For $0 < \eta, \epsilon < 1$, choose*

$$r = \min\{m, \lceil 2q/\eta \rceil\}. \quad (\text{V.145.5})$$

At the level of base cells times the final-coordinate set, the existing common-cover and interpolation conclusions apply with exceptional fraction at most $\eta + \epsilon$, width bound (V.145.3), and at most $rP + r^2P^2$ candidates, with P as in (V.145.2).

If, in addition, the labelled hereditary hypothesis (V.145.1) is used while preserving the required admissible base cells, the same width bound is obtained with candidate bound

$$rL + \binom{r}{2}L^2, \quad L = Q(\epsilon/(rb), \gamma, k)^b. \quad (\text{V.145.6})$$

Proof. Proposition V.145.1 and Corollary II.153.3 provide the sampled-or-anchored good set with error at most η and an r -term sample. The already established common-cover and recovered-slice conclusions then give the first assertion, losing another ϵ in the base. Equivalently, their purely algebraic covering step is the $t = 2$ case of Theorem II.160.1, with the common list bound P used for every anchor and an ordered-pair indexing convention.

For the labelled version, apply Theorem II.161.2 with $\tau_i = \epsilon/r$ and the one-slice controls (V.145.1). The product of the scale powers is

$$\prod_{i=1}^r c(\epsilon/(rb), \gamma, k)^b = c(\epsilon/(rb), \gamma, k)^{rb},$$

whereas each individual list has size at most $Q(\epsilon/(rb), \gamma, k)^b = L$. Corollary II.160.2 supplies (V.145.6). The same error addition applies. $\square$

The first part is a direct mathematical replacement at an existing interface; it requires no redesign of geometric synchronization. The second part is a proved refinement theorem with explicit hypotheses and a proposed way to retain more information in the implementation. It is not claimed that the new labelled version has already been formalized in the repository.

If the maximum permitted common list size is written as $P = L^r$, the old upper-budget expression is $rL^r + r^2L^{2r}$, while (V.145.6) is $rL + \binom{r}{2}L^2$. This comparison concerns *guaranteed list budgets*, not necessarily the actual number of distinct graphs produced by either method. Both arguments may have extensive redundancies in a particular instance.

V.145.4 Geometry must remain a separate hypothesis

A product of a refined base box and an arbitrary final-coordinate progression is not automatically a proper common-step box. The repository explicitly separates these issues. Its synchronization statement [178] uses a short parent progression for one axis of each refined base cell, parallel to the original final progression I , and with unit step. The parent is short relative to the ambient modulus, has length at most $|I|$, and contains the chosen refined axis. A further inequality of the form

$$v^2 \leq \text{refined base width} - 1$$

allows compatible final-axis tiling. Under these hypotheses it produces proper common-step boxes of width at least $v - 1$, without increasing the list of candidates or the exceptional set.

In the source’s assembled short-parent version, a sufficient real-valued budget is

$$v^2 + 1 \leq (m_0/8)^{c(\epsilon/(rb), \gamma, k)^{rb}}, \quad (\text{V.145.7})$$

where $m_0 \geq 4$ is an input common lower width, not the column-set cardinality m used in our sampling lemmas [179]. Appropriate properness, unit-step, and containment assumptions are also required.

Corollary V.145.3 (Conditional synchronized lift). *If the base refinement supplied in Theorem V.145.2 has the short-parent containment and width hypotheses of the source synchronization lemma, its rectangular cover can be replaced by the corresponding proper common-step box cover with the same exceptional fraction and the same candidate bound. This applies to the labelled bound (V.145.6) when the labelled refinement preserves those hypotheses.*

Proof. Synchronization partitions each rectangular product into compatible boxes and restricts the candidates from its base cell to the resulting boxes. Restriction preserves the candidate identities and multilinearity. The source tiling covers the whole rectangle, so there is no additional discarded mass. Its width conclusion is exactly the assumed synchronization conclusion. $\square$

This corollary is conditional on stated geometric input. It must not be read as proving that any abstract common refinement automatically satisfies that input, or as replacing an unproved scale comparison by the word “synchronization.”

V.145.5 Equal-error budget comparison

For a final sampling error allowance η , the inspected corrected sampler can use $\tau = \eta/2$ and the sufficient budget

$$r_{\text{corrected}} = \left\lceil \frac{24q}{\eta^2} \right\rceil, \quad (\text{V.145.8})$$

with the short-column alternative handled as in the source [175, 176]. Our sufficient distinct-anchor budget is (V.145.5). The comparison is at the same error allowance; comparing $6q/\tau^2$ with $2q/\eta$ without noting $\eta = 2\tau$ would conceal a change of convention.

As a numerical illustration, take $q = 100$, $\eta = 0.01$, and a column set large enough that neither of these budgets needs truncation. Formula (V.145.8) gives 24,000,000, while (V.145.5) gives 20,000. This is a comparison of sufficient local budgets, not an empirical running-time measurement. The asymptotic minimax budget in a sufficiently sparse-sampling limit is about 8,399.62, but that number is *not* a certified finite replacement for 20,000 at an unspecified value of m .

V.145.6 The closing comparison is not proved here

The inspected file `Proofs16ClosingComparison.lean` proves that the same-dimensional numerical comparison in the edited closing argument has the wrong direction [180]. In its parameter range,

$$Q(\rho, \gamma, k) < Q\left(\frac{\rho}{4p}, \gamma, k\right)^p \quad (0 < \gamma, \rho \leq 1, p \geq 1). \quad (\text{V.145.9})$$

It also records an endpoint obstruction with possibly different source and target dimensions: $Q(1, 1, d) = 1$, while shrinking the positive error argument below 1 and raising the corresponding graph budget to a positive power produces a number greater than 1.

The new sampler changes r , and the labelled refinement changes the local candidate count. Neither fact reverses (V.145.9) or proves every prescribed dimension-dependent control. Theorem V.145.2 therefore states the output bounds actually obtained. We do not conclude a new global bound for Szemerédi’s theorem, do not declare Lemma 16.10 fully repaired, and do not treat failure of a displayed proof step as a counterexample to the full mathematical lemma.

V.146 Exact checks, examples, and reproducibility

Source 39, delivered Section 13.

V.146.1 What was actually tested

The package contains a dependency-free Python implementation of the finite formulas, the dynamic program, the closed balanced-profile formula, the affine quadratic cap, and the deterministic sampling algorithm. The test programs use Python integers, integer square root, and `fractions.Fraction`; they do not use floating-point arithmetic for any assertion of equality or inequality.

Two certificate files record a total of 11,212 checked cases, all passing in the delivered run. Their categories are listed in Table V.146.1. A “case” means one loop instance in the named category; it is not a separately proved theorem or an independent review. Some cases contain several assertions. In particular, the second-difference cases compare the direct difference, the hypergeometric formula, and, when applicable, the factored sign formula.

Table V.146.1: Executed exact-arithmetic verification categories.

Category	Cases
Direct one-class averages and the $(r + 1)$ -sample identity	2,020
Dynamic programming versus exhaustive size profiles	315
Anchor sets in exact permutation-orbit extremizers	105
Weighted deterministic selection instances	80
Conditional-expectation identities	226
Nonsampled finite-field polynomial recoveries	257
Candidate index-set cardinalities	180
Closed balanced formula versus dynamic programming	2,496
One-class unimodality and initial discrete concavity	624
Exact second-difference identities	2,765
Affine quadratic cap versus exact marginal maximization	2,144
Total	11,212

The first certificate suite includes finite-field reconstruction over $\mathbb{F}_5$, $\mathbb{F}_7$, and $\mathbb{F}_{11}$, with thresholds 1 through 4. It checks Lagrange reconstruction at nonsampled targets having enough valid anchors; the already sampled targets require no interpolation. The second suite checks the closed finite formula against the independent dynamic program for $m \leq 13$, $q \leq 4$, thresholds through 6, and all sample sizes. The affine cap is compared against an exact scan through all class sizes for every $m \leq 64$ and $0 \leq r \leq m$.

These tests are designed to expose normalization errors, endpoint mistakes, off-by-one errors in distinct-hit thresholds, incorrect ceilings, and false maximizer claims. They supplement the proofs; none establishes a universal statement by finite exhaustion.

V.146.2 Representative exact finite values

Table V.146.2 shows values from `data/exact_profiles.csv`. The profiles listed there were originally found by the independent dynamic program. The closed balanced formula gives the same values, though in linear or plateau cases it may choose a different maximizing profile. This is expected: Theorem II.155.3 proves the existence of a balanced extremizer, not uniqueness of all extremizers.

Table V.146.2: Exact minimax values and simple universal bounds. All losses are fractions of ambient mass.

m	q	r	t	A maximizing profile	$\mathfrak{M}_{m,q,r,t}$	Bound (II.153.3)
20	2	2	2	(10, 10)	27/38	1
20	2	4	2	(7, 7)	1001/2850	16/25
20	2	8	2	(3, 3)	143/950	4/15
20	2	12	2	(2, 2)	2/25	8/65
20	2	16	2	(2, 2)	1/25	4/85
40	3	2	2	(13, 13, 14)	43/50	1
40	3	4	2	(13, 13, 13)	3159/5624	1
40	3	8	2	(7, 7, 7)	56637/209950	8/15
40	3	8	3	(10, 10, 10)	233595/525844	4/5
40	3	12	3	(7, 7, 7)	6867/25160	63/130

The table makes visible the distinction between a useful easy bound and the actual optimum. It also shows why equal-size classes with unused columns cannot be ruled out merely by assuming that a difficult example should use the whole domain.

V.146.3 Reproducing the results

From the package directory, run

```
python3 code/verify.py
python3 code/verify_balanced.py
python3 code/poisson_constants.py
make pdf
```

The first two commands regenerate the exact JSON certificates. The constants script uses high-precision decimal arithmetic only for the illustrative Poisson constants, clearly separated from the exact combinatorial checks. The PDF can alternatively be built by running `pdflatex` twice on `article.tex`. The manuscript uses no external figure files and no bibliography processor.

The code deliberately keeps both the dynamic program and the closed formula. Agreement between implementations using different mathematics is a useful regression check, although it is not a substitute for the proofs. The repository interface is documented in `FORMALIZATION_PLAN.md`; that file is a plan, not an executable Lean proof.

V.147 Further research questions and proposed next steps

Source 39, delivered Section 14.

The finite minimax value and the existence of balanced-and-capped extremizers are settled by the theorems above. The following are distinct follow-on questions; none is used as a hidden premise of the proved statements.

Research question V.147.1 (Classification of all finite extremizers). Characterize every maximizing profile, not just the balanced one, and every row family attaining the minimax value. The proof identifies equalization steps that preserve or improve the objective. Equality should be controlled by zero discrete curvature, flat first differences, and the distribution of rowwise losses across samples. A useful result would give a complete criterion for equality in Theorems II.154.2 and II.155.3, including the many nonunique cases with large sampling fraction.

Research question V.147.2 (Finite corrections to the golden-ratio law). Obtain explicit uniform error bounds for (II.157.7), separating finite-population corrections, integer rounding, and the approach of q/r to the transition. The affine radical formula makes the optimizing class size explicit, so an expansion of the hypergeometric marginal at that size could yield certified second-order sampling budgets rather than only an $o(1)$ term. Near the phase transition, rounding and whether the column budget is active should be treated together.

Research question V.147.3 (General-threshold cap computation). For fixed $t > 2$, derive an equally transparent description of the first maximizing size $a_{m,r,t}$. The first-difference identity is

$$\Delta \ell_{m,r,t}(s) = \frac{m-r}{m^2} [\mathbb{P}\{Z < t\} - t\mathbb{P}\{Z = t\}], \quad Z \sim \text{Hyp}(m-1, s, r).$$

After factoring binomial terms this gives a bounded-degree algebraic expression when t is fixed. The problem is to isolate its relevant root with exact boundary handling and a complexity bound independent of a scan through all m sizes.

Research question V.147.4 (Thresholds growing with sample size). Determine the asymptotics of λ_t and κ_t as $t \rightarrow \infty$, and prove a uniform version of Theorem II.157.2 when t also grows with r and m . The fixed- t proof uses finitely many low-count probabilities and does not establish such a regime. This extension would quantify the cost of interpolating increasing polynomial degree rather than only a fixed degree.

Research question V.147.5 (Algebra-aware improvements beyond certification). Find hypotheses under which the permutation-orbit lower bound ceases to apply because additional algebraic information is available. Examples include classes known to share a polynomial, restrictions on how class labels vary with the base point, or compatibility among overlapping fibre interpolants. The objective should be a precisely defined stronger recovery rule with its own upper and lower bounds, not an unsupported claim that arbitrary polynomial reconstruction requires $\kappa_t q/\sigma$ anchors.

Research question V.147.6 (Compressing labelled candidate lists). When can the upper count $\sum_a L_a + \sum_{|S|=t} \prod_{a \in S} L_a$ be reduced by algebraic dependence among lists? Is there a useful lower-bound model in which its leading order is necessary? Even the affine case may benefit from canonicalizing pairs of slice candidates that give the same lifted graph. Any proposed compression must retain the pointwise existence guarantee without assuming a globally consistent choice of branches.

Research question V.147.7 (Formal label preservation and geometry). Formalize the new sampler into the existing `Section16SampledOrAnchoredOn` interface, then formalize labelled hereditary refinement with a dependent list type indexed by the sampled column. Prove that the short-parent cover construction preserves the needed containments for the labelled lists. This is a concrete integration task: its goal is the exact bounds of Theorem V.145.2 and Corollary V.145.3, not a silent change to the source definition of multiply-linear control.

Research question V.147.8 (Nonuniform column costs and sampling designs). Extend the finite game to weighted columns or nonuniform sampling costs. Uniform row weights cause no difficulty here, and arbitrary row weights are already covered; nonuniform *column* weights are different. The $(r+1)$ -subset identity and permutation-orbit minimax argument depend on the uniform column law. A replacement should specify the admissible sampling design, the target mass measure, and the correct notion of a profile.

Research question V.147.9 (Robust recovery when good classes are unknown). Develop an algorithm that exploits Theorem II.159.5 without being given the good subset or its class partition. The additive error bound shows that correct interpolants exist in the generated list; it does not identify them. A useful result would combine shared sampling with an explicit consistency test or a list-decoding guarantee, with running time stated in terms of the actual representation of the fibres.

Research question V.147.10 (Repairing the global control recurrence). Replace the invalid closing comparison by a valid dimension-dependent recurrence for scale, graph count, and exceptional mass. The new local budgets should be substituted before attempting domination by a closed formula. Endpoint-safe controls may need a multiplicative slack factor strictly larger than one, since a graph budget equal to one at $(\rho, \gamma) = (1, 1)$ cannot dominate every nontrivial construction cost. The task is then to propagate the repaired recurrence through the subsequent sections and explicitly compute what global quantitative statement follows. This remains separate from the finite sampling problem solved here.

V.148 Conclusion

Source 39, delivered Section 15.

The shared interpolation step admits a direct mass-weighted treatment. The finite identity (II.153.1) eliminates the need to discard small classes and then impose a separate failure probability on every surviving class. It yields a uniform $O(q/\sigma)$ sample budget, while exact minimax symmetrization proves that the associated certification problem has no hidden dependence on the number of rows.

The finite problem is solved more explicitly than an averaging bound alone would suggest. Hypergeometric finite differences show that a balanced profile, capped at the first one-class maximum, is optimal. For affine interpolation the cap is the ceiling of an explicit quadratic root. In a sparse-sampling limit this finite structure becomes the golden-ratio coefficient $\varphi^3 e^{-\varphi}$, and the full transition between partial and saturated column profiles is given by (II.157.8).

On the algebraic side, interpolation is naturally performed from labelled slice lists. Retaining those labels gives the candidate count $rL + \binom{r}{2}L^2$ rather than using a common union list at every anchor. The theorem is compatible with the repository's existing sampled-or-anchored and synchronization interfaces, subject to the explicitly retained geometric hypotheses. It improves local information and local parameters; it does not supply the missing global closing comparison.

V.149 Proof dependencies and formalization targets

Source 39, delivered Appendix A.

V.149.1 A dependency map

The finite sampling and minimax results are independent of fields, polynomials, Gowers norms, and the source's control functions. Their logical chain is

$$\text{finite double count} \implies \text{shared-sample bound} \implies \text{minimax upper bound},$$

with permutation symmetrization supplying the matching lower bound. The finite-difference identities then give one-class shape, followed by balancing and the closed finite formula. The affine cap uses only a quadratic sign computation after the first-difference identity.

The Poisson results use these finite formulas plus an elementary product inequality, elementary limits, and single-variable calculus. They are not needed to obtain the nonasymptotic $O(q/\sigma)$ improvement or to compute the finite optimum.

The algebraic lift uses interpolation and the already proved sample certificate. The labelled refinement theorem uses restriction closure, finite partitions, and measure addition. Only the final source-interface section uses Gowers's particular single-slice and geometric hypotheses. Separating these layers should make a formal development substantially easier to audit than a single theorem combining all of them.

V.149.2 Suggested declaration boundaries

A proof-assistant implementation can first state everything in finite types and unnormalized counts. The following names are proposed; they do not refer to declarations already present in this delivery:

sharedAnchorDiscardCount

The sum of $(|C| - |C \cap R|) \mathbf{1}_{\{|C \cap R| < t\}}$ over disjoint row classes.

sharedAnchor_doubleCount

The bijection between (R, x) pairs and (T, x) pairs with $|T| = r + 1$. Proving the unnormalized integer identity first avoids probability-library and real-division overhead.

exists_sharedAnchorSet_mass

The finite average argument and the bound from $Z \mathbf{1}_{1 \leq Z \leq t} \leq t$. This is the shortest route to the local $O(q/\sigma)$ improvement.

sharedAnchor_minimax_profile

The symmetric-group action and its equal-size fibres, followed by the exact profile maximum. This is useful for optimality but is not a dependency of the interpolation application.

sharedAnchor_loss_secondDifference

The two distinguished-column coupling identities and the sign factorization in (II.155.4).

sharedAnchor_balanced_profile

Clipping at the first mode, filling the budget, and discrete balancing. The finite affine root may be handled by squared inequalities and an integer ceiling characterization rather than numerical square roots.

section16_subset_recovered_good_set

An application of the new sample bound that produces exactly the existing sampled-or-anchored interface. The whole-class set K in Proposition V.145.1 ensures that the anchors also belong to K .

labelled_common_slice_cover

Inductive refinement carrying a separate candidate family for each slice. A dependent index type avoids padding every slice list to the union size.

A formalization should establish an actual build at a pinned Lean/mathlib version before changing the status of any source lemma. This package contains no `sorry`-based Lean skeleton, no declaration of the new results as axioms, and no claim that a proposed theorem name has been compiled.

V.150 Notation and endpoint checklist

Source 39, delivered Appendix B.

Symbol	Meaning and restrictions
m	Number of final-coordinate columns; always a positive integer.
r	Number of distinct sampled columns; $0 \leq r \leq m$.
t	Number of distinct anchors sufficient for a class; degree bound is $t - 1$.
$q, q_h, \bar{q}$	Uniform, rowwise, and weighted-mean class counts. The finite minimax formula fixes an integer $q \geq 1$.
B_h	Partial domain in row h ; it need not equal J .
$K_h(R)$	All sampled domain points together with every class having at least t sampled members.
E_R	Ambient good set obtained by deleting uncertified domain points only.
$\ell_{m,r,t}(s)$	Expected discarded mass of one size- s class, normalized by m .
$a_{m,r,t}$	Least size attaining the maximum of ℓ , not its largest maximizing size.
$\mathfrak{M}_{m,q,r,t}$	Supremum over row families of the best shared r -sample loss for the stated rule.

Symbol	Meaning and restrictions
λ_t, κ_t	Unique Poisson-profile maximizer and its value. These are not finite-population constants.
b	Horizontal-section complexity in the source comparison; distinct from class size s .
M, m_0	Initial base scale and source short-parent width input; neither denotes $ J $ unless specified.
L, P	Individual slice-list and common union-list bounds. Keeping them distinct is the point of labelled refinement.

For $r = m$, every sampling loss is zero and the first mode is zero. For $r < t$, only sampled targets are certified and the minimax loss is $1 - r/m$. For $t = 1$, the direct lifts duplicate some one-point interpolation expressions, which is harmless for an upper bound. The finite formula uses a first mode so that plateau cases have an unambiguous cap. Sampled columns are distinct by construction. Field interpolation never divides by a zero difference. Exceptional mass is always ambient mass, and the corruption and base-refinement losses are added explicitly rather than hidden in a changed normalization.

V.151 Reproducibility, implementation, and formalization

Source 40, delivered Section 10.

V.151.1 What the finite checks establish

The accompanying standard-library Python program `verify_fejer_selection.py` uses exact integer and rational arithmetic for its mathematical checks. The JSON report records the chosen points and exact survival masses for every displayed orthogonality example. Its checks are as follows.

Check	Coverage and interpretation
Top-monomial rigidity	All 6 651 coefficient vectors over $\mathbb{F}_3$ for $k = 1, 2, 3$, with sidelengths one.
Total arrangement count	All 512 subsets of $\mathbb{F}_3^2$ for $k = d = 1$, including empty and full sets.
Small-field exceptional logic	All 625 ambient arrangements over $\mathbb{F}_5$ for $k = d = 1$, $H = 1$; all are exceptional, consistent with the bound, which is vacuous at that field size.
Kernel inequalities	156 exact (s, L) cases, for $s \in \{4, 8, 16, 32\}$ and $2 \leq L \leq 40$.
Selection constants	27 exact choices of s, α, η , checking the gain, ceiling estimate, score margin, and explicit retained mass.
Exact orthogonality	Four regular examples over $\mathbb{F}_{1000003}$: $(k, d, L) = (1, 1, 2), (1, 1, 3), (2, 1, 2), (1, 2, 2)$; full enumeration of bounded coefficient vectors, and exact good/bad Fourier sums.

The regular examples use $\phi = F$ for the good case. To form a bad case, the value of ϕ at one distinct vertex is increased by one. This changes the defect by a nonzero signed unit. The program checks that the good moment is exactly $a_{s,L}$ and the bad moment exactly $b_{s,L}$, not merely close in floating-point arithmetic.

The tests do not enumerate the enormous ambient fields in the main theorem, do not prove the assertions for all parameters, and do not verify a Lean development. The proofs in the article, not the sample computations, are the basis for the general theorem.

V.151.2 An explicit finite search procedure

The existence argument admits a finite, though generally impractical, construction. Enumerate the q^2 seed pairs (t, u) and compute the conditional expectation of the score $X - Y/\eta$ by enumerating labeled arrangements. Some seed pair has conditional expected score at least the unconditional lower bound. For this pair, expose the Bernoulli membership decisions one physical point at a time. At each decision, one of the two conditional expectations is at least their weighted average, so choose that outcome. At the end the realized score is at least the original guaranteed score.

This is a conditional-expectation proof of finite constructibility, not a near-linear-time algorithm. Direct evaluation can involve the q^M arrangement parameter space and $|B|$ decisions. If exact comparison of the trigonometric weights is desired, they lie in a cyclotomic number field; a certified algebraic-real representation can be used. For arbitrary real input η , exact effective comparisons also require a representation of that input. Taking rational accuracy parameters avoids this additional computability issue. No fast implementation of this construction is claimed or supplied.

V.151.3 Suggested Lean dependency structure

The existing mathematical project supplies a natural home for a formalization, but this package does not change its Lean files. The following proposed components isolate the substantial obligations.

Proposed component	Mathematical content
<code>CubeTopMoment</code>	Subset-sum inversion and the parity criterion of Lemma II.166.1.
<code>ArrangementFeature</code>	Parameterized arrangements, elimination of the last cross-section, and Theorem II.166.2.
<code>ShortRelationCount</code>	Finite coefficient boxes, sign pairing, polynomial zero-count, and repeated-vertex exclusion.
<code>PositiveKernelMoment</code>	Finite character orthogonality, nonnegative Fourier sums, and actual-versus-labeled survival.
<code>FejerSelection</code>	The score lemma, the exact theorem, ceiling arithmetic, and the density corollary.
<code>KernelGainBarrier</code>	The nonnegative-Fourier gain-mass inequalities, independent of arrangement geometry.

These are suggested names, not assertions that such modules already exist. A formalization should first fix the intended arrangement counting convention, particularly repeated vertices, before adapting existing interfaces. No uncompiled proof sketches with placeholder axioms are included as if they were verification.

V.152 Further research questions and integration priorities

Source 40, delivered Section 11.

The questions below distinguish a direct follow-up computation from a structural conjecture. None is asserted solved by the preceding proofs.

Research question V.152.1 (Sharp finite-bandwidth kernel optimization). For fixed s, H, Q , maximize $\sum_{a=-H}^H c_a^s$ subject to $c_{-a} = c_a \geq 0$, $0 \leq \sum c_a e^{ia\theta} \leq 1$, and $\sum c_a^s \geq Qc_0^s$. How close is the Fejér kernel to the optimum, including its dependence on s ?

The exponent is determined by Section II.172, but the constant and the necessary bandwidth are not. A useful first target is a rigorous solution for small H , with certified positivity rather than a sampled grid of angles. This would clarify whether better kernels can materially reduce the field threshold even when they cannot improve the powers of α and η .

Research question V.152.2 (Counting distinct short-relation hypersurfaces). How much can one improve $C_{k,s,H}$ by identifying scalar-equivalent or coincident zero sets among the coefficient vectors, and by using the geometry of their intersections?

Sign pairing is only the first such identification. Over a prime field, a projective count sensitive to the actual integer coefficient box may save more than a constant. Any refinement must still include zero sidelengths and coincident vertices. A credible target is an explicit bound of the form q^{M-1} times a substantially smaller coefficient complexity, rather than an unproved independence heuristic.

Research question V.152.3 (Threshold versus intrinsic complexity). Is a field-size requirement of roughly $\beta^{-(2d-1)}(s/(\alpha\eta))^{2s}$ necessary for an unconditional one-stage theorem of this kind, or can it be reduced while retaining the same arrangement mass?

Our requirement comes from making all exceptional bad arrangements cost at most the ordinary bad first moment. It may be wasteful to bound each exceptional arrangement's survival by one. Stratifying extra-relation ranks and calculating their survival could improve the threshold without changing the kernel or its exponent barrier.

Research question V.152.4 (Small-characteristic selection). Can a different family of probability kernels recover comparably strong selection in characteristic $p \leq 2(L-1)$, with a quantitatively controlled dependence on p ?

Two issues must be separated: modular collisions in the feature coefficient box and low-order target defects. Proposition II.171.2 computes the latter exactly. A successful approach cannot simply increase the extension degree of the field and ignore its fixed characteristic. Vector-valued frequencies, structured zero sets, or several genuinely different tests are plausible directions, but are not proofs.

Research question V.152.5 (Multiple universal relations). For a parameterized configuration whose polynomial feature relations form a lattice or vector space of rank greater than one, can the single-stage method be developed with constants controlled by the geometry of that relation space?

The exact Fourier sum is still available, but the good contribution becomes a weighted sum over a higher-rank coefficient section. Different nonzero defects can annihilate different subspaces, so the one-dimensional ratio calculation must be replaced rather than merely renamed. This is a natural route toward broader multilinear and hypergraph configurations.

Research question V.152.6 (Propagation through the remainder of Gowers' proof). What explicit bounds result from substituting Corollary II.170.1 into the subsequent strong-partial-multihomomorphism and multilinear-structure steps, while tracking every density, accuracy, and largeness condition?

The immediate task is a parameter ledger for each later invocation, not an asserted improvement in a final tower height. Other losses may dominate. This question is valuable for the repository even if the final asymptotic class does not change, because it would identify which local constants are actually bottlenecks.

Research question V.152.7 (Beyond the homogeneous positivity class). Can vertex-dependent kernels or adaptive selection beat the $\alpha^s \eta^{s-1}$ certificate scale, while retaining a usable exceptional-set estimate?

Theorem II.172.2 makes this a precise boundary question. A candidate improvement should state exactly which hypothesis of that theorem it leaves, and should exhibit either a new positivity mechanism or information about the configuration family absent from the scalar first-moment bound.

Research question V.152.8 (Formal proof and executable certification). Can the one-feature relation theorem, exact positive-kernel moment, and score selection theorem be formalized as reusable components, with the finite checks generated from the same definitions?

A practical first milestone is the algebraic universal-relation theorem, which does not require probability or analysis. A second is a finite Fourier moment theorem parameterized by a nonnegative coefficient family. A final milestone is the explicit arithmetic corollary with all characteristic and size inequalities present in the formal statement.

V.152.1 Integration recommendation

Place this package in a new subdirectory named `fejer-arrangement-selection` of the existing `local-quantitative-refinements` collection under `Research/GowersSzemerédi`. The accompanying README provides an index entry and a proof-status summary. Keep the original paper’s transcription unchanged: the new theorem should be a separate, explicitly cited refinement. Later Lean integration and any downstream constant propagation should be separate changes with their own verification record.

V.153 Conclusion

Source 40, delivered Section 12.

The repeated degree-one Riesz-product selection in Section 15 can be replaced by one high-bandwidth Fejér selection. The main quantitative benefit is a reduction from the exponent $s2^{s-1}$ to powers s and $s - 1$ in the input abundance and error parameters, together with a smaller explicit field-size requirement in the eight-arrangement case. The algebraic input is also compressed: the full coordinate product alone has precisely the intended universal relation, and all other bounded relations are controlled by a polynomial zero-count.

The argument is local, fully stated, and separates exact identities from conservative estimates. Its principal technical safeguards are the explicit treatment of repeated vertices, the characteristic condition preventing coefficient aliasing, and the accounting of exceptional bad arrangements before extracting a subset. The positive-Fourier obstruction identifies a genuine limit of this particular method, while the torsion formula and the research agenda identify concrete directions for further work.

V.154 The pinned source and classical context

Source 41, delivered Section 8.

V.154.1 The source implication in every degree

The precise target in the repository [193] is `corollary_5_8` in `Section05.lean`, lines 242–259, at commit

`c94998a5db18ba63c815a3bf6c3877a0fde91930`.

The source uses $K_k = (k!)^2 2^{(k+1)^2}$ and asks for length at least $S^{1/K_k}/8$ with gain $\alpha/16$. Its `PolynomialOn k Finset.univ` means a coefficient sum indexed by `Fin (k+1)`, exactly the notion used here. Its `ModAP.IsProper` says carrier cardinality equals parameter length, equivalently injectivity of the finite parameter map. It permits wrapping without repetition. Its density identity identifies the balanced function with $\mathbf{1}_A - \delta$.

Empty parents are syntactically allowed by the source. If one is empty, two-comparability forces every parent empty, and coverage makes A empty, contradicting positive correlation. The source’s remaining modulus $N = 1$ is also vacuous, since the balanced function vanishes. Thus our nonempty-parent and $N \geq 2$ presentation adds no nonvacuous hypothesis.

Since $D_1 = 4 \leq 16 = K_1$, and $D_k = K_k/4 + 1 \leq K_k$ for $k \geq 2$, $S \geq 1$ implies that (F.46.4) dominates the required length in every degree. The gain $\alpha/3$ dominates $\alpha/16$. There is no concluding parent-containment requirement in the source.

The target is a `Prop`-valued catalogue declaration. The argument proves its mathematical interface in writing; it does not add a theorem to the repository, run its build, or change its formalization status. Source links and fingerprints are recorded in `SOURCES.md`.

[write] 7 October 2026; sources 40–46. Checked at HEAD 6d4942222. Section05.lean and Definitions.lean have the blobs 882b17a and 97113b7 recorded in SOURCES.md (shipped as 41-all-degree-increments-SOURCES.md); corollary_5_8 occupies lines 242–256 (the cited range 242–259 runs into the docstring of lemma_5_9; immaterial); it now has the exact companion corollary_5_8_holds (Proofs05ThresholdFreeLocalization.lean, line 86). The pinned statement is described accurately above (gain $\alpha/16$, length $(N/M)^{1/K_k}/8$, Polynomial0n k as a coefficient sum, ModAP.IsProper as injectivity).

V.154.2 Primary literature and what is being claimed

Gowers [1], Section 5, develops the classical chain from Weyl recurrence to polynomial localization and local density increments. Its Corollary 5.8 on printed page 493 displays gain $\alpha/8$, while its displayed proof ends with $\alpha/16$. The pinned edited source uses $\alpha/16$. The present argument supplies explicit recurrence and localization budgets and uses a subgroup-coset variance alternative to handle the low-correlation branch. It does not import an internal large-threshold statement without checking that the available parent length pays for it.

Maynard [72], Theorem 1.1 and Corollary 1.2, gives coefficient-uniform simultaneous recurrence for systems of real polynomials vanishing at zero. For m polynomials of degree at most d , the corollary has fractional parts bounded by $\ll_{d,m} X^{-c_d/m}$ for some $1 \leq n < X$. The introduction explicitly leaves degree and dimension dependence of implied constants uncontrolled. That result gives important context, but its implicit constants are not substituted for the explicit constants proved here. In the cited arXiv version the Weyl estimate is Lemma 6.1; numbering need not agree with later versions.

The repeated-differencing and recurrence-to-localization mechanisms are classical. The explicit constants here are deliberately weak, and no literature-priority or optimality claim is made for either those constants or this local-cover formulation. This local theorem alone neither repairs other source sections nor produces an ordinary-integer rectification theorem or a better global quantitative Ramsey or Szemerédi bound. Those require separate statements and compatible downstream arguments.

V.155 Reproducibility and further questions

Source 41, delivered Section 9.

V.155.1 The role of exact diagnostics

The companion uses only the Python standard library, integer arithmetic, and exact rational arithmetic. Its bounded diagnostics check the recurrence and partition budget identities, ordered-divisor combinatorics, differencing coefficients, subgroup-coset second moments, removal of nonproper directions, residue-chain chunking and resplitting, modular polynomial pullbacks, cover mass, and rounding regressions. The JSON output reports the actual finite ranges and limitations. Small rational recurrence examples test an interface; they do not prove recurrence for arbitrary real coefficients.

The infinite-degree induction and the real-parameter recurrence are proved in this article. The program does not enumerate astronomical theoretical partitions or build a theorem-scale integer merely to display its digits. External numeric inputs have explicit runtime caps, active under optimized Python. Tests and diagnostics run both normally and with `-O`, and deterministic diagnostic stdout must agree.

The offline builder verifies an exact source inventory and, for a packaged distribution, manifest hashes. It runs bounded checks, rebuilds the PDF using an installed trusted TeX toolchain with shell escape disabled, and creates a deterministic ZIP with fixed order, timestamps, and permissions. It rejects unexpected source members, aliases, unsafe output locations, and oversized subprocess output. These are reproducibility and regression controls for trusted source, not a sandbox for hostile TeX or Python, and not a guarantee against an actively malicious concurrent filesystem owner. Hashes show byte agreement, not authorship or mathematical truth.

The package contains only the article, PDF, original exact diagnostics and tests, the builder, public documentation, and the manifest. Third-party papers are linked rather than bundled, and private review material is excluded. The ZIP digest is supplied outside the archive. Reproduction commands, environmental requirements, caps, and trust boundaries appear in `README.md`.

V.155.2 Focused further questions

1. **Improve the recurrence with fully explicit constants.** Can modern monomial or simultaneous recurrence estimates be made effective at all relevant small scales and then inserted into the exact recursion? An improved asymptotic exponent alone does not identify the required prefactor or cutoff. The conditional witness in Remark I.64.4 is not such an improvement.
2. **Reduce localization cost.** The induction suppresses the leading coefficient, then applies the lower-degree result at target $2L$ and resplits. Can one reduce the exponent e_k or constant c_k , perhaps by optimizing the allocation of phase error, while retaining every point and keeping an integer-scale proof?
3. **Optimize the final selection without losing scale control.** The exact-budget corollary exposes what the present recursion actually proves. Can a sharper variance estimate or a direct correlation argument improve its floor and prefactor, or trade the uniform gain $\alpha/3$ against a longer progression? Any comparison should retain singleton and boundary cases.
4. **Strengthen geometric conclusions.** When can the low-correlation branch be made parent-contained? When can a modular output be rectified to an ordinary integer progression with a useful length? Neither property follows from properness alone over arbitrary cyclic moduli.
5. **Formalize and connect the interface carefully.** The finite-group mass and variance lemmas, residue partitions, explicit recurrence, and numerical induction could be formalized as separate components and composed into the pinned predicate. Beyond that local task, what downstream statements would be needed before claiming a global quantitative consequence? This report provides no kernel-checked implementation or global conclusion.

V.156 Relation to prior arguments and further questions

Source 42, delivered Section 8.

V.156.1 What is strengthened and what is classical

The inspected variance argument in Report277 averages over all cyclic steps. Off-diagonal correlations are controlled by subgroup-coset averages; the nonproper directions are then removed using the estimate

$$\eta \leq \frac{L(L-1)}{2N}.$$

At $N \geq L^3$, this yields the gain $(1-\delta)/(2L)$. The present proof changes the step distribution before taking moments. Its only nonproper sampled direction is zero, with exactly controlled mass. That change leads to the quadratic condition, the arithmetic refinement, and the equality examples given here.

Autocorrelation positivity, finite Fourier inversion and Poisson summation, variance-to-range conversion, and positive-definite packing estimates are classical. The role of Kolountzakis–Révész is particularly direct: Proposition I.71.1 is an instance of their Theorem 2, rather than a new packing inequality. Bhatia–Davis supplies the standard name for Lemma I.69.2, whose elementary proof was included.

Fox, Xu and Zhou [183] study discrepancy of modular arithmetic progressions. Their Section 4, especially Lemmas 4.2–4.3 and Corollary 4.4, is a close neighboring second-moment mechanism: it uses Fourier weights, subgroup sums and the behavior of short-order directions. Their objective is two-sided discrepancy over

varying progression lengths. The fixed-length one-sided density statement and the explicit prime-quotient equality calculation are the claims isolated in this report. The comparison is a bounded source screen, not a proof of priority.

Lewko [101, Lemma 2 and Section 5] gives a close contemporary use of autocorrelation sums of squares, progression second moments and explicit zero-step removal in a prime cyclic group, with an additive-energy hypothesis. These are useful neighboring mechanisms; their use does not by itself supply the unconditional all-modulus coefficient proved here. In the pinned ProveIt research article [194], the source-10 contribution already records the elementary implication $M \geq \delta + \text{Var}(X)/\delta$. The present report does not claim that conversion as a new argument.

Gowers [1, Section 5] provides the polynomial localization and transfer context used in the earlier reports. The present standalone variance improvement does not reprove or improve their all-degree phase budget. A global quantitative Szemerédi or Ramsey improvement would require a separate, complete iteration or transfer argument. Likewise, the present written proof is not a Lean or other kernel-checked certificate.

V.156.2 Focused open directions

The theorem leaves several concrete questions.

1. *Fixed-density sharpness.* For δ bounded away from zero and one, what is the best uniform coefficient under $N \geq CL^2$, including $C = 1$? Theorem I.73.1 supplies a positive endpoint coefficient but does not prove it optimal. The sparse equality family does not decide the fixed-density minimax problem.
2. *Arithmetic pairs beyond the equality family.* For fixed N, L and permitted cardinality $|A|$, when is the arithmetic bound attained? The support optimum and the full extremal set problem are distinct. Nonzero off-diagonal squares and strict range inequalities may force additional gain.
3. *General finite abelian groups.* Theorem I.69.3 reduces one route to finding a large support with no nonzero short-order difference. A short-order subgroup supplies a packing upper bound, but there need not be a cyclic interval attaining it. Determining the best support and positive-definite weight parameters in more general groups is a separate problem.
4. *Containment and localization.* Can comparable arithmetic gains be obtained while keeping the output inside a specified parent or a cover? The global translation average used here does not supply that constraint. Any nonwrapping integer conclusion likewise requires an additional argument.

These questions concern added structure or stronger conclusions. None is required for the proofs above.

V.157 Reproducible bounded diagnostics

Source 42, delivered Section 9.

The archive contains the full TeX source and PDF, a standard-library Python companion, tests, a deterministic builder, a source note and a SHA-256 manifest. Exact integer and rational diagnostics check proper-window maxima, covariance squares, variance decomposition, admissible supports, bounded functions, prime-quotient examples, endpoint sliding and coset identities, and integer rounding. The full profile includes all 81,792 nontrivial triples (N, L, A) with $2 \leq N \leq 12$ and $2 \leq L \leq N$.

These are bounded diagnostics, not universal proofs, extremizer classifications or formal certificates. In particular, scalar affine examples do not certify an actual phase-correlation premise. The unrestricted mathematics is justified by the written proofs above. Public numerical helpers have explicit computational caps and runtime validation that remains active under Python optimization.

The builder runs the default diagnostics and both test suites normally and with optimization, requiring matching standard output. It compiles with shell escape disabled, uses fresh external output directories and fixed archive metadata, checks unchanged source bytes, and verifies the public inventory and hashes. A

pinned distribution must reproduce its PDF bytes exactly. The README gives all commands, caps and the fuller trust boundary. The builder assumes trusted sources and installed tools; it is not a sandbox for hostile code. Matching hashes certify bytes, not mathematical correctness or priority.

V.158 Relation to Gowers’s argument and the formal project

Source 43, delivered Section 10.

V.158.1 A precise crosswalk, not a replacement of hypotheses

The relevant formal definitions at the comparison snapshot are in `Sections17_18.lean`. The definition `proposition_17_2` has ambient group $\mathbb{Z}/N\mathbb{Z}$ with N prime, a disc-valued function, a frequency predicate `IsMultilinear`, and an explicit unit condition on $(k + 1)!$. It concludes the existence of a degree-at-most- $k + 1$ phase preserving the stated lower bound on the sum of squared zero-frequency derivative coefficients after twisting.

There is an important naming distinction. At the pinned snapshot, `Definitions.lean` defines `IsMultilinear` as a sum of square-free monomials *including constant and lower-order terms*. It is a multiaffine predicate. Our T is genuinely homogeneous multilinear in all its slots. A general multiaffine selector is not covered merely by taking its top homogeneous component.

For the homogeneous cyclic high-characteristic specialization, the usual diagonal primitive is available because the factorial is invertible. The present theorem addresses an obstruction that appears on vector spaces in characteristic two. It certifies the additional identities needed for a nonclassical primitive and preserves energy exactly once they hold. This is a local analogue in a broader class of ambient groups, with its own high-energy hypothesis, not a theorem that uniformly dominates Proposition 17.2 for every input covered by the repository.

The displayed degree correction from k to $k + 1$ in the source paper is already recorded by the repository. It is not a correction originating in this manuscript. Likewise we do not alter the local partition constants in Proposition 17.7 or any subsequent density iteration.

Target	Input retained or changed	Output here
Gowers global phase removal	Homogeneous selector on $\mathbb{F}_2^n$; new high-energy condition	Exact nonclassical phase removal, Theorem IV.38.4
Prior odd-characteristic symmetry criterion	All finite abelian groups; arithmetic radical profile	Theorem IV.36.4, including the sharp Boolean threshold
Tidor’s bilinear estimate	Same three-function finite-field problem; also finite abelian groups	Optimal fourth power instead of eighth, Theorem IV.40.1
Tidor’s symmetric trilinear repair	Same seven-function hypothesis	Codimension at most $\lfloor 2\log_2(1/\delta) \rfloor$, Theorem IV.40.3
One-function cubic repair	Prescribed symmetric cubic selector	Exact energy and optimal codimension, Theorem IV.39.4

V.158.2 An executable algebraic route

Given the coefficient table of a d -linear Boolean form, the certification and integration steps can be implemented exactly. First check symmetry on coefficient tuples, using adjacent transpositions. Once symmetry is known, the repeated-variable defect is multilinear, so checking it on basis arguments suffices. The test uses the coefficients

$$T(e_i, e_i, e_j, e_{a_1}, \dots, e_{a_{d-3}}) + T(e_i, e_j, e_j, e_{a_1}, \dots, e_{a_{d-3}}).$$

If they vanish, read one coefficient per nonempty support and construct (IV.37.2). A dense input has n^d coefficients; checking adjacent symmetries costs $O(dn^d)$ field operations, and the repeated-variable tests cost $O(n^{d-1})$ coefficient operations after symmetry has been established. The construction outputs $\sum_{s \leq d} \binom{n}{s}$ rational monomials, with denominator at most 2^d . These are algebraic operation counts, not a claim of sublinear access to a dense tensor.

For a cubic, form the $n \times n$ matrix $\Omega_{ij} = T(e_i, e_i, e_j) + T(e_i, e_j, e_j)$. Symplectic Gaussian elimination gives its rank, an optimal isotropic subspace, and the linear forms in (IV.39.6). This costs $O(n^3)$ field operations with a straightforward implementation. The normal form then provides a global phase extremizer and an optimal restriction primitive.

An observed energy lower bound is a different kind of input. If function values are numerical complex numbers, an interval or exact cyclotomic certificate is needed before a strict threshold can be invoked. An unchecked floating-point comparison is not a proof of (IV.38.8).

V.158.3 Proposed Lean boundaries

No new theorem in this package has been checked by Lean. A useful formalization order is the following mathematical dependency chain:

A first implementation can work solely over $\mathbb{F}_2^n$ and use matrix symplectic elimination. The full finite-abelian Lagrangian theorem can be added independently. The polynomial value group must include $2^{-d}\mathbb{Z}/\mathbb{Z}$; using only ZMod 2 would encode the wrong integration problem.

The relevant finite-dimensional analytic obligation is explicit: a positive operator commuting with the projective translations has nonzero eigenspaces of dimension at least d_B . Once its trace is computed, the sharp constant follows. There is no appeal to an unformalized inverse theorem hidden in that step. The quartic proof additionally needs the finite monomial identity and a disc-boundary maximum argument, or an equivalent real-algebraic certificate. The file `FORMALIZATION.md` expands these proposed interfaces without supplying placeholder Lean proofs.

V.159 Exact checks, provenance, and limitations

Source 43, delivered Section 11.

V.159.1 What the supplied computation establishes

The companion `checks/verify.py` uses only Python's standard library. All mathematical comparisons use integers, rational numbers, or exact arithmetic in $\mathbb{Q}(\sqrt{2})$. The fixed pseudorandom seed is 20261006; the randomized tests are exact evaluations of selected cases, not probability-based mathematical proofs.

Check	Finite scope	Result
Symmetric cubic census	16 tensors; 512 phase functions each	8,192 exact energies obey and attain $2^{-\text{rank } \Omega/2}$
Nonsymmetric cubic census	240 tensors; 64 phases each	15,360 exact energies; maximum 3/4
Primitive formula	All support coefficients on $\mathbb{F}_2^2$, degrees 2–5	217,600 pointwise top- and next-derivative checks
Pointwise shear	Gaussian rational values, including zero and nonunit amplitudes	15,360 exact pointwise equalities
Composite orthogonality	93 cyclic-pair coefficient cases	Radical sizes and equality factors agree exactly
Mixed estimates	Explicit sharp triangle and 1,024 sampled seven-function cases	Fourth-power equality and rank-bound checks
Quartic identity and phases	All 1,024 cube terms; 4,096 phase functions	29-monomial certificate and exact phase-grid maximum 11/16

The cubic phase census fixes $f(0) = 1$ and uses eighth roots of unity on the other three points. The nonsymmetric census uses fourth roots. The quartic phase census uses sixteenth roots. The monomial identity is checked before substituting phases, so it is not restricted to a phase grid. Additional tests verify the endpoint constructions, canonical cubic blocks through rank six, and all subspaces of $\mathbb{F}_2^n$ for $1 \leq n \leq 4$ in the isotropic repair calculation.

These checks detect sign, normalization, characteristic, and endpoint errors. They do not replace the proofs for arbitrary dimension, arbitrary complex amplitudes, or all finite abelian groups. In particular, the proof of the continuous quartic maximum is the subharmonic and trigonometric argument, not an inference from the 4,096 phase values.

V.159.2 Source audit and novelty boundary

The file `data/source_audit.json` records the exact repository revision and blob identifiers used for the source comparison. The prior manuscript [197] was read from the user’s Library; its source labels, rather than unstable printed page numbers, identify the questions addressed. The repository’s aggregate local-refinement README was also checked to avoid repeating the density, carry-pattern, cube-count, and Bohr-radius projects already represented there.

There are three distinct statuses. The mathematical theorems in this manuscript have supplied proofs. Their selected finite instances have executable exact checks. They have not been independently refereed or proved in a proof assistant, and the targeted literature search does not establish publication priority. The package’s suggested repository placement conveys no additional formal status.

V.159.3 Limits that affect downstream use

The universal Boolean threshold is a high-energy criterion for an already supplied multilinear selector. It is not an inverse theorem that constructs a selector from an arbitrary positive Gowers norm. The exact cubic law remains useful at all positive energies, but still assumes an exactly symmetric global cubic tensor. Producing or repairing that symmetry may itself be a substantial part of an application.

Uniform translation averages are essential to the projective twirl. Restricting the averaging set to a progression or a Bohr set generally breaks the commutation argument. No boundary-free local analogue is claimed. Similarly, multiaffine lower-order frequency terms cannot simply be discarded, and the higher-dimensional quartic maximum is not settled by its two-dimensional computation.

V.160 Further research questions and topics

Source 43, delivered Section 12.

The first questions below are sharply specified continuations of the proved results. The later ones concern their use in a complete inverse or density-increment argument. An assertion marked as a question is not used elsewhere as a theorem.

Research question V.160.1 (Does the quartic extremum stabilize?). Is $\mathcal{M}(C_{4,n}) = 11/16$ for every $n \geq 2$? Equivalently, by Corollary IV.41.4, is $11/16$ the exact universal energy threshold for symmetric nonintegrable quartics? A counterexample must use the extra coordinates in the optimizing function, since the tensor itself has already been reduced to two coordinates.

A useful first target is $n = 3$, retaining the exact shear identities rather than treating the sliced functions as independent optimizers. The interval $11/16 \leq M_{4,n} \leq 3/4$ is proved, not conjectural; constancy at the lower endpoint is a proposed conjecture here.

Research question V.160.2 (Exact mixed cubic repair). For a prescribed symmetric cubic T , determine $\sup_{|b_i| \leq 1} \Gamma_T(b_1, \dots, b_7)$. Does it depend only on $\text{rank } \Omega_T$, as the one-function extremum does? Is the upper bound $2^{-\text{rank } \Omega_T/4}$ attainable, and is coefficient two in (IV.40.8) optimal?

Sharpness of the triangle estimate does not settle simultaneous attainment by all the sheared seven-function slices.

Research question V.160.3 (Near-extremizers beyond their amplitudes). If $\mathcal{E}_T(f) \geq (1 - \varepsilon)2^{-m}$, classify f up to a cubic integrable twist and the projective eigenspace structure. Can a dimension-independent distance bound be proved for an appropriate explicit family of extremizers? The amplitude estimate (IV.39.13) is available; phase stability is not.

Research question V.160.4 (Higher-degree defect geometry). For $d \geq 5$, characterize the multilinear families $\mathbf{z} \mapsto \Omega_{\mathbf{z}}$ that actually arise from symmetric d -linear tensors. Which compatibility identities generalize (IV.41.6)? Can low-dimensional defect images reduce the sharp energy problem to finitely many canonical tensors?

The existing support bound treats an arbitrary multilinear family; using the additional compatibility is the natural place to improve it.

Research question V.160.5 (Odd small characteristic). For $p \leq d$, find a spectral identity detecting the p -repetition transfer conditions of nonclassical integration. Determine whether $1 - (1 - 1/p)^{d-1}$, already the sharp symmetry threshold, also certifies all the extra integrability identities. The Boolean shear exploits $2a = 0$ in an exact way; a p -cycle substitute is needed.

This asks for certification of known algebraic integration conditions, not for rediscovery of nonclassical polynomial theory.

Research question V.160.6 (Composite-group primitives). On a general finite abelian group, characterize which symmetric multiadditive $T : G^d \rightarrow \mathbb{T}$ have a degree-at-most- d primitive, and derive sharp energy certification using elementary-divisor data. Can the primary factorization of the symmetry profile be lifted to an equally explicit integration theorem?

The present paper settles the finite-abelian orthogonality and symmetry parts, not this full integration problem.

Research question V.160.7 (A boundary-sensitive local twirl). Replace the global translation average by an arithmetic box or a regular Bohr set. Can its failure to commute with projective translations be bounded in a norm that preserves a useful rank factor? A successful statement should give explicit boundary and normalization errors compatible with Gowers's localized phase step.

An estimate that simply repeats the global proof on a restricted set would miss its crucial invariance hypothesis.

Research question V.160.8 (Obtaining the high-energy selector). Identify a nontrivial inverse-theorem regime in which a global multilinear selector can be produced above the certification threshold, or in which the exact cubic repair law is useful below it. Track the selector, symmetrization, phase removal, and final density increment together before claiming a better global bound.

Research question V.160.9 (Multiaffine frequency offsets). Can lower-order components of a multiaffine selector be removed with an optimal quantified loss, or absorbed into a larger exact model? A satisfactory theorem must account for the constant and lower-order terms present in the repository’s `IsMultilinear` predicate.

Research question V.160.10 (Formal certificates for extremal identities). Formalize the projective eigenvalue-multiplicity argument and the Boolean primitive formula, then verify the cubic exact-rank theorem. For the quartic result, produce a small proof object combining the 29-monomial identity with the continuous optimization bound, rather than treating the finite phase census as a certificate of the maximum.

V.161 Conclusion

Source 43, delivered Section 13.

The additional characteristic-two integrability obstruction is not merely detectable near perfect energy. For symmetric cubics, its alternating rank determines the entire extremal value and the exact cost of removing the obstruction by restriction. For arbitrary degree, a division-free spectral argument plus a Boolean shear forces the full set of nonclassical integration identities at a sharp universal threshold, after which phase removal is lossless.

The same orthogonality mechanism is useful outside the one-function setting: it gives an optimal fourth-power bilinear estimate and a smaller codimension bound under the published seven-function repair hypotheses. The quartic analysis provides a second structural result: an exact two-dimensional value and a reduction of the general optimization to one explicit tensor. The remaining ambient-dimension question is isolated, not hidden in an assumed tensorization step.

These results are suitable as independent research additions beside the formal Gowers development. Their integration into a global Ramsey or Szemerédi estimate requires the further selector and localization work described above.

V.162 Verification, source comparison, and formalization targets

Source 44, delivered Section 11.

V.162.1 What was actually executed

The supplied verifier uses Python’s standard library and exact integers and rational numbers. Its default run computes through $d = 10$. It also performs checks which do not use the fixed-grid representation. The saved record is `data/verification.json`; every asserted check passed in the packaged run.

First, all 512 grid subsets are considered and all 458 spanning supports are reconstructed from their affine-value assignments. The universal eight-shape coefficient identity is checked over the complete support lattice, grouped by exact rational affine equivalence. This is stronger than comparing the compact formula with a few numerical values. The walk recurrence, exact-support Möbius transform, flat multiplicity formula, and both pair-consistency identities are then checked for $d = 1, \dots, 10$.

Second, the verifier generates every integer-balanced ternary normal for $d = 2, 3, 4$, canonicalizes its rational restriction, and groups every pair by primitive exterior-product coordinates. These independent pair-span

histograms match the grid answer. Modular two-row reduced echelon forms at $p = 17, 53$ give the same histograms. These calculations check examples of the determinant theorem; they do not replace its all-dimensional proof.

Third, affine ternary Boolean maps are exhaustively checked for $k = 1, \dots, 8$ at $p = 5, 7, 11$. The number of maps is $3 + 6k + 4\binom{k}{2}$, and none has more than two active slopes. The exact signed-collision counts are checked directly for $m = 4$, $p = 5, 7$, and $k = 1, 2, 3$. In characteristics two and three the quotient counts and the regular cross-section formula are checked using the prime-field vector-space models of $\mathbb{F}_4, \mathbb{F}_8, \mathbb{F}_9$. Only addition and prime-field scalar multiplication are needed for these checks; no assertion about an unimplemented field multiplication routine is made.

Finally, the seven-step walk recurrence is evaluated through $d = 64$. The scaled energy is compared numerically with the proved leading constant and its first correction at $d = 8, 16, 32, 64$. These floating-point ratios are explicitly labelled diagnostics. All preceding counts and certificate tests use exact arithmetic.

The run does *not* enumerate every full arrangement, verify a new Szemerédi bound, or execute a Lean build. A finite check is not called an independent mathematical review. The universal statements rest on the proofs; the eight-shape compression has the separately delimited finite rational component described above.

V.162.2 Contribution ledger

Statement	Relation to inspected baseline	Evidence in this package
First-order hyperplanes and H_d	Earlier manuscripts [199, 200]	Counting interpretation recalled here.
Direction inventory and non-core cubic bound	Earlier manuscript [200]	Reproved in Section II.177.
Width classification for every $p \geq 5$	Removes the earlier $p > 2k + 2$ cutoff	Direct translation-growth proof; finite checks.
Exact core products	Strengthens the earlier pairwise core bounds	Exact sequential counts in Sections II.176 and II.182.
Uniform rank-two characteristic cutoff	Makes the relevant incidence coefficient stable independently of k	Integer determinant proof.
Fixed-grid formula and polynomial-operation algorithm	Answers the explicit b_2 computation question	Weighted double count and walk recurrences, independent of compact certificate.
Eight-shape compression	Further simplification of the new formula	Complete finite rational coefficient certificate.
$d = 8$ second coefficient	Evaluates the previously unspecified invariant	Exact recurrence output, consistency identities, and proved reduction.
Deficit asymptotic	New secondary scale for the invariant	Seven-point support classification and Gaussian integral expansion.

V.162.3 Repository integration

A separate research directory is preferable to silently changing the statement of Lemma 15.4:

Combinatorics/Ramsey/Research/GowersSzemerédi/finite-grid-core-avoidance/

The intended interface is `GeneralArrangement.IsDegenerate`, `arrangementMoment`, and `degenerateGeneralArrangementCount` in the inspected `Sections14_15.lean`. The article's k, d agree with cube dimension and arrangement multiplicity there; $m = 2d$ counts cross-sections, and $v = m2^k$ counts labelled vertices. The zero-side convention and the modular-multiple exclusion are preserved.

For a first formalization, the characteristic-uniform width lemma and the signed-collision product are the smallest independent targets. Both can be expressed with finite sets and elementary linear maps. Next isolate the rank-two determinant comparison and the weighted profile-pair double count. A verified walk recurrence and a finite rational-affine checker can then certify the numerical specialization. The full geometric language of characteristic polynomials is not required to prove the finite-field second-order bound. No placeholder Lean code is included. The package does not modify the repository or its formalization ledger. `FORMALIZATION.md` records proposed theorem interfaces and dependencies, not completed proof-assistant results.

V.163 Further research questions and proposed next targets

Source 44, delivered Section 12.

The first two questions are the most direct mathematical continuations. The last one is the route toward a genuine improvement of a global Ramsey bound. These are proposed research questions of this manuscript; no claim is made that every formulation has previously appeared as a named open problem.

Question V.163.1 (Third Whitney coefficients from a fixed grid). *Can the third Whitney coefficient be expressed by balanced supports in $\{-1, 0, 1\}^3$, with weights determined by a finite rank-three incidence type, and evaluated in polynomially many arithmetic operations in d ?*

The rank-two proof uses ordered bases of a normal span and divides by the number of such bases through a flat. In rank three, the Möbius coefficient depends on the full rank-two incidence structure inside the span, not only on its number of hyperplanes. The finite grid has 27 points. A useful answer should specify the correct weight, exploit symmetry before enumerating its supports, and distinguish arithmetic complexity in d from the large universal preprocessing constant.

Question V.163.2 (The third term of the actual degeneracy count). *Which non-core directions contribute at order q^{-3} on the regular region, and what are the intersections of their irreducible components?*

A third Whitney coefficient alone is not enough to answer this. The rank argument separates directions with one extra cross-section equation from directions forcing two independent rank-two base systems. The latter cost q^{-4} . A structural classification of the former could replace the entire residual inventory by a smaller third-order family. The exact core product already settles all core intersections, so it need not be reanalyzed at that stage.

Question V.163.3 (Exact recurrences for the eight energies). *Find short polynomial-coefficient recurrences, with proofs, for the energies in (II.180.8), and determine whether their linear combination B_d has a substantially simpler minimal recurrence.*

The fixed-step walk model supplies exact data without guessing. A recurrence must be certified by a coefficient identity or a valid summation certificate, not just fitted to an initial segment. Such a result could reduce both storage and the number of arithmetic operations, and could supply all-orders asymptotics by an independent route.

Question V.163.4 (Sharp exceptional characteristics). *For each d , which primes actually change $b_{2,d,p}$, and is the universal bound 16 in Theorem II.178.1 optimal after the balancing relations are imposed?*

The determinant estimate intentionally ignores much of the structure. A prime can divide a possible minor without being realized by a balanced triple in the actual hyperplane arrangement. Intermediate characteristics also introduce additional balanced profiles when $p \leq 2d$; those are a separate effect from collapse of rational incidences. A complete answer should distinguish these mechanisms.

Question V.163.5 (Sharpness of the universal dimension barriers). *How large can k be for a nondegenerate d -arrangement to exist over a fixed field? How close are the necessary conditions in Corollary II.176.4 to sufficient ones?*

The core laws give exact capacities for the paired summaries. Realizing summaries within those capacities does not rule out non-core relations. A construction with certified absence of every ternary moment relation, or a stronger obstruction from the next coefficient layers, would settle an existence problem beyond the classified core.

Question V.163.6 (Relative and nonuniform arrangement distributions). *Can an analogue of the core product control arrangements sampled from a dense set, rather than the full ambient parameter space?*

The present product relies on uniform independent paired summaries. A relative version needs explicit hypotheses on their conditional concentration and collision probabilities. Total variation estimates, weighted sequential exposure, or a mixing condition on the base fibres are possible starting points. An ambient bound multiplied by the inverse collection density is not the desired improvement.

Question V.163.7 (Larger coefficient alphabets). *For $\{-M, \dots, M\}$ in place of $\{-1, 0, 1\}$, can one obtain a fixed-grid formula for the second incidence coefficient and an exact classification of the low-degree core events?*

The weighted profile-pair argument suggests a grid with $(2M + 1)^2$ points, but the number of alphabet representatives of an affine class is no longer determined solely by whether two or three values occur. The core event may involve more than signed collisions. A satisfactory extension should keep those multiplicities and the prime-dependent translation symmetries explicit.

Question V.163.8 (A small independently verified certificate). *What is the smallest trusted checker needed to certify the eight-shape formula and the $d = 8$ coefficient inside the repository's formal system?*

The general double-counting theorem should be proved once. The numerical part can then be limited to integer walk arrays, rational affine-map checks on at most nine points, and finite sums of rational weights. This suggests a certificate substantially smaller than enumerating the millions of hyperplanes in the $d = 8$ arrangement.

Question V.163.9 (Complete Section 15 propagation). *After inserting the exact principal term and the improved incidence coefficient into the corrected selection argument, which parameter actually controls the next inverse step and the final density increment?*

This requires a complete ledger of retained arrangement mass, the non-core error, repetition counts in the selection kernel, field-size thresholds, and progression widths. The negative second coefficient can improve a local estimate without changing the final asymptotic bound. Only a full calculation through the later stages can establish a global quantitative improvement.

V.164 Conclusion

Source 44, delivered Section 13.

The computational obstruction in the second degeneracy coefficient is not the number of ambient hyperplanes. Two ternary profiles can be recorded by their coordinate pairs in a fixed nine-point grid. Exact representative weights turn this observation into a double-counting identity and a polynomial-operation algorithm. The previously unspecified coefficient in the 8-arrangement setting is thereby evaluated, with a uniform characteristic range and a checkable finite certificate for a compact formula.

The core geometry also admits an exact count. In characteristics at least five it is a problem of avoiding a finite offset set and repeated sign orbits. In characteristics two and three it is a linear-independence problem in a quotient vector space. These descriptions eliminate the intermediate-characteristic gap and give exact finite products, universal dimension obstructions, and distinct growing-dimension laws.

The boundary of the advance is explicit. Non-core directions still contribute a cubic remainder, the eight-shape compression includes a finite computer-assisted component, and no global Szemerédi estimate has been propagated from the local refinements. The new formulae make those remaining tasks more focused rather than disguising them as completed results.

V.165 Reproduction and package contents

Source 44, delivered Appendix A.

The archive contains `article.tex`, its compiled `article.pdf`, a `Makefile`, `README.md`, `SOURCE_AUDIT.md`, `FORMALIZATION.md`, the standard-library verifier, and exact data and certificates. From the package directory,

```
python3 code/verify.py --max-d 10
latexmk -pdf -interaction=nonstopmode -halt-on-error article.tex
```

reconstructs the checks and the PDF. The verification program requires Python 3.10 or later and must not be run with assertion-disabling optimization. It performs no network requests and makes no repository changes. The TeX source uses ordinary packages and an embedded bibliography; it requires no shell escape, external figures, or external bibliography service.

The machine-readable verification record distinguishes exact checks from the floating-point asymptotic diagnostics. The rational normal lists for $d = 2, 3, 4$ are included to make the independent pair-span check inspectable. No fonts, downloaded papers, or earlier research manuscripts are redistributed in this package.

V.166 Further research questions and a proposed programme

Source 45, delivered Section 6.

The following questions isolate the remaining mathematical gaps. They are proposed directions, not consequences of the preceding theorems. The first group concerns finite classifications, the second concerns the best stability ranges, and the third concerns the functional extremizers that control cube counts.

V.166.1 The next energy levels

Question V.166.1 (All third-level extremizers). *Classify every m -element torsion-free set satisfying $E(A) = M_m - 8(m - 3)$. For sufficiently large m , are the only models, up to translation, dilation, and reflection,*

$$\{0, 1, \dots, m\} \setminus \{2\} \quad \text{and} \quad \{0, 2, 3, \dots, m - 1, m + 1\}?$$

What is the smallest valid threshold, and what additional families occur below it?

The second displayed model also has defect $2m - 6$: its prefix is $\{0, 2, \dots, m - 1\}$, of defect $m - 3$, and adding $m + 1$ makes exactly the $m - 3$ pairs of difference one fail. The third-gap induction therefore provides candidate branches, but it does not by itself classify every case of equality in those branches. An efficient next step is to classify endpoint Schur defect two before attempting a larger search.

Question V.166.2 (Bounded Schur defect). *For a fixed integer $s \geq 2$, describe all positive real sets $C = \{c_1 < \dots < c_n\}$ satisfying*

$$\binom{n}{2} - \#\{x + y = z : x, y, z \in C\} = s.$$

For n sufficiently large in terms of s , are all such sets positive real dilates of finitely many integer terminal perturbations of $\{1, \dots, n\}$? If so, obtain effective bounds on the length of the perturbed segment and on the required threshold in n .

The unit-defect proof uses the first imperfect reflection row and the next perfect row. With several defective rows, their locations can interact. A classification that keeps track of those interactions could turn the endpoint recurrence into a systematic description of the top of the energy spectrum.

Question V.166.3 (A larger rigidity window). *Determine sharp edit or containment bounds in terms of $D(A) = (M_m - E(A))/4$ when $D(A) = O(m)$ or $D(A) = o(m^2)$. For example, for each fixed K , does $D(A) \leq Km$ force all but $O_K(1)$ points into a single arithmetic progression whose length is $m + O_K(1)$? Identify any necessary exceptions and the optimal dependence on K .*

The theorem here proves exact one-point repair below the third level. Extending this to a fixed multiple of m would connect the finite classification to mesoscopic stability. A statement at this scale would require new arguments; the present induction does not supply uniform control once many endpoint defects are allowed.

Question V.166.4 (Weighted ordered defects). *Is there a useful nonnegative weighted analogue of (F.50.2), with an explicit extremal weighted profile and a rigidity statement at small deficit? Which choices of mass and magnitude constraints preserve an ordered-completion interpretation?*

Uniform indicator weights are essential to the integer-valued defect and its four-unit spacing. A weighted formulation should specify its normalization before guessing a counterpart of M_m ; the support cardinality alone does not control weighted energy.

Question V.166.5 (Effective cyclic rectification). *Find explicit, checkable hypotheses on $A \subset \mathbb{Z}/p\mathbb{Z}$ that allow the first three torsion-free energy levels to be transferred by a Freiman 2-isomorphism. Can a suitable density or sumset condition be combined with a near-extremal energy hypothesis to force those hypotheses, with useful constants?*

The full cyclic group has energy m^3 , so a torsion-free bound cannot hold for arbitrary cyclic sets. The useful objective is an effective rectification theorem that names and excludes its periodic or wraparound obstructions.

V.166.2 Coset envelopes and puncture rigidity

Question V.166.6 (The largest envelope range). *Determine the largest ε_* for which every nonempty finite set in every abelian group with $\varepsilon < \varepsilon_*$ has coset distance at most $\tau(\varepsilon)$. Determine separately the largest range in which the closest coset is unique and is given by the autocorrelation threshold $r(d) > m/2$.*

Our common sufficient range is $\varepsilon < 1/9$. The three properties need not have the same threshold. At $\varepsilon = 1/4$, a two-point set in $\mathbb{Z}/3\mathbb{Z}$ has several closest cosets, so uniqueness cannot be extended through that endpoint without modification. Failure of one step in the present proof is not evidence that the envelope itself fails there.

Question V.166.7 (A sharp pointwise autocorrelation inequality). *With $q(d) = |A \cap (A + d)|/|A|$, does the inequality*

$$q(d)(1 - q(d)) \leq \varepsilon$$

hold universally? If it fails, determine the best constant in $q(d)(1 - q(d)) \leq C\varepsilon$ and classify the limiting examples.

The proved inequality has $C = 2$. A punctured coset supplies equality in the proposed factor-one inequality for $d \in H \setminus L$ when $A = H \setminus L$, so a universal constant below one is impossible. A better constant would directly strengthen the subgroup bootstrap, while the remaining occupancy and complement steps would still need to be checked over the wider range.

Question V.166.8 (The maximal range of nested-hole repair). *Determine the largest range of $s = \eta/\delta^3$ and δ in which the finite repair bound*

$$\min_{D \subset C} |A \Delta (C \setminus D)|/m \leq \delta \tau(s)$$

holds, with D ranging over nonempty proper subcosets of the canonical coset C . Can the sufficient condition $s < 1/9$ be expanded to its optimal range? For a fixed ambient group and cardinality, how do subgroup indices and unattainable intermediate values of s strengthen this finite bound?

Theorem II.185.11 settles the asymptotic leading constant: it is exactly one. More precisely, its multiplier is $\tau(s)/s = 1 + s + O(s^2)$, and nested-hole examples attain the finite bound at $s = (u - 1)/u^2$ for every integer $u \geq 8$. The theorem also classifies all positive equality cases as two nested holes. Its proof applies the basic coset envelope to the missing set, so any suitable enlargement of that basic range propagates to the repair bound. The unresolved issues are the maximal validity range and the best group-sensitive bound between available equality parameters.

Question V.166.9 (Arithmetic restrictions on the envelope). *For a fixed finite group G and cardinality m , determine the best distance bound at every feasible energy. How much can the universal envelope be improved when G has no subgroup index corresponding to an exact puncture extremizer?*

Equality permits only $\varepsilon = (r - 2)/(r - 1)^2$ at positive defect. In a fixed group, r must be an available subgroup index; in $\mathbb{F}_p^n$ it is a power of p . The quantitative hole remainder and integer constraints on $|A\Delta C|$ provide two possible routes to a group-sensitive bound between those equality points.

Question V.166.10 (Stable collision equality and labels). *If coordinate-cube collisions nearly attain the coset-distance envelope, must the domain be close, at a quantitatively sharp rate, to a product with one punctured coordinate? Under an additional near-maximal labelled-collision condition, which labels can occur on such a domain, and how close must they be to compatible additive or multilinear labels?*

The equality argument separates the domain geometry from labels. A stability proof would have to convert a small failure of corner closure into a product approximation and then control the labels on the repaired domain. Domain closeness alone does not imply label compatibility. This is a natural continuation of the collision amplification work in report source 15 [202].

V.166.3 The fourth-uniformity extremal problem

Question V.166.11 (The exact value of c_4^{odd}). *Determine the constant in (F.50.4) for $d = 4$ and all its extremizers or extremizing sequences. Is the supremum attained on a finite group? Can an extremizer always be realized on a cyclic quotient, or is a higher-rank group needed?*

The established interval has width about 0.0880. The five-point function is an exact lower-bound witness, not a proposed solution of the optimization problem. Searches over small groups should retain exact or interval-certified witnesses; a floating-point local optimum does not certify a universal bound or even optimality on that group.

Question V.166.12 (A stronger moment certificate). *Improve the rational certificate in Section III.90 by using more of the joint constraints on $t(h) = (\mathbb{E}_x f(x)f(x+h))^2$ and $w(h) = \|f(\cdot)f(\cdot+h)\|_{U^2}^4 - t(h)^2$. Can a finite, exact sum-of-squares certificate reach the sharp constant, or is information beyond finitely many moments necessary?*

The proof drops several nonnegative Fourier contributions and applies Jensen to a quadratic expression. Optimizing its coefficients alone need not recover the true extremal value. A useful next certificate should record which relaxations can be simultaneously sharp and exploit any incompatibility.

Question V.166.13 (Spectral support and torsion). *Describe the Fourier support of a fourth-uniformity extremizer. What is the minimum possible number of opposite character pairs, and do two pairs suffice? Does order five play an intrinsic extremal role, or does it merely supply a convenient finite witness? Determine how the answer changes when all character orders are restricted to exceed a prescribed bound.*

The single-pair class is rigorously excluded. The dual identity $\mathcal{D}_4\phi_1 = 111\phi_1 + 27\phi_3 + \phi_5$ explains why a third harmonic is forced in an improving perturbation. Subsequent iterations may generate further harmonics or torsion-dependent aliases. Their compatibility is a structural question, not just a coefficient calculation.

Question V.166.14 (Stability and higher dimensions). *Prove a useful stability theorem for near-extremizers of c_4^{odd} , once its extremal models are identified. Determine the constants c_d^{odd} for $d \geq 5$ and whether there are strict gaps between consecutive values.*

Monotonicity supplies $c_d^{\text{odd}} \leq (832/4795)^{1/4}$ for $d \geq 4$, but does not identify any higher-dimensional extremal model. A repeated derivative argument must retain the mean of the derivative, as the proof here does; centering the original function does not center each derivative.

V.166.4 Integration and longer-term consequences

Question V.166.15 (Formal proof of the finite certificates). *Formalize the endpoint energy identity, the unit-Schur-defect lemma, the complement-energy identity, and the rational fourth-uniformity certificate in Lean. Which finite combinatorial identities can be checked by a small trusted kernel, and which analytic transitions need additional finite Fourier infrastructure?*

Appendix V.167 proposes a dependency order and gives the precise normalized-to-unnormalized translation. The shortest formalization route should begin with exact finite sums and rational polynomial identities, then add the structural equality arguments.

Question V.166.16 (Propagation to a global quantitative theorem). *Identify a complete quantitative argument in which one of the local gains here survives all subsequent losses. Does the improved fourth coefficient change a finite-parameter cube or progression threshold of independent interest? Can any such gain be propagated through a full density-increment proof with an explicit final bound?*

A convincing answer should expose every dependency and retain the same conventions for ambient density, uniformity, and degenerate cubes. Improving a supplementary local coefficient is not sufficient evidence of a better global Szemerédi bound.

For near-term work, the most concrete targets are the third-level energy classification, the sharp pointwise autocorrelation constant, and a better exact fourth-uniformity certificate. They each have a specified gap left by the present proofs, a finite test environment, and a plausible route to a further theorem.

V.167 Normalization and a formalization roadmap for ProveIt

Source 45, delivered Appendix A.

V.167.1 Relevant existing declarations

The inspected formal development is `Combinatorics/Ramsey/Lean/GowersSzemerédi/` at the pin in Appendix V.169. The following declarations give the useful interfaces. Their presence is a source-level observation; this report does not claim to have compiled a Lean extension.

File and declaration	Role for this manuscript
<code>Definitions.lean: cubeDifference, gowersNorm, cubeCount</code>	Iterated multiplicative differences, unnormalized Gowers norms, and ordered additive-cube counts
<code>Definitions.lean: UniformOfDegree, UniformSetOfDegree</code>	The parameter α in (III.91.5) is normalized so that degree $d - 1$ uniformity means $\ f\ _{U_d}^{2^d} \leq \alpha$
<code>Proofs03CubeUpper.lean: lemma_3_10_holds</code>	Existing proof of the cube upper bound using Minkowski; a strengthened corollary can be added beside it
<code>Sections06_07.lean: theorem_7_2, proposition_7_3</code>	Statements of the general structural energy reduction; the torsion-free top-level results are separate, stronger conclusions under much stronger energy hypotheses

The paper’s sign convention uses $x + \omega \cdot h$, while the development’s affine cube argument uses a minus sign. Replacing each h_i by $-h_i$ preserves the sum, so this difference has no numerical effect.

V.167.2 The essential scaling identity

Write $\Gamma_d(f)$ for the repository’s unnormalized `gowersNormdf`, and let $N = |G|$. For the finite cyclic instance implemented there and $d \geq 1$,

$$\Gamma_d(f) = N^{(d+1)/2^d} \|f\|_{U^d}, \quad \Gamma_d(\mathbf{1}_A)^{2^d} = \text{cubeCount}_d(A). \quad (\text{V.167.1})$$

The latter equality is proved locally in `Proofs03CubeUpper.lean` as `gowersNorm_indicator_pow`. It counts degenerate cubes as well.

In particular, the real fourth-uniformity theorem becomes the denominator-free inequality

$$4795 \Gamma_2(f)^{16} \leq 832 N^7 \Gamma_4(f)^{16} \quad (\text{V.167.2})$$

for real centered f on an odd cyclic group. Indeed $\|f\|_{U^2}^{16} = N^{-12} \Gamma_2(f)^{16}$ and $\|f\|_{U^4}^{16} = N^{-5} \Gamma_4(f)^{16}$. Omitting the factor N^7 would be a normalization error.

For the finite energy statements, $E(A) = \text{Finset.addEnergy}(A, A)$ under the ordered quadruple convention used by the inspected statements. The torsion-free theorem can be stated first for $\text{Finset } \mathbb{Z}$, with cardinality hypotheses made explicit. Generalizing the ambient group is a later interface step rather than a prerequisite for the first formal proof.

V.167.3 A proposed order of formalization

1. **Ordered finite counting.** Formalize the energy increment on adjoining a greatest element, the bound on its Schur count, and the ordered missing-completion identity. Use integer arithmetic for $4D(A) = M_m - E(A)$, or clear the denominator three in M_m .
2. **Equality and unit defect.** Encode the reflection characterization of each Schur row. Prove zero defect, then the unique defective-row lemma, then the second and third energy results. This order avoids a separate full classification of four-point energy sets.
3. **Autocorrelation and complements.** Establish $\sum_d r(d) = m^2$, $E(A) = \sum_d r(d)^2$, the overlap inequality, and the exact complement expansion. The polynomial remainder can be verified after clearing denominators. Construct the canonical subgroup with a finite-set closure argument before introducing the radical expression τ .
4. **Norm certificates.** Prove the Fourier square identity for U^3 and the opposite-frequency pairing inequality on odd-order groups. The rational quadratic certificate is a separate real polynomial identity; it should not be entangled with Fourier bookkeeping. Then formalize the nonnegative autocorrelation moment expansion and combine the lemmas.
5. **Exact finite examples.** Verify the five-point cube sums by finite enumeration over $\mathbb{Z}/5\mathbb{Z}$ and the cosine sign tables by Boolean enumeration. These have small, fully specified domains and require no numerical approximation.
6. **Cube-counting interface.** Prove the centered quartic expansion, including the odd-order rank argument, or reuse it if subsequently formalized in the repository. Combine with (V.167.2) to obtain (III.91.5) with the existing uniformity parameter.

No declaration names proposed here assert that such theorems have already been added to the repository. The package is a standalone article suitable for later integration under `Research/GowersSzemerédi/rigidity-gaps/`, or for a further source intake into the existing thematic report. If it is consolidated, retain the provenance distinctions and do not silently replace the earlier reports’ hypotheses or their historical claims.

V.168 Exact certificates and reproducibility

Source 45, delivered Appendix B.

The package contains three independent standard-library Python scripts. They use integers and `Fractions.Fraction` for all mathematical comparisons. Decimal values in the prose are evaluations of exact expressions and are not inputs to any theorem. The searches cover only the explicitly recorded finite domains. Their role is to expose counting, normalization, equality-case, and transcription errors; they do not replace the universal proofs.

V.168.1 Energy and Schur counts

`code/verify_energy.py` computes energy by counting pair-difference multiplicities and independently counts failed ordered triple completions. It verifies the endpoint recurrence using a reflected Schur count, checks progression equality, the first gap, the complete second-level classification in its stated range, and the third gap. The recorded run covers:

- all 12 911 subsets of $\{0, \dots, 14\}$ containing zero and having cardinality between one and nine;
- all 39 202 subsets of $\{1, \dots, 16\}$ with cardinality between one and eight for the positive Schur counts;
- all 276 single interior holes in $\{0, \dots, m\}$ for $2 \leq m \leq 24$, checking the exact one-hole formula;
- five additional rational or large-gap fixtures, together with explicit small-cardinality and torsion counterexamples to overbroad versions of the statements.

The five largest tested cardinalities give the following observed top three energies, consistent with the proved formula:

m	M_m	$M_m - 4(m - 2)$	$M_m - 8(m - 3)$
5	85	73	69
6	146	130	122
7	231	211	199
8	344	320	304
9	489	461	441

No full third-level equality classification is asserted or tested by this script. The output is `data/energy_checks.json`.

V.168.2 Cosets and coordinate collisions

`code/verify_cosets.py` computes exact energy and enumerates subgroup cosets to check the canonical construction and unique minimum. It verifies the full polynomial remainder after clearing denominators, checks the equality classification, checks puncture repair on its admissible finite cases, and counts coordinate-cube collisions directly in small product groups. The recorded run exhausts 131 053 nonempty cyclic subsets in groups of orders two through sixteen and examines 1 597 product-group subsets. Three further cyclic fixtures are added for the recursive puncture theorem. There are 328 high-energy cases overall, and 320 outer-envelope equality cases, of which 101 have positive defect.

For the nested-hole bound, the script minimizes over all coset holes inside the fixed canonical C in each of 107 admissible concrete cases. Six have positive η : five attain the bound and one is strict. Three lie beyond the smaller preliminary cutoff $\eta/\delta^3 \leq 1/16$. The radical-free comparison is

$$2j \leq d, \quad dj(d - j) \leq J_{\text{int}}, \quad J_{\text{int}} = m^3 - E(A) - dm^2 + d^2m,$$

where $d = |A \triangle C|$ and j is the minimum edit count. An additional 427 nested-hole equality examples and 18 strict outlier examples are checked through exact closed formulas; no large ambient groups are enumerated for these checks. The output is `data/coset_checks.json`. These numbers describe the test suite, not a count of all isomorphism types or a finite proof of the general theorems.

V.168.3 The fourth-uniformity certificate

`code/verify_u4.py` performs three complementary checks. First, it expands the rational quadratic certificate exactly and recovers

$$\frac{4795}{832} + \frac{3}{8} \left(V - \frac{3}{2} \right) + \frac{9}{8} \left(V - \frac{3}{2} \right)^2.$$

Second, it computes the fifteen-vertex dual-cube sign table by direct enumeration of 2^{15} assignments and independently by dynamic programming in the generating polynomial. It also checks the sixteen-vertex modular sign counts for character orders 3, 5, 7, 9, including the order-three phase terms. Third, it enumerates every ordered cube of dimensions two, three, and four on $\mathbb{Z}/5\mathbb{Z}$ for the specified vector $(2, 1, -2, -2, 1)$.

The fourth-dimensional count includes all $5^5 = 3125$ parameter tuples and yields the exact integer product sum 6 468 874. Both the histogram and its weighted sum are retained in `certificates/u4_certificate.json`. The generating identity in the proof, together with the finite recurrence printed there, makes the cosine counts independently reproducible without trusting floating-point software.

V.168.4 Commands and verification boundaries

From the package root, run:

```
python3 code/verify_energy.py --output data/energy_checks.json
python3 code/verify_cosets.py
python3 code/verify_u4.py --json certificates/u4_certificate.json
latexmk -pdf -interaction=nonstopmode -halt-on-error \
  gowers_rigidity_gaps.tex
```

The convenience command `python3code/verify_all.py` runs the three mathematical scripts in sequence. Python 3.10 or later is sufficient. The scripts using assertions explicitly reject optimized Python modes that would disable them. The energy script uses explicit failure checks. No internet access or third-party Python package is needed to reproduce the exact mathematical outputs.

Internal AI cross-checks of the proofs are included in `reviews/`. Different analysis passes checked the energy, coset, fourth-uniformity, and integration arguments. These records make the checks inspectable; they are not external peer-review reports or proof-assistant certificates. The final PDF was compiled, checked for unresolved references and layout warnings, and visually inspected. Build and package details are recorded in `data/build_report.json`.

V.169 Source ledger and limits of the audit

Source 45, delivered Appendix C.

The repository snapshot used for this article is

6ce33539ea468f51719a211c18aabdde262a24dd

from <https://github.com/VladimirReshetnikov/ProveIt>, inspected on 7 October 2026 UTC. All paths below are relative to `Combinatorics/Ramsey/`. Exact blob identifiers are also recorded in the machine-readable companion `data/source_manifest.json`.

1. `Papers/sz-thm-gowers-proof/sz-thm-gowers-proof.tex`. This is the edited repository transcription of the original paper. The primary published paper was checked separately. The principal local targets are Lemma 3.10 and the energy discussion in Section 7 immediately preceding Theorem 7.2 [1].
2. `Research/GowersSzemerédi/local-quantitative-refinements/README.md` and `article.tex` in the same directory. The consolidated article at this pin includes sources 01–14. Later sources 15–23 are represented in the directory by integration notes, manifests, scripts, data, and figures, rather than by a completed further consolidation into that article. Their available descriptions and relevant verification material were inspected for overlap; this was not a line-by-line audit of every earlier proof.
3. `Lean/GowersSzemerédi/Definitions.lean`, `Lean/GowersSzemerédi/Sections06_07.lean`, and `Lean/GowersSzemerédi/Proofs03CubeUpper.lean`. These were read to check definitions and interfaces. No new Lean theorem or compilation result is supplied.

V.169.1 Precise links to the existing research questions

The relevant consolidated labels are given literally so that future integration need not depend on page numbering.

Coset envelope and its range.

Source 14’s theorem `gsr:en:14:thm:energy-sharp-stability` proves the sharp envelope for $\varepsilon \leq 1/100$. Question 4, consolidated label `gsr:fz:q:II:cosetrange`, asks for a wider range and all exact equality examples. Section II.185 enlarges the range to $\varepsilon < 1/9$ and classifies every equality case in that range. It does not settle the largest possible range.

Coordinate collisions.

Source 14’s `gsr:en:14:thm:collision-sharp-stability` has the corresponding small-range product-coset conclusion. Its sharpness examples and exact endpoint results do not classify all positive-defect envelope equality domains. Source 15’s collision amplification material still uses $1/100$ in its verifier. The new range and punctured-coordinate equality classification are proved in Section II.185.

Higher real norm gaps.

The higher-dimensional question occurs in source 03 Question 1, source 04 Question 3, and source 14 Question 11, consolidated label `gsr:fz:q:III:normgap`. Section III.90 improves the $d = 4$ bounds and rules out the single-character model. The exact constant remains unresolved.

The fourth-order cube term.

Source 04’s proposition `gsr:cc:04:cub:quartic`, with corresponding results in sources 03, 08, and 09, gives the coefficient P_d . The real U^3/U^2 gap is also an existing result. Section III.91 credits these facts and substitutes the new fourth-uniformity constant.

V.169.2 Published context and priority

The primary-source comparison included Gowers’s original paper, the inverse Pollard theorem of Nazarewicz–O’Brien–O’Neill–Staples, Hegyvári’s paper on the additive-energy spectrum, Shao’s large-energy structural theorem, and Eisner–Tao’s near-extremal Gowers-norm work [1, 190, 189, 191, 7]. The first positive torsion-free energy gap is already implied by the inverse Pollard result. The endpoint recurrence, congruence, and displaced-endpoint construction are also credited to prior work. An independent elementary proof is included because of its role in the new finite classification.

No primary source inspected was found to contain the exact second-level classification, the third exclusion interval, the expanded coset range with its complete puncture equality theorem, or the fourth-uniformity constant proved here. Absence from this search is not a proof of global novelty. Before a publication claims priority, an expert review should check the relevant inverse sumset, rearrangement, and extremal-uniformity literature more broadly. The mathematical claims of the manuscript are its explicit statements with their proofs; the priority claim is deliberately narrower.

V.170 Algorithms, reproducibility, and proof status

Source 46, delivered Section 10.

V.170.1 An effective construction pipeline

Given the coefficients of a symmetric binary trilinear T in a basis, the proof is algorithmic. Compute the matrix $C_{ij} = T(e_i, e_i, e_j) + T(e_i, e_j, e_j)$. A symplectic elimination yields its rank, a maximal isotropic subspace, and a decomposition into elementary wedges. These determine a canonical correction S after choices of pivot ordering have been fixed. Then (IV.29.10) integrates $R = T - S$, and $e(P)$ is an extremizer.

The matrix calculations use ordinary finite-field Gaussian elimination, with cubic arithmetic complexity in the dimension. Once the trilinear coefficient table has been formed, subtracting the elementary corrections and writing the polynomial also takes polynomially many operations. The output can be kept symbolically with $O(n^3)$ coefficients; it need not be expanded into its 2^n -entry value table. A naive coefficientwise implementation of all corrections uses $O(n^4)$ field operations; this is an upper bound, not an optimal-complexity claim. For trace tensors the closed rank formula avoids constructing the matrix if only the extremal value or maximal restriction dimension is required.

For general p at degree $p + 1$, the same obstruction matrix and symplectic elimination construct an optimal elementary repair and an optimal-dimensional integrable restriction. Writing the full symmetric tensor in coordinates has a size depending on p and n ; no dimension-free runtime is claimed for an input that is already a high-order coefficient table.

V.170.2 Exact finite checks supplied with this paper

The accompanying `verify.py` uses only the Python standard library. It performs finite-field arithmetic in polynomial quotient representations, integer calculations, and rational comparisons. It does not use floating point to validate any theorem. The deterministic seed is 172917. The supplied `validation.json` records the field moduli, coefficients, phase numerators, witnesses, counts, and results.

Check family	Number checked
Scalar leading differences and phase orders, $p = 2, 3, 5, 7$, $1 \leq d \leq 20$	80
Explicit trace integrators: all listed direction tuples and basepoints	141 781
Nonzero trace coefficients: radical, isotropic, and wedge certificates	770
Explicit repeated-variable nonintegrability witnesses	5
Fourth-root single-function tables for binary spectral moments	692
General symmetric binary cubic extremizers: cube/basepoint checks	209 664
Mixed eight-function tests for general symmetric binary tensors	36
Seven-function tests for general symmetric binary tensors	36

The trace-coefficient checks cover every nonzero coefficient in $\mathbb{F}_{2^n}$ for $1 \leq n \leq 8$, in $\mathbb{F}_{3^n}$ for $1 \leq n \leq 4$, and in $\mathbb{F}_{5^n}$ for $1 \leq n \leq 3$. The general binary cubic checks use nine coefficient tables in dimensions two, three, and four. They explicitly construct an extremizing phase and check its total derivative against the residual tensor at every basepoint and every direction triple. The script also verifies the predicted Walsh spectral magnitudes and the exact extremal moments.

For the two specified coefficients over $\mathbb{F}_4$, all $4^4 = 256$ fourth-root function tables are exhausted. For $c = 1$, their maximum moment is 1; for $c = \theta$, it is $7/16$, whereas the unrestricted maximum proved in this paper is $1/2$. The latter value is attained using eighth roots. The larger-field function-table checks are sampled rather than exhaustive; the JSON explicitly distinguishes these cases. Their largest observed values must not be mistaken for the proved optima.

Run the checks with

```
python verify.py --output validation.json
```

The program raises an exception on a failed assertion and writes a final **PASS** status only after completing the checks. These computations are useful protection against normalization, sign, and phase-depth errors. They are *not* the proof of any universal theorem, and they are not a Lean kernel check. The general proofs are those in the preceding sections.

V.170.3 Repository integration and formalization boundary

A suggested destination is a new, descriptively named subdirectory under `Combinatorics/Ramsey/Research/GowersSzemerédi/`; this package does not modify any existing repository file. The source audit records the inspected blob identifiers of the Gowers transcription and the refinement inventory. Blob identifiers should not be mistaken for commit identifiers.

The most economical formalization order is to start with the finite binary core: alternating obstruction; quadratic Walsh spectrum; the cube change of variables; exact upper bound; explicit residual integrator; sharpness; and the seven-function corollary. The trace rank calculation and the general- p coordinate construction form subsequent independent modules. The accompanying `FORMALIZATION.md` spells out proposed statements and dependencies. It is a roadmap, not purported compiled Lean code.

V.171 Further research questions and concrete next targets

Source 46, delivered Section 11.

The questions below are proposed continuations of this work. Calling them questions means they are not resolved here; it is not a claim that each has never been considered elsewhere.

Research question V.171.1 (The exact seven-function norm). For a symmetric binary trilinear T , determine the exact supremum of $|\Gamma_T|$ over seven 1-bounded functions. Does it depend only on rank C_T , as the eight-function norm does? Is the exponent $r/4$ in Theorem IV.28.1 optimal?

The cube estimate is sharp, but equality must also survive the initial Cauchy–Schwarz step. An exact analysis of that compatibility would decide whether the codimension constant 2 can be decreased. Small-rank blocks and tensor products provide explicit test cases.

Research question V.171.2 (Classification of all cubic extremizers). Describe all f for which $M_T(f) = 2^{-r/2}$, modulo natural phase multiplications and linear changes of coordinates.

Proposition IV.28.4 says that every transformed four-point function must lie in the positive spectral subspace, and that $|f| = 1$. The missing step is to solve these simultaneous compatibility equations for f . The constructed nonclassical phases give one family, not an exhaustive classification.

Research question V.171.3 (From spectral to structural stability). If $M_T(f) \geq (1 - \varepsilon)2^{-r/2}$, can one approximate f in normalized L^2 by an exact extremizer, with a dimension-independent error tending to zero with ε ?

The exact defect identity is a useful starting point because it has no unspecified constants. The obstacle is that the favorable eigenspaces vary with (A, B) ; separate projection estimates do not immediately produce one globally consistent phase.

Research question V.171.4 (The ordinary slice-rank repair gap). Determine $\rho(T)$ within the interval $r/2 \leq \rho(T) \leq r$. Is $\rho(T) = r$ for all symmetric binary trilinear forms, or can several obstruction blocks be repaired more economically together?

The rank-two case is settled in Proposition IV.32.4. In larger rank, a sum of nonsymmetric slices can be symmetric without each summand being symmetric. This is exactly why the elementary repair theorem does not answer the ordinary slice-rank question.

Research question V.171.5 (Higher phase-alphabet constraints). Determine the maximum of $M_T(f)$ when f is restricted to a prescribed finite root-of-unity alphabet, especially fourth roots rather than eighth roots in characteristic two.

The exhaustive $\mathbb{F}_4$ calculation exhibits a strict gap $7/16 < 1/2$. A general theorem should describe which residual diagonal coefficients force this gap and whether product constructions preserve an exact alphabet-dependent norm formula.

Research question V.171.6 (Odd-characteristic analogues). At degree $p + 1$, is there a sharp mixed cube inequality controlled by the rank of C_T over $\mathbb{F}_p$, and can its extremizers be constructed by symplectic blocks?

The algebraic restriction and repair statements already hold for every prime. The analytic proof in Section IV.27 exploits a special binary reparametrization of the eight vertices and a quadratic kernel. An odd-characteristic replacement would require a different analytic mechanism, not just changing signs in the present proof.

Research question V.171.7 (Higher-degree trace restrictions). For $d \geq p + 2$, determine the largest subspace $W \leq \mathbb{F}_{p^n}$ on which $T_{c,d}$ integrates.

Theorem IV.31.1 excludes integration on the whole extension field. On a subspace, the repeated-variable constraints involve all products of the extra directions from W . This becomes a simultaneous isotropy problem for a family of forms C_{cz} , rather than one alternating form. Product-set structure of W should therefore become relevant.

Research question V.171.8 (Robustness before exact symmetry). Can a quantitatively approximate symmetric tensor be brought into the framework of Theorem IV.27.1 with a loss that improves a complete low-characteristic symmetrization pipeline?

A useful result must separately track the error of symmetrization, the rank of the repeated-variable obstruction, and the cost of restriction or repair. The sharp symmetric estimate alone does not justify silently replacing constants at all those earlier stages.

Research question V.171.9 (Frobenius-twisted trace families). Extend the exact obstruction-rank calculation to symmetric forms built from sums of trace monomials involving Frobenius powers in the arguments.

The radical will again be described by a linearized polynomial, but the number of roots need not have the two-regime form of (IV.32.1). Explicit families could provide a broader supply of sharp cubic examples and nontrivial restriction geometries.

Research question V.171.10 (Formal certificates and algorithmic output). Construct machine-checkable certificates for the symplectic decomposition, residual integrator, and extremal value, and formalize their verification in Lean with finite normalized sums.

A certificate-based implementation can separate potentially elaborate search from a short verifier. The package's exact arithmetic checks are prototypes of the data to certify; they are not a substitute for the kernel-verified implications.

V.172 Conclusion

Source 46, delivered Section 12.

The factorial restriction in polarization is not one uniform obstruction. On the scalar prime field it can always be repaired, at exactly the phase order $p^{\lceil d/(p-1) \rceil}$. For extension-field trace tensors it can be a genuine obstruction to every circle-valued integrator. At the first obstructed degree, an alternating form measures the exact geometric cost of restriction and the exact number of elementary symmetric repairs.

For binary cubic tensors, that same form has an exact analytic meaning: the twisted mixed cube norm is $2^{-\text{rank } C_T/2}$. The quadratic convolution proof and the matching nonclassical-phase construction yield sharp agreement thresholds and an explicit stability identity. They also improve the symmetric seven-function restriction bound from $8 \log_2(1/\delta)$ to $2 \log_2(1/\delta)$. These are local, fully specified advances at a genuine structural bottleneck of the Gowers method, rather than an unverified claim of a new global Szemerédi bound.

V.173 Proof dependency map and scope checks

Source 46, delivered Appendix A.

The main analytic theorem has the following dependency chain:

binary cube change of variables $\longrightarrow$ quadratic Walsh spectrum $\longrightarrow$ mixed upper bound,
alternating-form decomposition + explicit binary cubic integration $\longrightarrow$ matching extremizer.

Neither chain uses an inverse theorem. The seven-function corollary adds one application of Cauchy–Schwarz and the maximal-isotropic dimension formula. The trace applications add only Frobenius adjointness, nondegeneracy of the trace pairing, and root counts in the cyclic group $\mathbb{F}_q^\times$.

The most consequential scope checks are these. Symmetry of T is essential in the sharp cubic proof. Tensor degree three and characteristic two are essential to its quadratic-kernel reduction. “Integrates” permits nonclassical circle-valued polynomials unless “classical” is explicitly specified. The exact repair number refers to the elementary family (IV.32.5), whereas ordinary slice-rank repair only has the bounds in Proposition IV.32.4. The exact seven-function norm, the complete extremizer classification, and an improved global progression-free-set bound are not proved in this article.

Original archive docs/incoming/gowers_cubes_degeneracy_partitions.zip, recoverable at commit f7efeb4f5a7250876ac6fed4116d5fb9ebecd543; inner manuscript gowers_cubes_degeneracy_partitions/gowers_cubes_degeneracy_partitions.tex. [write] Source 18 of this report.
- [165] [source 35] ProveIt research report, source 23, *Sharp Thresholds and Extremal Constants in Gowers’s Szemerédi Framework: numerical semigroups, characteristic-five cube asymptotics, and common partitions for affine fibres*, 6 October 2026. Original archive docs/incoming/gowers_sharp_thresholds.zip, recoverable at arrival commit 26908b3b6; inner manuscript gowers_sharp_thresholds/gowers_sharp_thresholds.tex. [write] Source 23 of this report.
- [166] [source 36] V. Reshetnikov, *ProveIt*, Ramsey subtree, snapshot 6c2e2172bab8 (6 October 2026). [Pinned repository tree](#). Corrected paper transcription, source lines 3530–3610; research README and formalization-status file inspected. Full blob identifiers are in SOURCE_AUDIT.md (shipped as 36-symmetry-certification-SOURCE_AUDIT.md).
- [167] [source 37] V. Reshetnikov, maintainer, *ProveIt: Combinatorics/Ramsey*. Inspected Section 5 sources at revision 869289aa38d59354e8dac2213df08ae0dd256415, 6 October 2026. <https://github.com/VladimirReshetnikov/ProveIt/tree/869289aa38d59354e8dac2213df08ae0dd256415/Combinatorics/Ramsey>. See the source audit in Appendix V.141.
- [168] [source 38] V. Reshetnikov and contributors, *ProveIt: Ramsey development*, inspected at commit 12da356730b12cb73c276a258aaadf3223e3662b, 6 October 2026. [Pinned Ramsey directory](#). Exact inspected paths and blob hashes are in SOURCE_LEDGER.json (shipped as data/38-quotients-SOURCE_LEDGER.json).
- [169] [source 38] ProveIt research collection, *Local Quantitative Refinements of Gowers’s Proof of Szemerédi’s Theorem*, consolidated AI-assisted research report, 6 October 2026, at the checkpoint in [168]. The inspected article incorporates source reports 01–10. [Pinned consolidated report](#). [write] This report at its second write.

- [170] [source 38] *Sharp Characteristic-Five Cube Bounds in Gowers’s Framework*, AI-assisted research report prepared for Vladimir Reshetnikov, 6 October 2026. Inspected source: `gowers_characteristic_five.tex`. This report proves the sharp secondary coefficient uniformly in dimension and the eighth-order coefficient on the five-point group. The source hash is recorded in `SOURCE_LEDGER.json`. *[write]* Source 21 of this report.
- [171] [source 38] *Sharp Thresholds and Extremal Constants in Gowers’s Szemerédi Framework*, AI-assisted research report prepared for Vladimir Reshetnikov, 6 October 2026. Inspected source: `gowers_sharp_thresholds.tex`; see the sharp secondary three-cube asymptotics and further questions. The source hash is recorded in `SOURCE_LEDGER.json`. *[write]* Source 23 of this report.
- [172] [source 38] *Weighted Derivative Spectra and Sharp Local Rigidity in Gowers’ Argument*, AI-assisted research report prepared for Vladimir Reshetnikov, 6 October 2026. Inspected source: `gowers_weighted_spectrum_rigidity.tex`. Its coarse subgroup argument and all-group extremal profile precede the sharp odd-order refinement here. The source hash is recorded in `SOURCE_LEDGER.json`. *[write]* Source 31 of this report.
- [173] [source 38] *Degree Filtrations in Gowers’ Ramsey Framework*, AI-assisted research report prepared for Vladimir Reshetnikov, 6 October 2026. Inspected source: `gowers_degree_stratification.tex`. See its exact polynomial-pattern bounds and independent-extension obstruction. The source hash is recorded in `SOURCE_LEDGER.json`. *[write]* Source 22 of this report.
- [174] [source 39] V. Reshetnikov’s `ProveIt` repository, inspected snapshot `869289aa38d59354e8dac2213df08ae0dd256415`, `Proofs16DistinctSampling.lean`, under `Combinatorics/Ramsey/Lean/GowersSzemerédi/`. Corrected distinct-anchor counts and the repeated-sampling obstruction. [Pinned source at the inspected commit](#).
- [175] [source 39] Same repository and snapshot, `Proofs16AnchoredFibres.lean`. The corrected affine-cover anchored good-set theorem. [Pinned source at the inspected commit](#).
- [176] [source 39] Same repository and snapshot, `Proofs16ShortColumns.lean`. Directly sampled points, short-column recovery, and the `Section16SampledOrAnchoredOn` interface. [Pinned source at the inspected commit](#).
- [177] [source 39] Same repository and snapshot, `Proofs16RecoveredSliceCover.lean`. The existing common slice-cover bounds and candidate indexing. [Pinned source at the inspected commit](#).
- [178] [source 39] Same repository and snapshot, `Proofs16SynchronizedCover.lean`. Geometric synchronization without additional candidates or mass loss. [Pinned source at the inspected commit](#).
- [179] [source 39] Same repository and snapshot, `Proofs16SynchronizedSliceCover.lean`. Assembled short-parent and width hypotheses for synchronized slice covers. [Pinned source at the inspected commit](#).
- [180] [source 39] Same repository and snapshot, `Proofs16ClosingComparison.lean`. The numerical closing-comparison obstruction, not a counterexample to the full assertion of Lemma 16.10. [Pinned source at the inspected commit](#). *[write]* Source 39’s seven `Proofs16` files have the same blobs at HEAD `bec460a33` as at its pin (checked at the write); none of its research reports is cited, although source 19 had been placed (note in Section F.44).

Added in the eighth write (sources 40–46, 7 October 2026). Works above that sources 40–46 also cite: [1] (all seven; source 40 the DOI, “Section 15, especially Corollary 15.2 and Lemmas 15.4–15.5”; source 41 a copy under `~zeilberg`, “Section 5, especially printed pp. 489–493”; source 42 the same copy, Section 5; source 43 the DOI, “Section 17, especially Lemma 17.1 and Proposition 17.2; original printed page 578 inspected”; source 44 the DOI and the copy under `users/gasarch`, “Section 15, especially pp. 562–565”; source 45 the DOI and the copy under `~gasarch`; source 46 the DOI); [2] (sources 40 and 46; source 40 as version 2, 29 February 2024, “used only to distinguish the local refinement”); [72] (source 41, as arXiv:2011.12275v1, 24 November 2020, “Theorem 1.1, Corollary 1.2, and Lemma 6.1”); [101] (source 42, “Lemma 2 and Section 5”); [150] (sources 43 and 46; source 43 “Definition 3.1, Proposition 3.5, Lemma 4.1, and Proposition 4.6”); [98] and [99] (source 44, as background); [7] (source 45, as Journal d’Analyse Mathématique **117** (2012), 133–186). The entries below are new.
